ANNALS OF BOTANY

EDITED BY

DUKINFIELD HENRY SCOTT, M.A., LL.D., D.Sc., F.R.S.

LATELY HONORARY KEEPER OF THE JODRELL LABORATORY, ROYAL BOTANIC GARDENS, KEW

JOHN BRETLAND FARMER, D.Sc., M.A., F.R.S.

PROFESSOR OF BOTANY, ROYAL COLLEGE OF SCIENCE, LONDON

FRANCIS WALL OLIVER, M.A., D.Sc., F.R.S.

QUAIN PROFESSOR OF BOTANY, UNIVERSITY COLLEGE, LONDON

AND

ROLAND THAXTER, M.A., Ph.D.

PROFESSOR OF CRYPTOGAMIC BOTANY IN HARVARD UNIVERSITY, CAMBRIDGE, MASS., U.S.A

ASSISTED BY OTHER BOTANISTS

VOLUME XXVI

With Ninety-eight Plates, and Two Hundred and Thirty-two
Figures in the Text

LONDON

HENRY FROWDE, OXFORD UNIVERSITY PRESS

AMEN CORNER, E.C.

LIBRARY

No. CI, January, 1912.

	PAGE
EVANS, A. W.—Branching in the Leafy Hepaticae. With thirty-six Figures in the Text	I
SCOTT, D. H.—On a Palaeozoic Fern, the <i>Zygopteris Grayi</i> of Williamson. With Plates I-V and one Figure in the Text	39
MACDOUGAL, D. T.—The Water-balance of Desert Plants. With Plates VI-X	71
BRENCHLEY, WINIFRED E.—The Weeds of Arable Land in relation to the Soils on which they grow. II	95
BOTTOMLEY, W. B.—The Root-nodules of <i>Myrica Gale</i> . With Plates XI and XII	111
SPRATT, ETHEL R.—The Morphology of the Root Tubercles of <i>Alnus</i> and <i>Elaeagnus</i> , and the Polymorphism of the Organism causing their Formation. With Plates XIII and XIV	119
DALE, ELIZABETH.—On the Cause of 'Blindness' in Potato Tubers	129
DALE, ELIZABETH.—A Bacterial Disease of Potato Leaves. With Plates XV and XVI	133
BLISS, MARY C.—A Contribution to the Life-history of <i>Viola</i> . With Plates XVII-XIX	155
HOLDEN, RUTH.—Reduction and Reversion in the North American <i>Salicales</i> . With Plates XX and XXI	165
HILL, T. G., and DE FRAINE, ETHEL.—On the Seedling Structure of certain <i>Centrospermae</i> . With eight Figures and seven Diagrams in the Text	175
BENSON, MARGARET.— <i>Cordaitea Felicis</i> , sp. nov., a Cordaitan Leaf from the Lower Coal Measures of England. With Plate XXII and one Figure in the Text	201
BARRETT, J. T.—Development and Sexuality of some Species of <i>Olpidiopsis</i> , (Cornu) Fischer. With Plates XXIII-XXVI	209
WELSFORD, EVELYN J.—The Morphology of <i>Trichodiscus elegans</i> , Gen. et Sp. Nov. With Plate XXVII	239

NOTE.

COMPTON, R. H.—Note on a Case of Doubling of Embryo-sac, Pollen-tube, and Embryo	243
--	-----

No. CII, April, 1912.

DAVIE, R. C.—The Structure and Affinities of <i>Peranema</i> and <i>Dialalpe</i> . With Plates XXVIII and XXIX	245
BOWER, F. O.—Studies in the Phylogeny of the Filicales. II. Lophosoria, and its Relation to the Cyatheoideae and other Ferns. With Plates XXX-XXXVI	269
FAULL, J. H.—The Cytology of <i>Laboulbenia chaetophora</i> and <i>L. Gyrinidarum</i> . With Plates XXXVII-XL	325
DIGBY, L.—The Cytology of <i>Primula kewensis</i> and of other related <i>Primula</i> Hybrids. With Plates XLI-XLIV and two Figures in the Text	357
REED, T.—Some Points in the Morphology and Physiology of Fasciated Seedlings. With nine Figures in the Text	389
DELÉ, E. MARION.—The Attaching Discs of the Ulvaceae. With Plate XLV and three Figures in the Text	403
DELÉ, E. MARION.—Transpiration in Succulent Plants. With one Figure in the Text	409
STILES, W.—The Podocarpeae. With Plates XLVI-XLVIII and eight Figures in the Text	443
GIBBS, L. S.—On the Development of the Female Strobilus in <i>Podocarpus</i> . With Plates XLIX-LIII	515
HUME, E. M. MARGARET.—The Histology of the Sieve Tubes of <i>Pteridium aquilinum</i> , with some Notes on <i>Marsilia quadrifolia</i> and <i>Lygodium dichotomum</i> . With Plates LIV and LV	573
HILL, A. W.—The Production of Hairs on the Stems and Petioles of <i>Tropaeolum peregrinum</i> , L. With Plate LVI and seven Figures in the Text	589
DUTHIE, AUGUSTA V.—Anatomy of <i>Gnetum africanum</i> . With Plates LVII-LIX	593

	PAGE
PEARSON, H. H. W.—On the Microsporangium and Microspore of <i>Gnetum</i> , with some Notes on the Structure of the Inflorescence. With Plate LX and six Figures in the Text	603
✓ THODAY (SYKES), M. G.—Note on the Inflorescence Axis in <i>Gnetum</i>	621
NOTE.	
FARMER, J. B.—Telosynapsis and Parasynapsis	623

No. CIII, July, 1912.

✓ KERSHAW, E. M.—Structure and Development of the Ovule of <i>Bowenia spectabilis</i> . With Plate LXI and sixteen Figures in the Text	625
BAILEY, IRVING W.—The Evolutionary History of the Foliar Ray in the Wood of the Dicotyledons: and its Phylogenetic Significance. With Plates LXII and LXIII	647
BROWNE, ISABEL M. P.—Contributions to our Knowledge of the Anatomy of the Cone and Fertile Stem of <i>Equisetum</i> . With Plates LXIV and LXV and ten Figures in the Text	663
BEER, RUDOLF.—Studies in Spore Development. II. On the Structure and Division of the Nuclei in the Compositae. With Plates LXVI and LXVII	705
LEE, E.—Observations on the Seedling Anatomy of Certain Sympetalae. I. Tubiflorae. With Plate LXVIII and eight Figures in the Text	727
BACHMANN, FRED A.—A New Type of Spermatogonium and Fertilization in <i>Collema</i> . With Plate LXIX	747
BLACKMAN, V. H., and WELSFORD, E. J.—The Development of the Perithegium of <i>Poly-stigma rubrum</i> , DC. With Plates LXX and LXXI	761
SCHWARTZ, E. J.—Observations on <i>Asarum europaeum</i> and its Mycorrhiza. With Plate LXXII	769
HOLDEN, H. S.—Some Wound Reactions in Filicinean Petioles. With Plates LXXIII and LXXIV and one Figure in the Text	777
BETTS, ANNIE S.—A Bee-hive Fungus, <i>Pericystis alvei</i> , Gen. et Sp. Nov. With Plates LXXV and LXXVI	795
✓ SPRATT, ETHEL ROSE.—The Formation and Physiological Significance of Root Nodules in the Podocarpaceae. With Plates LXXVII-LXXX	801
YAPP, R. H.— <i>Spiraea Ulmaria</i> , L., and its Bearing on the Problem of Xeromorphy in Marsh Plants. With Plates LXXXI-LXXXIII and eleven Figures in the Text	815
MOCKERIDGE, FLORENCE A.—Some Conditions influencing the Fixation of Nitrogen by <i>Azotobacter</i> and the Growth of the Organism	871
MILLER, EDWIN C.—A Physiological Study of the Germination of <i>Helianthus annuus</i> . II. The Oily Reserve	889
✓ BRENCHEY, WINIFRED E.—The Development of the Grain of Barley. With twenty-two Figures in the Text	903
LEE, D. G.—Notes on the Anatomy and Morphology of <i>Pachypodium namaquanum</i> , Welw. With Plate LXXXIV and eight Figures in the Text	929

NOTES.

SAXTON, W. T.—Note on an Abnormal Prothallus of <i>Pinus maritima</i> , L. With one Figure in the Text	943
DÜMMER, R. A.— <i>Peloria</i> in <i>Saintpaulia ionantha</i> , Wendland, and <i>Choris</i> in <i>Aristea dichotoma</i> . With three Figures in the Text	946
CLARK, J. J.—Abnormal Flowers of <i>Amelanchier spicata</i> . With twelve Figures in the Text	948
JOHNSON, J. CHARLES.—On Well-marked Aerotropic Growths of <i>Bacillus megatherium</i>	949
GIBSON, R. J. HARVEY.—The Extent of the Root-system of <i>Cucumis sativus</i>	951

No. CIV, October, 1912.

THODAY (SYKES), MARY G., and BERRIDGE, EMILY M.—The Anatomy and Morphology of the Inflorescences and Flowers of <i>Ephedra</i> . With Plate LXXXV and twenty-one Figures in the Text	953
--	-----

BERRIDGE, EMILY M.—The Structure of the Female Strobilus in <i>Gnetum Gnemon</i> . With four Figures in the Text	987
GATES, R. R.—Somatic Mitoses in <i>Oenothera</i> . With Plate LXXXVI	993
SCOTT, D. H.—The Structure of <i>Mesoxylon Lomaxii</i> and <i>M. poroxyloides</i> . With Plates LXXXVII-XC	1011
DE FRAINE, E.—On the Structure and Affinities of <i>Sutcliffia</i> , in the Light of a newly discovered Specimen. With Plates XCI and XCII and nineteen Figures in the Text	1031
STEPHENS, EDITH L.—The Structure and Development of the Haustorium of <i>Striga lutea</i> . With Plate XCIII	1067
THOMPSON, W. P.—The Anatomy and Relationships of the Gnetales. I. The Genus <i>Ephedra</i> . With Plates XCIV-XCVII and two Figures in the Text	1077
WARD, F. KINGDON.—Some Plant Formations from the Arid Regions of Western China	1105
MICHELL, MARGARET RUTHERFORD.—On the Comparative Anatomy of the Genera <i>Ceraria</i> and <i>Portulacaria</i> . With Plate XCVIII and four Figures in the Text	1111
NOTES.	
DÜMMER, R. A.—A Bisexual 'Gymnospermous' <i>Begonia</i> . With one Figure in the Text	1123
GROOM, PERCY.—The Medullary Rays of <i>Fagaceae</i>	1124
STEPHENS, EDITH L.—Note on the Anatomy of <i>Striga lutea</i> , Lour.	1125

INDEX.

A. ORIGINAL PAPERS AND NOTES.

BACHMANN, FRED A.—A New Type of Spermogonium and Fertilization in <i>Collema</i> . With Plate LXIX	747
BAILEY, IRVING W.—The Evolutionary History of the Foliar Ray in the Wood of the Dicotyledons: and its Phylogenetic Significance. With Plates LXII and LXIII	647
BARRETT, J. T.—Development and Sexuality of some Species of <i>Olpidiopsis</i> , (<i>Cornu</i>) Fischer. With Plates XXIII-XXVI	209
BEER, RUDOLF.—Studies in Spore Development. II. On the Structure and Division of the Nuclei in the Compositae. With Plates LXVI and LXVII	705
BENSON, MARGARET.— <i>Cordaites Felicis</i> , sp. nov., a Cordaitan Leaf from the Lower Coal Measures of England. With Plate XXII and one Figure in the Text	201
BERRIDGE, EMILY M.—The Structure of the Female Strobilus in <i>Gnetum Gnemon</i> . With four Figures in the Text	987
— see THODAY (SYKES), M. G.	
BETTS, ANNIE S.—A Bee-hive Fungus, <i>Pericystis alvei</i> , Gen. et Sp. Nov. With Plates LXXXV and LXXXVI	795
BLACKMAN, V. H., and WELSFORD, E. J.—The Development of the Perithegium of <i>Polystigma rubrum</i> , DC. With Plates LXX and LXXI	761
BLISS, MARY C.—A Contribution to the Life-history of <i>Viola</i> . With Plates XVII-XIX	155
BOTTOMLEY, W. B.—The Root-nodules of <i>Myrica Gale</i> . With Plates XI and XII	111
BOWER, F. O.—Studies in the Phylogeny of the Filicales. II. <i>Lophosoria</i> , and its Relation to the <i>Cyatheoideae</i> and other Ferns. With Plates XXX-XXXVI	269
BRENCHLEY, WINIFRED E.—The Weeds of Arable Land in relation to the Soils on which they grow. II	95
— The Development of the Grain of Barley. With twenty-two Figures in the Text	903
BROWNE, ISABEL M. P.—Contributions to our Knowledge of the Anatomy of the Cone and Fertile Stem of <i>Equisetum</i> . With Plates LXIV and LXV and ten Figures in the Text	663
CLARK, J. J.—Abnormal Flowers of <i>Amelanchier spicata</i> . With twelve Figures in the Text	948
COMPTON, R. H.—Note on a Case of Doubling of Embryo-sac, Pollen-tube, and Embryo	243
DALE, ELIZABETH.—On the Cause of 'Blindness' in Potato Tubers	129

	PAGE
DALE, ELIZABETH.—A Bacterial Disease of Potato Leaves. With Plates XV and XVI	133
DAVIE, R. C.—The Structure and Affinities of <i>Peranema</i> and <i>Diacalpe</i> . With Plates XXVIII and XXIX	245
DE FRAINE, E.—On the Structure and Affinities of <i>Sutcliffia</i> , in the Light of a newly discovered Specimen. With Plates XCI and XCII and nineteen Figures in the Text	1031
— see HILL, T. G.	
DELF, E. MARION.—The Attaching Discs of the Ulvaceae. With Plate XLV and three Figures in the Text	403
— Transpiration in Succulent Plants. With one Figure in the Text	409
DIGBY, L.—The Cytology of <i>Primula kewensis</i> and of other related <i>Primula</i> Hybrids. With Plates XLI-XLIV and two Figures in the Text	357
DÜMMER, R. A.— <i>Peloria</i> in <i>Saintpaulia ionantha</i> , <i>Wendland</i> , and <i>Chorisia</i> in <i>Aristea dichotoma</i> . With three Figures in the Text	946
— A Bisexual 'Gymnospermous' <i>Begonia</i> . With one Figure in the Text	1123
DUTHIE, AUGUSTA V.—Anatomy of <i>Gnetum africanum</i> . With Plates LVII-LIX	593
EVANS, A. W.—Branching in the Leafy Hepaticae. With thirty-six Figures in the Text	1
FARMER, J. B.—Telosynapsis and Parasynapsis	623
FAULL, J. H.—The Cytology of <i>Laboulbenia chaetophora</i> and <i>L. Gyrinidarum</i> . With Plates XXXVII-XL	325
GATES, R. R.—Somatic Mitoses in <i>Oenothera</i> . With Plate LXXXVI	993
GIBBS, L. S.—On the Development of the Female Strobilus in <i>Podocarpus</i> . With Plates XLIX-LIII	515
GIBSON, R. J. HARVEY.—The Extent of the Root-system of <i>Cucumis sativus</i>	951
GROOM, PERCY.—The Medullary Rays of <i>Fagaceae</i>	1124
HILL, A. W.—The Production of Hairs on the Stems and Petioles of <i>Tropaeolum peregrinum</i> , L. With Plate LVI and seven Figures in the Text	589
HILL, T. G., and DE FRAINE, ETHEL.—On the Seedling Structure of certain <i>Centrospermae</i> . With eight Figures and seven Diagrams in the Text	175
HOLDEN, H. S.—Some Wound Reactions in Filicinean Petioles. With Plates LXXIII and LXXIV and one Figure in the Text	777
HOLDEN, RUTH.—Reduction and Reversion in the North American <i>Salicales</i> . With Plates XX and XXI	165
HUME, E. M. MARGARET.—The Histology of the Sieve Tubes of <i>Pteridium aquilinum</i> , with some Notes on <i>Marsilia quadrifolia</i> and <i>Lygodium dichotomum</i> . With Plates LIV and LV	573
JOHNSON, J. CHARLES.—On Well-marked Aerotropic Growths of <i>Bacillus megatherium</i>	949
KERSHAW, E. M.—Structure and Development of the Ovule of <i>Bowenia spectabilis</i> . With Plate LXI and sixteen Figures in the Text	625
LEE, D. G.—Notes on the Anatomy and Morphology of <i>Pachypodium namaquanum</i> , Welw. With Plate LXXXIV and eight Figures in the Text	929
LEE, E.—Observations on the Seedling Anatomy of Certain <i>Sympetalae</i> . I. <i>Tubiflorae</i> . With Plate LXVIII and eight Figures in the Text	727
MACDOUGAL, D. T.—The Water-balance of Desert Plants. With Plates VI-X	71
MICHELL, MARGARET RUTHERFORD.—On the Comparative Anatomy of the Genera <i>Ceraria</i> and <i>Portulacaria</i> . With Plate XCVIII and four Figures in the Text	1111
MILLER, EDWIN C.—A Physiological Study of the Germination of <i>Helianthus annuus</i> . II. The Oily Reserve	889
MOCKERIDGE, FLORENCE A.—Some Conditions influencing the Fixation of Nitrogen by <i>Azotobacter</i> and the Growth of the Organism	871
PEARSON, H. H. W.—On the Microsporangium and Microspore of <i>Gnetum</i> , with some Notes on the Structure of the Inflorescence. With Plate LX and six Figures in the Text	603
REED, T.—Some Points in the Morphology and Physiology of Fasciated Seedlings. With nine Figures in the Text	389
SAXTON, W. T.—Note on an Abnormal Prothallus of <i>Pinus maritima</i> , L. With one Figure in the Text	943
SCHWARTZ, E. J.—Observations on <i>Asarum europaeum</i> and its Mycorrhiza. With Plate LXXII	769

	PAGE
SCOTT, D. H.—On a Palaeozoic Fern, the <i>Zygopteris</i> Grayi of Williamson. With Plates I-V and one Figure in the Text	39
——— The Structure of <i>Mesoxylon Lomaxii</i> and <i>M. poroxyloides</i> . With Plates LXXXVII-XC	1011
SPRATT, ETHEL R.—The Morphology of the Root Tubercles of <i>Alnus</i> and <i>Elacagnus</i> , and the Polymorphism of the Organism causing their Formation. With Plates XIII and XIV	119
——— The Formation and Physiological Significance of Root Nodules in the Podocarpaceae. With Plates LXXXVII-LXXX	801
STEPHENS, EDITH L.—The Structure and Development of the Haustorium of <i>Striga lutea</i> . With Plate XCIII	1067
——— Note on the Anatomy of <i>Striga lutea</i> , Lour.	1125
STILES, W.—The Podocarpeae. With Plates XLVI-XLVIII and eight Figures in the Text	443
THODAY (SYKES), M. G.—Note on the Inflorescence Axis in <i>Gnetum</i>	621
———, and BERRIDGE, EMILY M.—The Anatomy and Morphology of the Inflorescences and Flowers of <i>Ephedra</i> . With Plate LXXXV and twenty-one Figures in the Text	953
THOMPSON, W. P.—The Anatomy and Relationships of the Gnetales. I. The Genus <i>Ephedra</i> . With Plates XCIV-XCVII and two Figures in the Text	1077

——— see BLACKMAN, V. H.	
YAPP, R. H.— <i>Spiraea Ulmaria</i> , L., and its Bearing on the Problem of Xeromorphy in Marsh Plants. With Plates LXXXI-LXXXIII and eleven Figures in the Text	815

B. LIST OF ILLUSTRATIONS.

- a. PLATES. I-V. *Zygopteris* Grayi (SCOTT).
 VI-X. Desert Plants (MACDOUGAL).
 XI, XII. *Myrica* Gale (BOTTOMLEY).
 XIII, XIV. Root-tubercles of *Alnus* and *Elacagnus* (SPRATT).
 XV, XVI. Bacterial Disease of Potato (DALE).
 XVII-XIX. *Viola* (BLISS).
 XX, XXI. *Salicales* (HOLDEN).
 XXII. *Cordaites Felicis* (BENSON).
 XXIII-XXVI. *Olpidiopsis* (BARRETT).
 XXVII. *Trichodiscus elegans* (WELSFORD).
 XXVIII, XXIX. *Peranema* and *Diacalpe* (DAVIE).
 XXX-XXXVI. *Lophosoria* and other Ferns (BOWER).
 XXXVII-XL. *Laboulbenia* (FAULL).
 XLI-XLIV. Cytology of *Primula* (DIGBY).
 XLV. *Ulva* (DELF).
 XLVI-XLVIII. Podocarpeae (STILES).
 XLIX-LIII. *Podocarpus* (GIBBS).
 LIV, LV. *Pteridium aquilinum* (HUME).
 LVI. *Tropaeolum* (HILL).
 LVII-LIX. *Gnetum* (DUTHIE).
 LX. *Gnetum* (PEARSON).
 LXI. *Bowenia* (KERSHAW).
 LXII, LXIII. Foliar Ray (BAILEY).
 LXIV, LXV. *Equisetum* (BROWNE).
 LXVI, LXVII. Spore-development (BEER).
 LXVIII. Seedling Anatomy (LEE).
 LXIX. *Collema* (BACHMANN).

PLATES. LXX, LXXI.	Polystigma (BLACKMAN and WELSFORD).
LXXII.	Asarum, Mycorhiza (SCHWARTZ).
LXXIII, LXXIV.	Filicinean Wound Reactions (HOLDEN).
LXXV, LXXVI.	Pericystis (BETTS).
LXXVII-LXXX.	Nodules of Podocarpaceae (SPRATT).
LXXXI-LXXXIII.	Leaves of Spiraea (YAPP).
LXXXIV.	Pachypodium (LEE).
LXXXV.	Ephedra (THODAY and BERRIDGE).
LXXXVI.	Oenothera (GATES).
LXXXVII-XC.	Mesoxylon (SCOTT).
XCI, XCII.	Sutcliffia (DE FRAINE).
XCIII.	Striga (STEPHENS).
XCIV-XCVII.	Ephedra (THOMPSON).
XCVIII.	Ceraria and Portulacaria (MICHELL).

	PAGE
δ. FIGURES. 1, 2.	Diagrams representing the sequence of segments cut off from apical cells. (1) Spiral dextrorse; (2) Spiral sinistrorse (EVANS)
3, 4.	Diagrams representing the first two walls formed in a lateral segment and the establishment of the segment-halves (EVANS)
5.	Diagram representing the establishment of two branches of the Frullania type (EVANS)
6.	Frullania Asagrayana (EVANS)
7.	Frullania aculeata (EVANS)
8.	Lepidozia reptans (EVANS)
9.	Sprucella succida (EVANS)
10.	Mastigophora Woodsii (EVANS)
11, 12.	Mastigophora Woodsii (EVANS)
13.	Pleuroclada albescens (EVANS)
14.	Lophocolea heterophylla (EVANS)
15.	Harpantus Flotowianus (EVANS)
16.	Plagiochila frondescens (EVANS)
17, 18.	Lophozia Wenzelii (EVANS)
19.	Lophozia attenuata (EVANS)
20.	Lophozia Floerkei (EVANS)
21, 22.	Lophozia inflata (EVANS)
23.	Jamesoniella autumnalis (EVANS)
24.	Zoopsis argentea (EVANS)
25.	Cephalozia bicuspidata (EVANS)
26.	Cephalozia curvifolia (EVANS)
27.	Bazzania tricenata (EVANS)
28.	Lepidozia (Microlepidozia) setacea (EVANS)
29.	Diagram representing the establishment of branches of the Microlepidozia and Frullania types (EVANS)
30.	Diagram representing the establishment of branches of the Acromastigum and Frullania types (EVANS)
31.	Radula aquilegia (EVANS)
32.	Euosmolejeunea duriuscula (EVANS)
33.	Lejeunea cavifolia (EVANS)
34.	Micropterygium Pterygophyllum (EVANS)
35.	Plagiochila Sullivantii (EVANS)
36.	Bazzania Brighami (EVANS)
1.	Zygopteris Grayi (SCOTT)
	Diagram 1. 1-7, Calandrinia; 8, Portulaca (HILL and DE FRAINE)
	Diagram 2. Silene Schafta (HILL and DE FRAINE)
1.	A, Saponaria Vaccaria; B, S. cerastoides (HILL and DE FRAINE)
2.	Obione portulacoides (HILL and DE FRAINE)

FIGURES.		PAGE
3.	<i>Salicornia europaea</i> (HILL and DE FRAINE)	184
	Diagram 3. <i>Salicornia</i> (HILL and DE FRAINE)	185
4.	<i>Salsola Kali</i> (HILL and DE FRAINE)	186
5.	A, <i>Mesembryanthemum crystallinum</i> ; B, <i>M. Bolusii</i> (HILL and DE FRAINE)	187
6.	<i>Abronia villosa</i> (HILL and DE FRAINE)	189
	Diagram 4. <i>Abronia umbellata</i> (HILL and DE FRAINE)	190
	Diagram 5. <i>Abronia umbellata</i> (HILL and DE FRAINE)	191
	Diagram 6. <i>Allionia albida</i> (HILL and DE FRAINE)	192
7.	<i>Mirabilis longiflora</i> (HILL and DE FRAINE)	193
	Diagram 7. <i>Mirabilis longiflora</i> (HILL and DE FRAINE)	194
8.	<i>Mirabilis multiflora</i> (HILL and DE FRAINE)	196
1.	<i>Cordaitea Felicis</i> , sp. nov. (BENSON)	204
1.	Somatic division in <i>Primula</i> and <i>Galtonia</i> (DIGBY)	362
2.	Univalent lengths of spireme joining to form the bivalent combinations (DIGBY)	366
1-4.	<i>Phaseolus multiflorus</i> (REED)	394
5-8.	<i>Phaseolus multiflorus</i> (REED)	395
9.	<i>Phaseolus multiflorus</i> (REED)	396
1.	Longitudinal section through attaching disc of <i>Ulva</i> (D ELF)	404
2.	Diagram of longitudinal section through disc of <i>Ulva latissima</i> (D ELF)	405
3.	Diagram of longitudinal section through disc of <i>Ulva latissima</i> (D ELF)	406
1.	Detached shoot of <i>Salicornia</i> (D ELF)	430
1.	Diagrams of transverse sections through primary stems of the Podocarpeae (STILES)	450
2.	Diagrams of transverse sections of leaves of the Podocarpeae (STILES)	456
3.	Transverse sections through microsporophylls of the Podocarpeae (STILES)	461
4.	Diagrams of a series of transverse sections through the ovule of <i>Podocarpus macrophyllus</i> (STILES)	471
5.	Diagrams of a series of transverse sections through the ovule of <i>Podocarpus latifolius</i> (STILES)	473
6.	Diagrammatic representation of a transverse section through an ovule of <i>Podocarpus nagi</i> (STILES)	475
7.	Diagrams of transverse sections through an ovule of <i>Podocarpus nagi</i> (STILES)	476
8.	Diagrammatic representation of megasporophylls to show the relation of ovule and sporophyll throughout the Podocarpeae (STILES)	491
1-6.	<i>Tropaeolum peregrinum</i> (HILL)	591
7.	<i>Tropaeolum majus</i> (HILL)	591
1.	Diagram of transverse section of peduncle of male spike of <i>Gnetum africanum</i> (PEARSON)	608
2.	Diagram of longitudinal section through node and internode of male spike of <i>Gnetum scandens</i> (PEARSON)	609
3.	Longitudinal section through two nodes and an internode of <i>Gnetum Buchholzianum</i> (PEARSON)	610
4.	Longitudinal section through a node and parts of two internodes of <i>Gnetum africanum</i> (PEARSON)	611
5.	Longitudinal section through apex of inflorescence of <i>Gnetum scandens</i> (PEARSON)	612
6.	Longitudinal section through apex of male inflorescence of <i>Gnetum africanum</i> (PEARSON)	613
1-4.	Series of median longitudinal sections of ovules of <i>Bowenia</i> of various ages (KERSHAW)	627
5.	Portion of longitudinal section of ovule represented in Text-fig. 3 (KERSHAW)	628

	PAGE
FIGURES.	
6. Diagrammatic transverse sections of the ovule (KERSHAW) . . .	632
7. Longitudinal section of sporophyll (KERSHAW) . . .	632
8-12. A series of transverse sections through the sporophyll (KERSHAW) . . .	633
13. Longitudinal section of an ovule (KERSHAW) . . .	634
14. Outline drawing of median longitudinal section of young abnormal ovule (KERSHAW) . . .	639
15, 16. Outline camera lucida drawings of median longitudinal sections of old abnormal ovules (KERSHAW) . . .	639
1. Longitudinal reconstruction of the xylem of Cone A of Equisetum (BROWNE) . . .	667
2. Longitudinal reconstruction of the xylem of Cone C of Equisetum arvense (BROWNE) . . .	669
3. Longitudinal reconstruction of the xylem of Cone A of Equisetum palustre (BROWNE) . . .	671
4. Longitudinal reconstruction of the xylem of Cone D of Equisetum palustre (var. polystachion) (BROWNE) . . .	672
5. Longitudinal reconstruction of the xylem of Cone A of Equisetum limosum (BROWNE) . . .	676
6. Longitudinal reconstruction of the xylem of Cone B of Equisetum limosum (BROWNE) . . .	677
7. Different forms of course of the strands at the nodes (BROWNE) . .	681

Branching in the Leafy Hepaticae.

BY

ALEXANDER W. EVANS,

Professor of Botany in Yale University.

With thirty-six Figures in the Text.

THE branching of the shoot in the Hepaticae was carefully studied by Leitgeb ('71 a, '71 b, '72, '75) about forty years ago. Although most of the previous writers on this subject had confined their attention to a few thalloid genera, Leitgeb extended his observations to include a large number of leafy forms. He was able to demonstrate the fact that throughout the Jungermanniales (comprising the Metzgeriaceae and the Jungermanniaceae of many recent writers) the branches are never formed by a true dichotomy; that, in other words, the apical cell of a branching shoot never gives rise by a median longitudinal wall to the apical cells of two branches, a process which takes place in certain dichotomous Algae, such as *Dictyota*. In the Jungermanniales the branches invariably arise in segments cut off from the apical cell, and it is the persistence of the latter in the branching axis which indicates that the branching is monopodial in character.

Leitgeb showed further, however, that the apical cell of a future branch often made its appearance in an exceedingly young segment. Under these circumstances, if the branch grows vigorously and deflects the main axis to one side, the branch-system may simulate a dichotomy very closely. This is the case, for example, in *Metzgeria furcata* and in the genus *Bazzania* (Fig. 27). If, on the other hand, the branch grows less vigorously than the main axis and assumes a distinctly lateral position the branching is obviously of the monopodial type. *Riccardia multifida* and *Lepidosia reptans* (Fig. 8) may be cited as examples of this condition. When the branches arise close to the apical cell, as in the cases just considered, Leitgeb distinguishes the process as 'Endverzweigung' or 'Terminal Branching'. He contrasts with this 'Intercalary Branching', in which the branches first appear at some distance from the apical cell. In this latter type of branching the monopodial character is always apparent. It should be noted also that segments in which terminal branches begin their development are embryonic in character and are still undergoing cell-divisions; those where intercalary branches arise, on the other hand, have become more or less completely differentiated, and their cells have apparently ceased dividing.

Although Leitgeb's distinctions are based on differences in development, the two types of branches can usually be recognized in mature plants on account of the fact that terminal branches arise exogenously while intercalary branches arise endogenously. The result is that the superficial tissues of a terminal branch are continuous with those of the axis, while an intercalary branch shows a distinct sheath at its base formed by ruptured cortical tissues. In the present paper the branching in the Jungermanniaceae will alone be considered. This group, which is the equivalent of the Jungermanniae akrogynae of certain writers, includes the vast majority of the leafy genera and illustrates both terminal and intercalary branching much more fully than the other groups of the Hepaticae.

In order to give a clear idea of the way in which branches arise it will be necessary to describe briefly the normal divisions which take place in young segments. Here again our knowledge is largely based upon the work of Leitgeb. With the exception of the genus *Pleurozia*, where Goebel

FIGS. 1 and 2. Diagrams representing the sequence of segments cut off from apical cells.
Fig. 1. Spiral dextrorse. Fig. 2. Spiral sinistrorse.

('93, p. 453) has demonstrated a two-sided apical cell, the Jungermanniaceae all grow by means of a tetrahedral apical cell, which cuts off three longitudinal rows of segments in the usual way. On account of the orientation of the shoot one row of these segments will occupy a ventral position and the other two lateral positions (Fig. 1). When the segments are first cut off they are approximately in the form of flat triangular prisms, each bounded by two broad faces or walls and three narrow walls. One of the broad faces will lie in contact with the apical cell and may, as Leitgeb suggests, be designated the acroscopic wall; the other broad face, lying in contact with the next older segment of the same row, may then be distinguished as the basiscopic wall. Of the three narrow faces one, the free wall, will be exposed at the apex of the shoot, while the two others will come into contact with segments of the two other rows. In the lateral segments these two narrow faces may be distinguished as the dorsal and ventral walls respectively. They may be distinguished also according to the direction of the spiral in which the leaves are arranged. In Fig. 1, for example, which represents a dextrorse spiral, the dorsal wall in segment 4 is cathodic and the ventral wall anodic; in segment 3, on the other hand, the dorsal wall

is anodic and the ventral wall cathodic. In Fig. 2, which represents a sinistrorse spiral, segment 4 agrees with segment 3 of Fig. 1 in having its dorsal wall anodic and its ventral wall cathodic, while segment 2 agrees with segment 4 of the same figure. Speaking generally, therefore, it may be stated that with a dextrorse spiral the anodic walls of the lateral segments will be ventral on the right-hand side (when a shoot is viewed from the ventral surface), while with a sinistrorse spiral they will be ventral on the left-hand side. In the ventral segments the narrow enclosed walls are both lateral, but may be distinguished as anodic and cathodic. Of course the descriptive terms which have just been applied to the walls may also be applied to portions or regions of a segment.

The early divisions in a segment follow a definite sequence, and Leitgeb was therefore able to assign the branches which he studied to definite regions. In the lateral segments the first two walls are at right angles to

FIGS. 3 and 4. Diagrams representing the first two walls formed in a lateral segment and the establishment of the segment-halves.

the two broad faces. The first wall (Fig. 3, 1) extends from the middle of the free face to one of the enclosed narrow faces; the second wall (Fig. 4, 2) connects the first wall with the other narrow face. The segment thus becomes divided into an internal cell and two external cells, the latter being designated by Leitgeb the 'segment-halves'.¹ These halves may be distinguished as dorsal and ventral and also as anodic and cathodic. In the ventral segments the first wall brings about a division into an inner and an outer cell, the latter usually becoming subsequently subdivided by one or more anticlinal walls. In the further development of the shoot the internal cells of the segments are destined to give rise to the axial tissues of the stem, while the external cells will form the cortical tissues of the stem and also the leaves or other appendages. Each lateral segment develops normally a single leaf, which represents the entire breadth of the segment, and Leitgeb has clearly shown that in bilobed leaves the dorsal lobe has been formed from the dorsal segment-half and the ventral lobe from the ventral half. Even in leaves which are undivided at maturity the young rudiments show evidence of being bilobed, but the shallow sinus between them soon becomes obliterated. In leaves with more than two

¹ Leitgeb really applied the term 'segment-halves' to the two unequal cells formed by the first division wall in a lateral segment. The slight alteration in the application of the term, indicated above, makes it possible to homologize better the ventral segments with the lateral segments.

lobes one or both of the external cells of the young segment divide before the development of the leaf is clearly begun, and in this way the extra lobes are provided for. In the development of a leaf the segment-halves project and become divided by periclinal walls; these cut off the rudiment of the leaf from the cells which, by their further divisions, will form the cortical tissues of the stem. In ventral segments where underleaves are formed the development proceeds in much the same way.

Terminal Branching.

According to Leitgeb ('71 *b*) terminal branches always arise in the ventral portions of the lateral segments. He recognizes, however, two distinct kinds of terminal branching. In the first, which he describes as branching from a segment-half, the branch represents the entire ventral half of a segment, the apical cell of the branch making its appearance before the walls separating the leaf-rudiment from the cortical cells have been laid down. For the sake of convenience this may be designated the '*Frullania* type' of branching. In the second kind, which he describes as branching from the basiscopic basilar portion of a segment, the apical cell of the branch arises in a cortical cell of the axis after the leaf-rudiment has been cut off. The branch represents therefore a much smaller portion of the segment than a branch of the first kind. Branching of the second kind may be distinguished as the '*Radula* type'.

About ten years ago the writer discovered in the Hawaiian genus *Acromastigum* ('00) a third kind of terminal branching, in which the branch represents a half of one of the ventral segments. No other representatives of this kind of branching have been discovered and it may be called the '*Acromastigum* type', although other kinds of branching occur in the same genus. A fourth kind of terminal branching, in which the branch represents the dorsal half of a lateral segment, is described below. It is known only in the subgenus *Microlepidozia* of the genus *Lepidozia*, and may therefore be characterized as the '*Microlepidozia* type'.

THE FRULLANIA TYPE.

Leitgeb ('71 *b*) describes the development of branches of this type very clearly, and his diagram of a sinistrorse branching axis, which is here reproduced in a slightly modified form (Fig. 5), illustrates the sequence of the early divisions. In segments 1 and 2 the ventral halves have each undergone four divisions, which have cut off the tetrahedral apical cells of the future branches. In fact each of these segment-halves is essentially an apical cell from the beginning, the three cells first cut off acting as the first three segments of the branch. It will be noted that the walls in the segment-halves are in the following sequence: the first wall extends from the first division wall of the segment to the acroscopic wall, meeting the

latter near its ventral extremity; the second wall extends from this first wall to the division wall, lying approximately parallel with the acroscopic wall; the third wall connects the first two walls. This sequence is the same in both segments, although segment 1 is situated on the right-hand side of the apical cell and segment 2 on the left-hand side, a difference which brings the branch in segment 1 in the kathodic segment-half and that in segment 2 in the anodic half. As Leitgeb points out further, this will make the spiral of the branch on the left-hand side sinistrorse, and therefore homodromous with that of the branching axis, while the branch on the right will be dextrorse and antidromous. If the branching axis were dextrorse the left-hand branch would still be sinistrorse and therefore antidromous, while the right-hand branch would be dextrorse and homodromous. In other words, the branches which arise in the anodic segment-halves are homodromous with the branching axis, those arising in the kathodic halves being antidromous.

Of course the relationships which have just been brought out remain equally evident after the axis and its branches have developed further, and it is usually quite possible, from the study of an older shoot, to recognize the *Frullania* type of branching at a glance and to refer the various appendages of the branch to their appropriate segments. As might naturally be expected, the first cell cut off from the segment-half gives rise to the first underleaf of the branch, the second cell to the first lateral leaf (always situated on the side of the branch turned towards the apex of the branching axis), the third cell to the second lateral leaf (on the opposite side), the fourth cell to the second underleaf, and so on. With regard to the spirals, the branches on the left-hand side (when the shoot is viewed from the ventral surface) will all be sinistrorse and those on the right-hand side will all be dextrorse, whatever may be the direction of the spiral in the branching axis.

On account of the fact that a branch represents an entire ventral segment-half, only the dorsal half is left to form the leaf adjacent to the branch. This leaf consequently differs more or less from normal leaves, the most important differences being in form and in the number of lobes present. Sometimes, however, the leaf shows interesting peculiarities in its method of attachment. The leaves and underleaves at the base of a branch are also subject to more or less modification, both in form and in position. The differences in position are largely due to the fact that the first segments cut off from the original segment-half are less definitely

FIG. 5. Diagram representing the establishment of two branches of the *Frullania* type.

orientated than those which come later. Segment 1', for example, in Fig. 5, is not exactly ventral, but forms a considerable angle with the lower surface of the shoot, and segments 2' and 3' are also somewhat displaced. The differences in form are partly to be looked upon as reversions to a more juvenile condition, and partly as modifications associated with differences in environment.

The *Frullania* type of branching is more widely represented among the Jungermanniaceae than any of the other types of terminal branching. Some of the genera which show it have incubous leaves, some have succubous leaves, and some have complicate leaves. They include members of all the subfamilies recognized by Schiffner ('93-'95) with the exception of the Scapanioideae, the Stephanoideae (Raduloideae), and the Pleurozoideae. In certain genera, such as *Frullania*, *Porella*, and *Blepharostoma*, the branches all conform closely to this type; in other genera the *Frullania* type of branching occurs in connexion with other kinds. In *Bazzania*, for

FIG. 6. *Frullania Asagrayana*. Ledyard, Connecticut (A. W. E.). $\times 36$.

example, branches of the *Frullania* type and intercalary branches are both present, while in *Stictolejeunea* and a few other genera of the Lejeuneae terminal branches of both the *Frullania* type and the *Radula* type are developed. A number of characteristic examples of the *Frullania* type of branching will now be considered in detail. They are selected in order to show the modifications associated with the various methods of leaf-attachment.

Frullania.—The normal leaves throughout this genus are deeply complicate-bilobed, the dorsal lobe being much the larger of the two. The ventral lobe, or lobule, usually develops a hollow water-sac with the opening turned towards the base of the stem or branch. The underleaves are almost always bifid. The modifications usual at the base of a branch are clearly shown in *F. Asagrayana*, a common species of eastern North America. A fragment of a branching stem is represented in Fig. 6 with the base of the branch on the left-hand side, and it will be noted that both spirals shown are sinistorse. The incomplete leaf developed from the same segment as the branch consists of the dorsal lobe only; it spreads more obliquely than the other leaves, being almost symmetrically situated with respect to both stem and branch. The line of attachment (not shown in the figure) is partly on the stem and partly on the branch. The first underleaf of the branch is at the junction with the stem, and its line of attachment extends around the base of the branch until it almost meets the line of attachment of the incomplete leaf. Apparently, however, the

leaf is never coalescent with the underleaf. The latter is not essentially different in form from other underleaves, except that it frequently bears a small tooth at about the middle of its anodic edge. The first leaf of the branch is completely covered over by the incomplete stem leaf; it shows a well-developed lobule, usually in the form of a water-sac, but the dorsal lobe is very narrow and short, scarcely exceeding the lobule in length. The following leaves and underleaves are normal in structure and exhibit a gradual increase in size, rarely, however, becoming as large and as highly differentiated as the leaves and underleaves of the stem.

The modifications noted in *F. Asagrayana* are less striking than in certain other species of *Frullania*, and the remarkable *F. aculeata*, of western South America, may be chosen to illustrate a more pronounced specialization. In this species (Fig. 7) the first underleaf of the branch is divided to the very base. The anodic division is in the form of a slender subulate lamina, but the cathodic division is a well-formed water-sac, similar in all respects to those found on normal leaves. This water-sac, from its position, looks very much as if it belonged to the incomplete leaf, which covers over the base of the branch. The first leaf of the branch has a lobule in the form of a water-sac, just as in *F. Asagrayana*, but the dorsal lobe, instead of being a lamina, is also a water-sac of the same type. The development of three water-sacs at the base of a branch, where in most species a single one is found, is apparently associated with a more xerophytic habit. The condition seems to be especially frequent in species belonging to the subgenera *Meteoriopsis* and *Diastoloba*.

Although in the two species just noted the first segment of a branch forms no appendicular organs except the first underleaf, Leitgeb ('75, p. 25) calls attention to the fact that in some species it often forms in addition short lobe-like appendages, which grow out between the underleaf and the incomplete leaf. These appendages, which are exceedingly variable even on an individual plant, are of considerable interest and help to explain certain peculiar structures found in other genera.

Lepidozia.—Only the subgenus *Eulepidozia* will be considered here, the discussion of *Microlepidozia* being deferred until the *Microlepidozia* type of branching is described. The common and widely distributed *L. reptans*, of

FIG. 7. *Frullania aculeata*. Galapagos Islands (A. Stewart, No. 2770). $\times 17$.

Europe, Asia, and North America, represents *Eulepidozia* adequately and is shown in Fig. 8. It will be noted that both stem and branch are dextrorse in the fragment drawn. The normal leaves in *L. reptans* are three- or four-cleft to about the middle, but the incomplete leaf at the base of a branch is only two-cleft, the apices of the lobes showing in the figure. This leaf is attached partly to the stem and partly to the branch, but is separated by a considerable distance from the first underleaf. The latter is usually bifid, although undivided or even trifid underleaves sometimes occur in this position. It is strongly concave and is inserted in such a way* that the branch seems to arise in its axil. In fact, Stephani speaks of it as a sub-

FIG. 8. *Lepidozia reptans*. Huelgoat (Finistère), France (F. Camus). $\times 40$.

FIG. 9. *Sprucella succida*. N'dian, Kamerun (P. Dusen, Ileap. Afr., No. 100). $\times 40$.

tending leaf ('91, p. 215). The sequence, however, shows clearly that it ought to be considered an underleaf, and this conclusion is supported by the fact that hyaline papillae are present at the apices of the lobes. In a leaf arising from a lateral segment there are no such papillae in the apical region. With the exception of the first underleaf the leaves of a branch show no special modifications, although a gradual increase in size is usually apparent.

Sprucella.—The genus *Sprucella* of Stephani ('91, p. 214), which includes the single African species *S. succida*, is closely allied to *Lepidozia*. The incubous leaves, which are almost longitudinally attached, are shortly bidentate at the apex, but are otherwise entire. The underleaves are much smaller; on robust stems they are nearly always quadrifid, but they may be only trifid or bifid. The terminal branching is essentially as in *Lepidozia*, but shows a few differences in detail. The incomplete leaf, for example,

which arises from the same segment as the branch (see Fig. 9), is much smaller than normal leaves and shows no indication of teeth, being merely acuminate at the apex. The first underleaf of the branch is so nearly ventral in position that it cannot be seen when the shoot is viewed from the dorsal surface. This underleaf is very minute and is undivided; it is subulate in form and is usually only four or five cells long and three cells wide at the base. The second underleaf of the branch is normal in structure, and the same is true of the other leaves.

In comparing *Lepidozia* with *Sprucella* Stephani remarks that one of the most important differences between the genera is in the insertion of the branches. He states that in *Lepidozia* a branch springs from the inner angle of a stem-leaf, which turns its concave surface towards the branch and thereby subtends it. In *Sprucella*, on the contrary, he describes the branch as springing from the outer angle of a stem-leaf, that is, from the angle which the ventral margin of the leaf forms with the stem. As the branch develops the leaf is said to be displaced to the dorsal surface of the stem and to appear partly on the stem and partly on the branch. He states further that there is no subtending leaf as in *Lepidozia*. It will be seen from the account given above that the branches in both genera spring from the outer angles of incomplete stem-leaves, belonging to the same lateral segments, and that the subtending leaf in *Lepidozia* is nothing more than the first underleaf of the branch, and is therefore homologous with the subulate underleaf at the base of the branch in *Sprucella*. If Stephani's figure is examined ('91, Pl. XXIX, Fig. 35) it will be seen that this diminutive underleaf in *Sprucella* did not escape his attention, because he shows it clearly in the first branch on the left. He makes no allusion to it, however, in his description.

FIG. 10. *Mastigophora Woodsii*. Moidart, Scotland (S. M. Macvicar). $\times 40$.

Mastigophora.—The rare *M. Woodsii* of western Europe is a somewhat doubtful member of this genus because its organs of reproduction are still unknown. When compared with the species already considered it shows an interesting peculiarity in its branches connected with the method of attachment of the first underleaf. The leaves in *M. Woodsii* are deeply bifid, the ventral lobe being smaller than the dorsal and usually more or less deeply subdivided (Fig. 10). The lobes are connected by a rounded

keel and tend to be slightly complicate. The underleaves are large and bifid. When a branch is formed the leaf arising from the same segment is broad but undivided (Fig. 11), and its line of attachment extends across the dorsal base of the branch. The first underleaf is remarkable because it is apparently not attached to the branch at all, but to the stem at some distance below the base of the branch. It seems to be laterally inserted on the stem, and its line of attachment is almost transverse as in ordinary underleaves. This underleaf is strongly concave, but when dissected off presents no unusual features either in form or size (Fig. 12).^{*} In such a case as this it must apparently be assumed that the base of the branch is coalescent with the stem. The description just given applies most forcibly to primary branches. When these become subdivided there is little or no coalescence at the base of a secondary branch, the first underleaf occupying much the same position as in *Lepidozia*.

FIGS. 11 and 12. *Mastigophora Woodsii*. Same material as Fig. 10.
Fig. 11. Incomplete leaf at base of branch. Fig. 12. First underleaf of branch. $\times 40$.

Pleuroclada.—Large and conspicuous underleaves are rarely associated with succubous leaves in the Jungermanniaceae. This condition, however, is found in *Pleuroclada albescens*, a widely distributed species of Europe and North America at high altitudes. The branching in this species is invariably of the *Frullania* type, and the structures at the base of a branch show a few distinctive features. Unfortunately the succubous insertion of the leaves, even here, is less distinct than in such genera as *Lophocolea* and *Chiloscyphus*, apparently on account of the fact that the bilobed leaves show a tendency to be complicate. If the line of attachment is examined it will be seen that the portion corresponding to the dorsal lobe is almost transverse, and that it is only in the portion corresponding to the ventral lobe that the obliqueness is clearly apparent. The leaves are strongly convex and appear almost hemispherical, the acute lobes being separated by a narrow sinus (Fig. 13). The underleaves approach the leaves in size, but are normally undivided and acute; their margins are either entire or unidentate on one or both sides. Two and sometimes three papillae can be demonstrated on an

underleaf, one at the apex and the others on the lateral teeth or in a corresponding position on the sides.

The leaf at the base of a branch shows its incomplete character by being undivided; its line of attachment extends until it almost meets the first underleaf, very much as in *Frullania*. In the figure only the apex and a portion of the base are visible. The first underleaf differs from ordinary underleaves in being distinctly bilobed, thus bearing a marked resemblance to a normal leaf arising from a lateral segment. It betrays its true nature, however, by the presence of a papilla at the apex of each lobe. The second underleaf of the branch is normal in form and position, and the other leaves show no striking peculiarities.

Lophocolea.—In this genus the leaves are distinctly succubous, and the underleaves are well developed, although relatively smaller than in *Pleuro-*

FIG. 13. *Pleuroclada albescens*. Valais Alps, Switzerland (F. Camus). $\times 40$.

FIG. 14. *Lophocolea heterophylla*. Stafford, Connecticut (G. E. Nichols). $\times 27$.

clada albescens. The branching is largely intercalary, but terminal branches of the *Frullania* type are not unusual. The plant chosen to represent this type of branching is a small and juvenile form of *L. heterophylla*, an exceedingly common species throughout Europe, Asia, and North America. In the portion of the plant shown in Fig. 14 it will be seen that the leaves are bifid and that the underleaves are either deeply bifid or quadrifid. The leaf which belongs to the same segment as the branch does not lie over the angle between the branch and the axis as in the species previously considered. It is situated instead below the branch, although its line of attachment extends nearly or quite to the base. The leaf is nearly as broad in the basal portion as normal leaves, but is undivided, the apex being sharply acuminate. The first underleaf of the branch is normal in position, and is often larger and more complex than the second underleaf. The first leaf is small but bifid, and is completely covered over by the leaves of the

branching axis which come after the incomplete leaf. The second and later leaves of the branch show a rapid progression in size. The modifications just described are shown equally well by *L. bidentata* (see Leitgeb, '75, p. 24), another species with an exceedingly wide distribution, and are doubtless to be found in other members of the genus.

Harpanthus.—The present genus is composed of two species, *H. Flotowianus* and *H. scutatus*, both of which are widely distributed in the Northern Hemisphere. According to the published descriptions the branching is invariably intercalary and ventral, and this statement is apparently true of *H. scutatus*. In robust forms of *H. Flotowianus*, however, branches of the *Frullania* type occasionally occur. The leaves of this

FIG. 15. *Harpanthus Flotowianus*. Riesengebirge, Bohemia (V. Schiffner, in Hep. Eur. Exsic., No. 294 b). $\times 17$.

FIG. 16. *Plagiochila frondescens*. East Maui, Hawaiian Islands (D. D. Baldwin, No. 85). $\times 17$.

species are decurrent and spread obliquely. They are distinctly succubous and are attached by an almost longitudinal line. The apex is very shallowly indented, the apical lobes or teeth varying from rounded to pointed. The much smaller underleaves are lanceolate and acute, and are sometimes unidentate on one or both sides. When a terminal branch is developed it shows a coalescence with the branching axis very much as in *Mastigophora Woodsii*, the first underleaf being apparently situated at some little distance from the base of the branch (Fig. 15). The incomplete leaf occupies much the same position as in *Lophocola heterophylla*; it is nearly as large as the other leaves, but differs from them in being rounded and undivided at the apex. The first underleaf of the branch is considerably larger than normal underleaves and is deeply bifid with acute divisions.

The first leaf is almost transversely inserted and is much more symmetrical than the other leaves, the apical sinus being deeper and the lobes tending to be more acute. The other leaves and underleaves of the branch are not specialized.

Plagiochila.—The leaves in this genus are undivided, so that it stands in sharp contrast to the genera so far considered. Branching of the *Frullania* type is apparently restricted to species in which the secondary shoots are copiously subdivided and give rise to complex branch-systems. As an example *P. frondescens*, a widely distributed palaeotropic species, may be cited. The leaves in this plant (Fig. 16) usually show about half a dozen sharp teeth at the apex and along the ventral margin. They are attached by an oblique line which becomes abruptly arched at the ventral end. The underleaves consist of clusters of minute cilia bearing hyaline papillae. The incomplete leaf adjacent to a branch occupies the same position as in *Lophocolea* and *Harpanthus Flotowianus*; it is somewhat narrower than the other leaves, but is much like them in other respects and is attached by a line of the same type. The first underleaf of the branch is slightly displaced towards the basiscopic side (with respect to the branching axis), but shows no other modifications. The first leaf is more or less reduced in size, being sometimes very small indeed. In the example figured it appears as a lanceolate, entire lamina, but it is subject to variation and is often toothed. The succeeding branch-leaves are essentially like other leaves.

In the genus *Chiloscyphus*, as recently restricted by Schiffner ('10), branches of the *Frullania* type are not infrequent. They agree closely with those just described for *Plagiochila frondescens* and, like them, are usually associated with leaves which are undivided at maturity. Müller, however, refers these branches to the *Radula* type ('06-'11, p. 818).

Lophozia.—With the exception of subfloral innovations branches are difficult to demonstrate in most species of *Lophozia*. Terminal branches of the *Frullania* type, however, have been recognized in *L. inflata* and *L. acutiloba*, two species which Müller ('06-'11, p. 738) separates from *Lophozia*, reviving for them the old generic name *Gymnocolea*. Müller (p. 675) has also noted the exceptional occurrence of such branches in *L. longiflora*, var. *uliginosa*, and in *L. Wenzelii*, while the writer has been able to demonstrate them in several other members of the genus, some belonging to the subgenus *Dilophozia* and some to the subgenus *Barbilophozia*. As an example of *Dilophozia*, *L. Wenzelii*, an alpine and arctic species of Europe, Asia, and North America, will be described. The leaves are distinctly succubous and have a shallow apical sinus with broad and bluntly pointed lobes. The line of attachment is long and oblique and the leaves are normally plane or nearly so. Underleaves are represented by minute hair-like structures tipped with hyaline papillae and are usually short-lived and difficult to

demonstrate. Fig. 17 shows a branch of the typical *Frullania* type. It will be noted that the leaf belonging to the same segment as the branch is similar to the other leaves, but is undivided, and that the line of attachment comes to an end at some little distance from the base of the branch. The first underleaf is a distinct though small lamella, and the first leaf of the branch differs from normal leaves in being somewhat complicate. The modifications are comparable with those seen in *Harpanthus Flotowianus*, although there is no marked coalescence between the branch and the axis.

In Fig. 18 an interesting variation is shown, in which the incomplete leaf is attached by a line which seems to be prolonged as far as the first underleaf of the branch. The part adjacent to the underleaf corresponds

FIGS. 17 and 18. *Lophozia Wenzelii*. Near Hallen (Jemtland), Sweden (H. W. Arnell and A. Grape, in Hep. Eur. Exsic., No. 172). $\times 17$.

to a sharp lobe-like tooth, which is united to the leaf at its ventral base. This tooth might perhaps be considered the first underleaf of the branch; it might be considered an accessory lobe of the incomplete leaf; it might be considered an appendage of the first segment of the branch, borne in addition to the first underleaf and similar to the appendages described by Leitgeb in *Frullania*. The first interpretation is hardly permissible, because a minute underleaf very much like the one shown in Fig. 17 is visible at the base of the tooth; there are also objections to the second interpretation on account of the long line of attachment; the third interpretation, however, seems to accord well with the conditions present. An examination of Fig. 5 shows that the first segment of the branch and the dorsal segment-half are adjacent, so that a coalescence between the

appendicular organs which spring from these regions would not be at all surprising. Similar unions, in fact, are frequently met with between bracts and bracteoles and are not unusual between ordinary leaves and underleaves.

As members of the subgenus *Barbilophozia*, *L. attenuata* and *L. Floerkei* may be considered. Both of these species are widely distributed in the northern parts of Europe, Asia, and North America. In *L. attenuata* the leaves are commonly trifid, although bifid leaves are not unusual. They are attached by an oblique line, but often show more or less tendency to be complicate, the dorsal lobe being connected with the rest of the leaf by a rounded keel. Sometimes the dorsal portion is attached by an almost transverse line. The underleaves are minute and inconspicuous, and were not made out in the material studied on account of the thick felt of rhizoids. When a branch is developed (Fig. 19) the leaf belonging to the same segment is undivided and acute, corresponding clearly to the dorsal lobe of an ordinary leaf. At some little distance from the incomplete leaf, on the ventral surface of the shoot, another leaf-like structure, which is also undivided and acute, can be discerned. This should apparently be interpreted as an appendage of the first segment of the branch but distinct from the first underleaf. It differs from the homologous appendage in *L. Wenzelii* in being entirely free from the incomplete leaf. The first branch-leaf in *L. attenuata* is small and often undivided; it is usually covered over by the next stem-leaf on the same side as the branch. The remaining leaves of the branch show no special modifications.

A study of *L. Floerkei* adds further support to the interpretation just given of *L. attenuata*. The leaves in *L. Floerkei* are normally trifid and the distinct underleaves are bifid.

At the base of a branch a structure like that shown in Fig. 20 can be demonstrated. The first underleaf of the branch (at the left-hand end of the figure) is similar to the other underleaves, but is undivided; the incomplete leaf is also undivided and clearly represents a dorsal lobe; between the two and somewhat coalescent with the leaf is a broad bifid structure, which is evidently homologous with the lobe-like tooth

FIG. 19. *Lophozia attenuata*. Helsingfors, Finland (H. Lindberg, in Hep. Eur. Exsic., No. 95). $\times 40$.

FIG. 20. *Lophozia Floerkei*. Bethesda, Wales (W. H. Pearson). $\times 27$.

described in *L. Wenzelii*. The examples just considered thus form a kind of series with respect to the structures at the base of a branch. In Fig. 17 of *L. Wenzelii* the first ventral segment of the branch has formed simply the first underleaf; in Fig. 18 of the same species it has formed in addition a small appendage coalescent with the incomplete leaf; in *L. Floerkei* the appendage is much larger and the coalescence is less extensive; in *L. attenuata* the appendage is also large, but is entirely free from the leaf. In all probability an extensive study of the species here considered and allied species would show more or less variation in the structures described.

The branches in *L. inflata* and *L. acutiloba* offer a few further points of interest. *L. inflata* is one of the most widely distributed and variable

FIG. 21. *Lophozia inflata*. Riesengebirge, Bohemia (V. Schiffner and E. Bauer, Bryoth. Bohem., No. 294). $\times 17$.

FIG. 22. *Lophozia inflata*. Same material as Fig. 21. $\times 17$.

species in northern Europe, Asia, and North America; the closely related *L. acutiloba*, on the other hand, is known from only a few European localities. Schiffner ('03, p. 28) states that in *L. inflata* the leaf developing from the same segment as a branch is undivided, thus differing from the normal two-lobed leaves, and he also makes similar statements about *L. acutiloba* ('09). In Fig. 21, which represents a robust aquatic form of *L. inflata*, the conditions described by Schiffner are clearly shown. The normal leaves are here somewhat more explanate than in some of the other forms of the species; they show a long oblique line of attachment and two rounded lobes separated by an obtuse sinus. The incomplete leaf is at some little distance below the branch; it is attached by a shorter line and is merely rounded at the apex. The leaves of the branch are essentially normal

from the beginning. In the form figured there are no distinct underleaves, the only ventral appendages being hyaline papillae which sometimes cut off a few cells at the base. A group of these papillae can usually be distinguished at the base of a branch in the position where an underleaf would naturally appear.

In addition to the branches just discussed, Müller, in both *L. inflata* and *L. acutiloba*, describes cases in which the leaf below the branch is bilobed instead of being undivided. This condition does not seem to be infrequent and is shown in Fig. 22. It will be seen that the leaf below the branch (the lower leaf on the right-hand side) looks like the other leaves except that its line of attachment is shorter. If it were not for this slight difference and for the difference in the sequence in which the leaves are borne, it would be difficult to distinguish the branch from the branching axis. Müller refers branches like this to the *Radula* type instead of to the *Frullania* type. There are, however, two objections to this interpretation: first, the sequence in which the leaves of the branch are borne, and, second, the short line of attachment of the leaf below the branch. In the writer's opinion the branches shown in the two figures of *L. inflata* ought both to be referred to the *Frullania* type. The presence of two lobes in one of the incomplete leaves could then be ascribed to the tendency, which so many species of *Dilophozia* show, to develop more than the normal number of lobes. The terminal branches in *L. acutiloba* are in all essential respects like those of *L. inflata*.

FIG. 23. *Jamesoniella autumnalis*. Cromwell Connecticut (A. W. E.). $\times 17$.

Jamesoniella.—In *J. autumnalis*, a species which is aberrant in certain respects, branching of the *Frullania* type can occasionally be observed. In all typical members of the genus the branches are apparently always intercalary and ventral. *J. autumnalis* is widely distributed throughout North Temperate regions. The leaves (Fig. 23) are undivided and rounded, and the line of attachment is long and oblique. The minute underleaves are often short-lived and difficult to demonstrate among the rhizoids. The incomplete leaf at the base of a branch is coalescent with a lobe-like appendage at the ventral base, similar to the one figured in *Lophozia Wenzelii*. The appendage varies considerably in size and in the extent of coalescence; the apex varies also from acute (as shown in the figure) to obtuse or rounded. The first underleaf of a branch tends to be a trifle larger than normal underleaves, but the other branch-leaves show no modifications of interest.

Zoopsis.—Among the genera which Spruce ('82) included under *Cephalozia*, branching of the type now being discussed seems to be exceedingly rare. It has been reported, in fact, in scarcely a half-dozen species, two of which belong to the genus *Zoopsis* and the others to the genus *Cephalozia* in its restricted sense (the subgenus *Eucephalozia* of Spruce). In *Zoopsis* Leitgeb ('76) alluded briefly to the branching and stated that only vegetative branches ever conformed to the *Frullania* type. His observations were largely based on *Z. argentea*, a widely distributed species the range of which extends from New Zealand and Australia into tropical Asia. The leaves in this species are probably the most rudimentary found in the genus (Fig. 24). Each consists of only four cells, two of which form the base. The other two cells are in the form of papilla-like appendages attached more or less trans-

FIG. 24. *Zoopsis argentea*. New Guinea (L. Loria, No. 63). $\times 80$.

versely to the basal cells, the one belonging to the more dorsal cell being about twice as long as the other. Although at first sight the leaves appear longitudinally inserted, they are really very slightly succubous. The underleaves are minute, but are apparently always present. In the figure the branch is on the right-hand side, and it will be seen that the leaf belonging to the same segment consists of only two cells, the long apical papilla indicating that the dorsal half is the one represented. It should also be noted that this incomplete leaf seems to be situated at the base of the branch instead of on the branching axis. Aside from this peculiar leaf there is little to show that the branch-

system is not a dichotomy, the first leaf of the branch being normal in structure and position and the first underleaf (not shown in the figure) being ventral and like the other underleaves of the plant.

Cephalozia.—The *Frullania* type of branching has been noted by Leitgeb ('75) in *C. bicuspidata* and *C. curvifolia*, by Spruce ('82) in *C. tubulata*, and by Stephani ('06-'09) in *C. hamatiloba* and *C. asperrima*. Only the first two of these species will be considered here. They are both widely distributed in Europe, Asia, and North America. In *C. bicuspidata* Leitgeb calls attention to the undivided leaf at the base of a branch and notes that he has observed branching of this type in but a single instance. Apparently, however, the phenomenon is less uncommon than he implies. The writer has found it to occur not infrequently in specimens from British Columbia collected by Macoun and by Brinkman, and also in a specimen from Baden collected by Jack and distributed in Gottsche and Rabenhorst's *Hepaticae Europaeae* (No. 353). In Fig. 25, which represents one of

Macoun's plants, it will be noted that the sharply bilobed leaves are distant and tend to be somewhat complicate. The dorsal lobe is almost transversely inserted, but the line of attachment of the ventral lobe is distinctly oblique, the conditions being much the same as in *Pleuroclada albescens*. No underleaves are present, each ventral segment bearing instead a single hyaline papilla. The incomplete leaf at the base of the branch is undivided and acuminate. The first segment of the branch bears a hyaline papilla (not visible in the figure) and, in addition, a large leaf-like appendage. Apparently there is never coalescence between the appendage and the incomplete leaf, although their lines of attachment sometimes approach each other very closely. The branches in this plant bear a strong resemblance to those described in *Lophozia attenuata*.

FIG. 25. *Cephalozia bicuspidata*. Ucluclet, British Columbia (J. Macoun, No. 115). $\times 40$.

FIG. 26. *Cephalozia curvifolia*. Franconia Mountains, New Hampshire (A. W. E.). $\times 40$.

In *C. curvifolia* (sometimes made the type of the distinct genus *Nowellia*) branching of the *Frullania* type is not unusual. The leaves in this species are attached in much the same way as in *C. bicuspidata* and are characterized by the strongly inflated base of the ventral lobe (Fig. 26). The ventral segments produce hyaline papillae, just as in *C. bicuspidata*. The leaf at the base of a branch, lacking the ventral lobe, is reduced to a narrow lanceolate lamina with a very short line of attachment. The first segment of the branch bears a hyaline papilla, but no leaf-like appendage, thus differing markedly from *C. bicuspidata* and agreeing with such species as *Lophozia inflata* and *L. acutiloba*.

Bazzania.—The terminal branching in *Bazzania*, which conforms closely

to the *Frullania* type, exhibits a number of interesting peculiarities. The modifications which occur at the base of a branch are shown in Fig. 27, which represents *B. tricrenata*, a widely distributed species in the northern and mountainous regions of Europe, Asia, and North America. The spirals shown in the figure are both dextrorse, and it will be noted that the distance between a leaf on the right-hand side and the next underleaf is much less than the distance between the underleaf and the next leaf on the left-hand side. An occasional leaf in *B. tricrenata* is bluntly tridentate at the apex, but most of the leaves diverge from this typical condition. The underleaves are broader than long, and are either entire or irregularly toothed or lobed at the apex. The incomplete leaf at the base of a branch is always undivided at the apex and acute, and its line of attachment, as in similar cases, is partly on the stem and partly on the branch.

FIG. 27. *Bazzania tricrenata*. Beacon Falls, Connecticut (A. W. E.). $\times 27$.

The first underleaf of a branch is smaller than the other underleaves and tends to be distinctly bilobed; it is displaced in such a way that its line of attachment almost reaches that of the next underleaf in the stem-spiral. The first leaf of the branch is small, but the later leaves and underleaves show no special modifications.

In the genera previously considered the branches have been partly on one side of the main axis and partly on the other. This has made the branching axis and the branch sometimes homodromous and sometimes antidromous. In *Bazzania*, however, Leitgeb ('71 b) brings out the fact that the spirals in a branch-system are invariably homodromous, although in some plants they may be dextrorse and in others sinistrorse. He shows that this condition is due to the restriction of the branches to anodic segment-halves. This being the case a dextrorse branching axis would develop branches on the right-hand side only (when viewed from the ventral surface) and a sinistrorse axis on the left-hand side. On account of the simulated dichotomy in *Bazzania* the shoot-system never appears one-sided, as it necessarily would if an obvious monopodium were maintained.

From the standpoint of comparative morphology Velenovský ('05, p. 112) concludes that terminal branching, especially of the *Frullania* type, represents a true dichotomy. In his opinion evidence derived from developmental study is of no value in deciding questions of this kind. Unfortunately he fails to give reasons for his opinion in this particular case. It cannot be based upon the fact that the two new axes which result from

the branching are alike in all respects. Even in *Bazzania*, where the dichotomous appearance is so strongly marked, the branch can at once be distinguished from the branching axis by comparing the sequences of the leaves. It will be seen in Fig. 27, for example, that the spiral in the branch (on the right) is not continuous with that of the main axis below the branch, while the spirals in the two portions of the main axis (below and above the branch) are continuous. Of course, in such a genus as *Frullania*, the differences between a branching axis and a branch are still more striking.

According to Servit ('07), who accepts Velenovský's idea of a dichotomy, the genus *Bazzania* does form two equivalent new axes, and his Fig. I, representing the common *B. trilobata*, seems to support his assertion. A close scrutiny of this figure, however, will show that it is incorrect and that, in the axis on the left (the main axis), the leaf on the left-hand side should precede and not follow the leaf on the right-hand side. In other words, the spirals ought to be homodromous and not antidromous, as the figure indicates and as a true dichotomy would require. Servit goes so far as to homologize the incomplete leaf in *Bazzania* (and in other genera showing the *Frullania* type of branching) with the 'Angularblatt' which Velenovský describes in the dichotomous Pteridophytes ('05, p. 249). He states that an 'Angularblatt' is distinguished from other leaves by its form, by its position in the angle formed by a dichotomy, and by its being attached equally to the two new axes. His characterization applies in all essential respects to many Jungermanniaceae with incubous or complicate leaves, but breaks down more or less in genera with succubous leaves. In *Lophocolea*, for example, the incomplete leaf is situated below the branch and shows no relation to the angle between the branch and the main axis. On the whole it seems unnecessary to consider the incomplete leaf as a special morphological modification; it would certainly be simpler to regard its peculiarities as due to the restricted portion of the segment which takes part in its formation.

THE MICROLEPIDOZIA TYPE.

The condition of homodromy which *Bazzania* secures through the suppression of branching on one side of a branching axis is secured by the subgenus *Microlepidozia* in a different way, an obvious monopodium with homodromous branches on both sides being the result. Here, as in *Bazzania*, the branches are restricted to the anodic segment-halves, but while this brings them in the ventral segment-halves on one side of a branching axis it brings them in the dorsal segment-halves on the other. This remarkable peculiarity of *Microlepidozia* is clearly illustrated by *Lepidozia setacea*, a widely distributed species in northern Europe and North America. In Fig. 28 a portion of a dextrorse axis with two branches is shown, and it will be

noted that both branches are dextrorse also, that the branch on the right-hand side has arisen in a ventral segment-half, and that the branch on the left has arisen in a dorsal segment-half. In other words, the branch on the right conforms to the *Frullania* type and that on the left to the *Microlepidozia* type.

FIG. 28. *Lepidozia* (*Microlepidozia*) *setacea*. Franconia Mountains, New Hampshire (A. W. E.). $\times 100$.

in the *Frullania* type, the only difference being that they are situated on the ventral surface of the shoot instead of on the dorsal. It will be seen from

FIG. 29. Diagram representing the establishment of a branch of the *Microlepidozia* type on the left and one of the *Frullania* type on the right.

the figure that the first branch-leaf in the *Microlepidozia* type is not an underleaf, as in the *Frullania* type, but a lateral leaf on the side of the branch turned away from the main axis, that the second leaf also is a lateral leaf but on the other side, and that the third leaf represents the first underleaf formed. None of these branch-leaves show special modifications. Sinistrorse branching systems as well as dextrorse may be observed in *Microlepidozia* just as in *Bazzania*.

The accompanying diagram (Fig. 29) illustrates the terminal branching in *Microlepidozia*. The oldest segment on the right shows the *Frullania* type and agrees with Fig. 5; the segment on the left shows the establishment of the apical cell of a branch in the dorsal segment-half, according to the *Microlepidozia*

type. It will be noted that the segments on this side follow the same sequence as on the other side and correspond with the leaves and underleaves described above. In addition to terminal branching *Microlepidozia* shows intercalary branching from ventral segments.

THE ACROMASTIGUM TYPE.

The genus *Acromastigum* contains the single Hawaiian species *A. integrifolium*. Since a detailed description of the branching in this plant has already been published by the writer ('00), only the more essential features of the *Acromastigum* type will be mentioned here. The species shows in addition terminal branching of the *Frullania* type and ventral intercalary branching. In the development of a ventral segment the first wall laid down is periclinal and gives rise to an internal and an external cell, the latter soon dividing by an anticlinal wall into two cells or segment-halves. If the development continues in the usual way one of the external cells again divides by an anticlinal wall, so that the segment shows three external cells. These

three cells give rise to three hyaline papillae, which are carried forward on the apex of the underleaf developed from the segment. When a terminal branch is to be formed from a ventral segment the apical cell of the branch becomes differentiated in one of the segment-halves, leaving a single external cell for the underleaf. The result is that the underleaf is much narrower than usual and shows only one apical papilla. The branch is situated at one side of this narrow underleaf, sometimes on the right and sometimes

FIG. 30. Diagram representing the establishment of a branch of the *Acromastigum* type on the right and one of the *Frullania* type on the left.

on the left. In Fig. 30 the establishment of a branch of this character is shown diagrammatically on the right-hand side, while a branch of the *Frullania* type is shown in the lateral segment on the left. The first two segments cut off in the ventral branch give rise to lateral leaves and the third to an underleaf. It will be noted that the spiral is sinistrorse in the branch figured; if the branch had been on the left-hand side the spiral would have been dextrorse. The same thing would have been true if the spiral of the main axis had been dextrorse instead of sinistrorse. In other words, the branches arising in anodic segment-halves are homodromous with the main axis, while those arising in kathodic segment-halves are antidromous, the relation being the same as in branching of the *Frullania* type. Branches of the *Acromastigum* type are apparently always flagelliform, and their minute leaves and underleaves present no modifications of special interest.

THE RADULA TYPE.

The *Radula* type of terminal branching was the one first described by Leitgeb ('71 a) and has already been briefly characterized. It has sometimes been referred to as the '*Lejeunea* type' by the writer ('07, '08). On account of the late differentiation of the apical cell of a branch, the leaf belonging to the same segment is normally developed and shows none of the interesting peculiarities described under the previous types of terminal branching. As Leitgeb points out, a branch of the *Radula* type always arises in a cortical cell adjacent to the base of a leaf on the basiscopic side and in the ventral portion of the segment. In the genus *Radula* the branches all conform to this type, and it is also found throughout the vast group of the Lejeuneae. In most of the genera of this group the branching is entirely of the *Radula* type. In a few genera of the Lejeuneae Holostipae, however, such as *Stictolejeunea* and *Bryopteris*, branching of the *Frullania* type also occurs. These genera, together with the related genus *Fubula* (in which likewise both types of branching are found), have already been discussed by the writer in other connexions ('07, '08). Whether the *Radula* type of branching occurs in other members of the Jungermanniaceae is doubtful, although Leitgeb assigns it to *Scapania* ('75, p. 29), Goebel to *Anomoclada* ('06, p. 130), and Müller to *Lophozia inflata*, *L. acutiloba*, and *Chiloscyphus* ('06-'11). The terminal branching in *Lophozia* and *Chiloscyphus*, as interpreted by the writer, has been described under the *Frullania* type, and the branching in *Scapania* and *Anomoclada* will be considered in connexion with intercalary branching.

The development of the branches in *Radula* and the Lejeuneae is treated by Leitgeb at considerable length, but his statements with regard to the sequence of the segments in the branch-rudiments are not altogether consistent. This is probably due to the fact that the sequence conforms less rigidly to rule than in the other types of terminal branching, a condition clearly brought out by a comparison of fully developed shoots. In describing *Radula* ('71 a, p. 37) he states that the first segment of the branch is basiscopic (with respect to the main axis), the second acroscopic, and the third ventral. This would bring the first branch-leaf on the side of the branch turned away from the apex of the main axis, in marked contrast to what is found in the *Frullania* type. It would also make the spirals of the branches on the left-hand side of the axis dextrorse and those on the right-hand side sinistrorse. In describing the Lejeuneae, however, he states that the first branch-leaf is an underleaf ('75, p. 28). This would imply that the first segment of the branch instead of the third was ventral in position. Even under these circumstances, if the first lateral leaf retains its basiscopic situation, the branches on the left-hand side would still be dextrorse and those on the right-hand side sinistrorse. The examination of a branch in

Radula (Fig. 31) or in one of the *Lejeuneae* (Fig. 32) shows that his statements with regard to the lateral leaves are correct, the first leaf being constantly basiscopic. The spirals, however, show certain deviations. The determination of a spiral in *Radula* is beset with difficulties because the ventral segments bear no appendages. It is only by studying the apical cell and the young segments that the direction of the spiral can be positively demonstrated. This was done in the species figured, *R. aquilegia* of western Europe, and it was found that the branch-spirals on the left-hand side of a branching axis were sinistrorse instead of dextrorse as Leitgeb's account demands. This would, of course, make the ventral segment in the branch-rudiment second instead of third in the sequence, the basiscopic segment still being first. The conditions just described are found in both vegetative branches and subfloral innovations and are apparently constant throughout the genus.

FIG. 31. *Radula aquilegia*. Moidart, Scotland (S. M. Macvicar). $\times 27$.

FIG. 32. *Euosmolejeunea duriuscula*. Sanford, Florida (S. Rapp). $\times 40$.

In most of the *Lejeuneae* underleaves are present, so that the determination of a spiral is an easy matter. It is necessary here to distinguish between subfloral innovations and vegetative branches because they sometimes show differences which are not to be found in *Radula*. In the species figured (Fig. 32), *Euosmolejeunea duriuscula* of tropical and subtropical America, the peculiarities and variations of the innovations are well shown. It will be seen that the innovation on the right conforms closely to Leitgeb's conception, the first branch-leaf being an underleaf, the first lateral leaf being basiscopic, and the spiral being sinistrorse. The innovation on the left, however, is also sinistrorse, the first leaf being basiscopic and the underleaf being second in the sequence. A study of numerous innovations has shown that there is apparently no relation between their spirals and the spiral of the flowering axis, although the condition shown by the left-hand innovation seems to be much commoner than the other. This condition is of course identical with what has just been described for *Radula*.

In the vegetative branches the differences noted in the innovations do not seem to occur. In a large series examined the spirals were all found to agree with those in *Radula*. It may be stated, therefore, that in the *Radula* type of branching the spirals usually run in the same direction as in the *Frullania* type, dextrorse branches being on the right-hand side of a branching axis and sinistrorse branches on the left-hand side. In the *Radula* type, however, the first underleaf (or first ventral segment) comes second in the sequence instead of first.

Although the branches in *Radula* and the innovations in the Lejeuneae are clearly exogenous, the exogenous nature of the vegetative branches in the Lejeuneae is less apparent, each branch bearing at its base a sheath which seems at first sight to be composed of ruptured cortical tissue. The common *Lejeunea cavifolia*, of Europe, Asia, and North America (Fig. 33),

FIG. 33. *Lejeunea cavifolia*. Huelgoat (Finistère), France (F. Camus). $\times 40$.

may be chosen to illustrate the conditions present. According to Leitgeb ('75, p. 28) this sheath is really composed of the first leaf-cycle of the branch, the first underleaf and the first two lateral leaves having coalesced by their margins. The leaves are very rudimentary and form at first a covering through which the developing branch must push its way. In favourable cases he was able to demonstrate the boundaries between the leaves. He associates these foliar sheaths with the fact that the branches in the Lejeuneae, although laid down near the apex, often remain latent for a considerable period.

Leaving the foliar sheaths out of consideration, the first leaves on branches of the *Radula* type show less definite modifications than in the other types of terminal branching. They are usually smaller than normal leaves, and their lobules (ventral lobes) are often very rudimentary. The first underleaves, also, are sometimes smaller and less complex than those afterwards formed. In most cases there is a transition, sometimes very gradual, between the basal leaves and the more typical leaves which the branch later develops. The modifications present may be looked upon as reversions to a more juvenile condition.

Intercalary Branching.

Terminal branching of the *Radula* type, as Leitgeb intimates, is intermediate in certain respects between terminal branching of the *Frullania* type and intercalary branching. In the *Frullania* type (and the same thing is true of the *Microlepidozia* and *Acromastigum* types) the branches arise very close to the apex, their leaves follow a definite sequence, the branch-spirals conform to definite rules, and the exogenous origin is perfectly clear.

In the *Radula* type the formation of the branches is longer delayed, the sequence of the branch-leaves is less definite, the spirals conform less rigidly to rule, and, in the vegetative branches of the *Lejeuneae* at least, basal sheaths are present, whatever the morphological nature of these sheaths may be. In intercalary branching the formation of the branches is still longer delayed, the sequences of the branch-leaves are indefinite, the spirals show no conformity to rule, and the basal sheaths are constant and evidently represent ruptured cortical tissue. The peculiar features of intercalary branches are illustrated below by concrete examples.

According to Leitgeb ('72, '75) intercalary branches almost invariably arise in ventral segments. Even in cases where they appear lateral he considers that they are probably ventral in origin but displaced through subsequent inequalities of growth. The only case in which he assigns intercalary branches to lateral segments is in *Jubula Hutchinsiae*, a rare species of western Europe ('75, p. 36). In this plant the vegetative branches conform closely to the *Frullania* type and the subfloral innovations to the *Radula* type. The branches which he regards as intercalary are the short male branches, which are situated behind normal leaves, bearing the same relation to them as the subfloral innovations do to the perichaetial bracts. His opinion is based upon the fact that each branch has a distinct basal sheath, and, since he was unable to demonstrate the boundaries of coalesced leaves and saw in the sheaths evidence of active cell-division, he concluded that they represented cortical tissue. Unfortunately his explanation and figure are not convincing, and there seems to be no imperative reason why these sheaths should not be interpreted in the same way as the very similar sheaths in the *Lejeuneae*.

Although this doubtful case is the only one recognized by Leitgeb, the writer would refer certain intercalary branches in a number of species to lateral segments rather than to ventral. This course seems justifiable from the position which these branches occupy on adult shoots, although it has unfortunately been impossible to trace out their development from the earliest beginnings or to assign them to definite portions of the original segments. The genera where branches of this kind occur are the following: *Micropterygium*, *Diplophyllia*, *Scapania*, *Sphenolobus*, *Cephalozia* (subgenus *Prionolobus*), *Odontoschisma*, *Anomoclada*, *Plagiochila*, and *Chiloscyphus*. In all probability this list could be considerably increased. As an illustrative example of lateral intercalary branching the genus *Micropterygium* of tropical America may be selected. In *M. Pterygophyllum*, a widely distributed species (Fig. 34), the large underleaves are very much like those of *Bazzania*, but the lateral leaves show a very peculiar structure. They are distinctly complicate, but only the dorsal lobe is attached to the axis, the ventral lobe being formed by a folding back of its lower margin. Along the keel thus formed, in well-developed leaves, a wing of variable

extent may be seen. The branches are situated in the axils of the leaves and show a distinct basal sheath. In the majority of cases, as in the branch on the right, the first leaf is basiscopic with respect to the main axis, the second leaf is an underleaf, and so on. In the figure the first leaf is only partially visible and is considerably displaced from its theoretical position. In the branch on the left it will be noted that the first leaf is acroscopic, and cases may also be found where the first leaf is an underleaf. The main axis in the figure is sinistrorse, the branch on the right is dextrorse. Other cases were observed, however, in which dextrorse spirals occurred in branches on the left and sinistrorse spirals in branches on the right. So far as can be learned the spiral of the main axis exerts no influence upon the spirals

FIG. 34. *Micropterygium Pterygophyllum*.

FIG. 35. *Plagiochila Sullivantii*. Quarry Run, West Virginia (A. L. Andrews). $\times 17$.

of the branches. In the genera *Scapania*, *Diplophyllcia*, *Sphenolobus*, and *Cephaloziella* (subgenus *Prionolobus*) the leaves are bilobed and more or less complicate, but their lobes are both attached to the axis. With the exception of certain species of *Cephaloziella* none of these genera produce underleaves. Their lateral intercalary branches are distinctly axillary and resemble in most essential respects the branches of *Micropterygium*.

The other genera, where lateral branches are here interpreted as intercalary, are all distinguished by succubous undivided leaves. *Plagiochila Sullivantii*, a species of the eastern United States, shows the usual conditions present (Fig. 35). The branch figured is borne in the axil of a leaf but close to the ventral margin, and an examination of *Chiloscyphus* will show that the female branches arise in much the same position. Apparently in branching of this kind there is more or less variation in the relative positions

of leaf and branch, although the latter may always be described as axillary. In the common *Plagiochila asplenioides*, for example, Servit ('07, Fig. 3) figures a branch much nearer the middle of a leaf than is shown above, while in the South American *Anomoclada mucosa*, as well as in certain species of *Odontoschisma*, the lateral branches are close to the dorsal margins of the leaves. In all these cases, so far as examined, the branch-spirals and the sequences of the branch-leaves exhibit as great an irregularity as in *Micropterygium* and the other genera with complicate leaves.

The ruptured cortical sheath at the base of a lateral intercalary branch is usually conspicuous, but aside from this the basal structures show no very striking modifications. In most cases the first few cycles of leaves are rudimentary and often more or less displaced from their theoretical positions. As the branch develops the leaves gradually become more and more definite in position and in form, and the branch soon acquires the appearance

FIG. 36. *Bazzania Brighami*. Oahu, Hawaiian Islands (C. M. Cooke, Jun.). $\times 40$.

characteristic of the species. Occasionally, as in *Cephaloziella Turneri*, a species of Europe, Africa, and North America, the base of a branch bears underleaves, even although these are absent from fully developed shoots. The modifications mentioned are apparently all reversionary in character.

Intercalary branches arising from ventral segments are far more common than those just described and have been less subject to discussion. Certain genera, such as *Herberta*, *Anastrophyllum*, and *Saccogyna*, seem to branch invariably in this way, and the same thing is true of many species of *Cephalozia* and *Odontoschisma*. In other cases ventral branches of this type occur in connexion with lateral intercalary branches, as in *Cephaloziella Turneri*, or with terminal branches, as in the genera *Lepidozia* and *Bazzania*. When found in connexion with lateral branches the ventral branches are usually specialized in some way. In *Lepidozia*, for example, the ventral branches are almost always sexual, while in *Bazzania* they are mostly sexual or flagelliform. Even in this latter genus, however, ventral branches with normal leaves are occasionally produced, and Fig. 36, which is drawn from

the Hawaiian *B. Brighami*, shows a branch of this kind and may be considered as representative of ventral intercalary branches in general. These branches, as Leitgeb long ago pointed out, are usually situated in the axils of underleaves or in corresponding positions in species where underleaves are not formed. In the example figured it will be noted that the underleaf with the axillary branch is strongly reflexed.

There seems to be no definite sequence in the leaves of a ventral intercalary branch; neither is there any apparent relation between the spiral of a branch and that of the branching axis. The modifications present are similar to those described under lateral branches. Although ventral branches of this type usually occur singly in the axils of underleaves, in certain genera, such as *Calypogeia* (*Kantia*), two or three of them are sometimes found side by side. In other cases, such as *Cephalosia bicuspidata*, a branch may develop from any part of a ventral segment. Sometimes branches of this character arise directly from fully differentiated cortical cells and are thus destitute of basal sheaths. Such branches are to be regarded as adventive rather than as intercalary, although the distinctions between the two are not always hard and fast. Adventive branches in this position are essentially like those which sometimes spring directly from leaf-cells. They represent a type of regenerative process and scarcely come within the scope of the present paper.

Subfloral innovations in *Radula*, *Fubula*, and the Lejeuneae have already been spoken of in connexion with the *Radula* type of branching. They apparently arise whether fertilization has taken place or not. In many plants with intercalary branching subfloral innovations are also found, but their development, in certain cases at least, is dependent upon an absence of fertilization. Such innovations, which seem to be always intercalary in origin, usually occur singly, although groups of from two to four are not infrequent in certain species. They arise both in lateral and in ventral segments, the latter position being somewhat more common. The innovations are usually more robust than other intercalary branches, but show no further distinctive characteristics.

General Considerations.

From his study of the various types of branches in the Jungermanniaceae, Leitgeb ('75, '77) reached the conclusion that they had made their appearance in a definite phylogenetic sequence. He believed that branches of the *Frullania* type came first, that these were followed by branches of the *Radula* type, and that intercalary branches came last. He obtained support for these ideas not only from the Jungermanniaceae themselves but also from the Metzgeriaceae, the branches of which he homologized with those of the Jungermanniaceae. In the more primitive Metzgeriaceae, for

example, such as *Riccardia* (*Aneura*) and *Pellia*, he considered the terminal branching to be essentially the same as that of the *Frullania* type; in more advanced genera, such as *Hymenophyton* (*Umbraculum*) and *Symphyogyna*, he distinguished terminal branches of both the *Frullania* and the *Radula* types; while in the ventral sexual branches of *Metzgeria* and *Hymenophyton* he found typical intercalary branches comparable with those of *Lepidozia* and *Cephalozia*. In the Metzgeriaceae, therefore, there is at least a vague indication that the types of branches which he regarded as the more recent are associated with genera which show other advanced characteristics.

If it is assumed that the Jungermanniaceae are descended from some thallose member of the Metzgeriaceae, it would be natural to conclude that the various types of branches were among the characteristics directly inherited. The probability of a polyphyletic origin of the Jungermanniaceae must, however, be kept in mind, especially in view of the fact that the leafy genera of the Metzgeriaceae are doubtless descended from more than one thallose ancestor. There is some evidence, for example, that the Jubuloideae (of Schiffner) are descended from the Metzgerioideae, while the Epigoni-antheae came from such genera as *Pellia* and its allies. If this is the case it is of course possible that some of the primitive Jungermanniaceae came from thallose ancestors showing only one or two of the types of branching characteristic of the Metzgeriaceae as a whole. The result would be that the lines of development commenced by such primitive forms would either lack the types of branches which they failed to inherit or would acquire them independently. Probably both courses were pursued by different evolutionary lines. If it is admitted, therefore, that the branches appeared in the sequence indicated by Leitgeb, it must also be admitted that this sequence may have appeared in various distinct phyla.

Aside from the unsatisfactory phylogenetic evidence just brought forward, there is also ontogenetic evidence supporting Leitgeb's ideas of sequence. In a species where several types of branching are present it will be found that terminal branching tends to appear first in the life-history of an individual plant, and that branches of the *Frullania* type tend to come before those of the *Radula* type. This is well illustrated by both the Jungermanniaceae and the Metzgeriaceae. In *Lepidozia* and *Metzgeria*, for example, the terminal vegetative branches precede the sexual intercalary branches, while in *Bryopteris* the vegetative branches of the *Frullania* type precede the sexual and flagelliform branches of the *Radula* type.

Leitgeb concluded further that the various types of branches were genetically related to one another. He considered that the *Radula* type was derived from the *Frullania* type through a delay in the process of branch formation, and that intercalary branches represented the culmination of this tendency to delay. Even if the importance of such a tendency as an evolutionary factor is recognized, it is difficult to understand how one type

of branching can have been directly derived from another. Ordinarily, when two organs are genetically related, they are alike at the beginning and acquire the differences which they show at maturity during the course of their development. In other words they represent diverging lines. This is clearly seen in such organs as the scale leaves and the foliage leaves of the higher plants, the earliest rudiments of which are quite indistinguishable. In dealing with structures of this kind, Goebel ('98-'01, p. 577) has shown by experiment that it is possible to alter the course of development of a particular rudiment. He has shown, for example, that a rudiment, which from its position on a growing point would normally develop into a scale leaf, can be acted upon in such a way that it will develop into a foliage leaf instead. Nothing of the sort is conceivable with regard to the branches of the Jungermanniales. These show their distinctive differences at the beginning and tend to become more and more alike as development proceeds. Instead of representing diverging lines of development they represent converging lines (except in cases of marked specialization), and it would be quite impossible to convert a young branch of the *Frullania* type into a branch of the *Radula* type. To do so would necessitate a change in the position of the first branch-segment or else in the direction of the branch-spiral, either of which would of course be out of the question. On the whole it seems most logical to consider the differences in the branches as really due to mechanical causes, which in some way determine the position of the first branch-segment and the direction of the branch-spiral. This would obviate the necessity of looking for a genetic connexion between the various types.

The development of a branch is undoubtedly to be looked upon as a response of the shoot to some kind of a stimulus. The different kinds of branches might then be due to the same stimulus acting upon segments of different ages or to distinct stimuli. To a certain extent at least the latter hypothesis seems to correspond better with the facts, and there are even reasons for believing that intercalary branches in different positions may sometimes be induced by unlike stimuli. These ideas are best supported by the study of species in which branching is a more or less unusual phenomenon. To illustrate the conditions under which terminal branches are developed *Cephalozia bicuspidata* may be selected, while *Plagiochila Sullivantii* and *P. asplenioides* may be chosen to illustrate intercalary branching.

In *Cephalozia bicuspidata* it will be found that terminal branching is not only associated with exceedingly young segments and with young individual plants, but that the conditions necessary for a vigorous vegetative development must be present before the appearance of such branching can be induced. Under ordinary circumstances, therefore, a plant will go through life without branching at all until the characteristic intercalary

branches are formed. The plants discussed in the present paper, however, grew in places where there was an abundant water supply, together with the other factors favourable for growth. Apparently, in response to these conditions, terminal branches are of frequent occurrence. It would appear as if the increased stimulus for growth had acted upon some of the young segments in the same way that it acted upon the apical cell of the shoot, the result being that new apical cells became differentiated in the segments and thus gave rise to new terminal branches.

In *Plagiochila Sullivantii* and *P. asplenoides* the leafy shoots represent branches of a prostrate caudex. These shoots continue growing for a considerable period but usually remain unbranched. It will be found, in fact, that the very conditions which induce a vigorous apical growth and terminal branching in *Cephalozia bicuspidata* tend to inhibit the formation of intercalary branches in these species of *Plagiochila*. It is only when the apical growth is diminished or brought to an end, perhaps through the enfeeblement or death of the apical region, perhaps through the production of archegonia, that intercalary branches can make their appearance. Even under these circumstances branching rarely occurs. In his interesting researches on regeneration in the Hepaticae, Kreh ('09, p. 249) has recently brought out an important fact about *P. asplenoides* (and certain other species). He finds that, when fragments of a shoot are placed under favourable conditions, the regenerative branches appear in the axils of the leaves, that is, in the position where intercalary branches would normally occur. Of course, under these circumstances, the inhibitory action of the apical region has been rendered ineffective by direct removal. From these various observations it would appear that intercalary branches are not only associated with old segments and mature plants, but that the stimulus inducing branch-formation of this type must be distinct from the stimulus which induces a vigorous growth of the shoot, and therefore distinct also from the stimulus which causes terminal branching in such a species as *Cephalozia bicuspidata*.

Terminal branching in *Lophozia* is due to stimuli which are apparently similar to those indicated in the case of *Cephalozia bicuspidata*. In *L. Wenzelii*, for example, branches of the *Frullania* type are not infrequent. The plant grows in cold bogs and is therefore under favourable conditions for vegetative growth. In the closely related *L. alpestris*, which grows in drier localities, branching is much more unusual. In this connexion *Lophocolea heterophylla* may also be mentioned. The juvenile condition in this species, in which the leaves are uniformly bifid, is often greatly prolonged. During this period the conditions favourable for growth are present, and terminal branches occur frequently. As the plant approaches maturity the shoots develop irregularly lobed or undivided leaves, and finally the sexual organs with their bracts. After these changes, associated with repro-

duction and the cessation of vegetative growth, have begun to make their appearance, terminal branches become very rare.

In *Cephalozia*, *Lophozia*, and *Lophocolea* the formation of terminal branches cannot be looked upon as a firmly established habit. Certain species fail to show them at all, and even in species where they may occur it is often possible for an individual plant to go through life and produce organs of reproduction without being stimulated to develop branches of this character. It is very different with such genera as *Frullania* and *Lepidozia*, where the habit of forming terminal branches is firmly fixed. Here the branches arise at fairly definite intervals as long as the conditions necessary for ordinary growth are present. Even here, however, there are a few facts which point to a slight connexion between vigorous growth and branching. In plants growing in dense shade, for example, there are often more leaves between successive branches than in plants growing under more favourable conditions. In branches, also, the growth of which seems to be more or less inhibited by the vigorous development of the main axis, branches of a higher order less frequently occur. It is only when such branches overcome the inhibitory action and assume the characteristics of the main axis that they branch with the same degree of frequency. In the first case the conditions unfavourable for growth (and for branching) are due to an unfavourable environment, in the second case to correlative influences. The second case, however, must not be confused with the one described under *Plagiochila*, where the formation of intercalary branches is inhibited by the growth of the branching axis itself, and not by the growth of an axis of higher rank.

The antagonism between apical growth and intercalary branching, which is shown so clearly by *Plagiochila Sullivantii* and *P. asplenioides*, is usually present even in cases where intercalary branching has become a characteristic habit. To illustrate this point *Cephalozia bicuspidata* may again be selected. The sexual branches in this species, which are commonly intercalary and ventral, make their appearance when a certain degree of maturity is reached. Their development, however, is longer deferred in vigorous plants, and especially in plants so vigorous that terminal branches are present. An important difference between the *Cephalozia* and the two species of *Plagiochila* in this respect is that the antagonism in the *Cephalozia* is less strong, the result being that the inhibitory influence of the apical region is more easily and more regularly overcome.

The ventral flagelliform branches in *Bazzania*, which are also intercalary, stand in marked contrast to the branches just considered, although the sexual branches in the same genus are apparently dependent upon the same conditions as those of *Cephalozia bicuspidata*. These flagelliform branches make their appearance only a short distance away from the apical region, and there is no evidence that their development is inhibited by

apical growth. In fact the stimulus which induces growth and the stimulus which induces branches of this character apparently act in harmony. From the consideration of this peculiar case, therefore, it seems very probable that the stimuli inducing intercalary branching are not always identical.

Summary.

Two distinct kinds of branching, terminal and intercalary, may be distinguished in the Jungermanniaceae. In terminal branching the branches arise in very young segments; in intercalary branching they arise in segments which are more or less mature.

Terminal branching includes four distinct types, characterized by the portion of the segment which takes part in branch formation. These four types are here designated the *Frullania* type, the *Microlepidozia* type, the *Acromastigum* type, and the *Radula* type, respectively. In the *Frullania* type the branch represents the ventral half of a lateral segment; in the *Microlepidozia* type, the dorsal half of a lateral segment; in the *Acromastigum* type, one of the halves of a ventral segment; in the *Radula* type, a portion only of the ventral half of a lateral segment.

In the *Frullania*, *Microlepidozia*, and *Acromastigum* types the branch is always accompanied by an incomplete leaf, which represents the other half of the same segment; in the *Radula* type the branch is accompanied by a complete leaf, which belongs to the same segment.

In the *Frullania* type the first branch-segment is ventral, and usually gives rise to an underleaf, the second segment is acroscopic (with respect to the branching axis) and gives rise to the first lateral leaf, while the third segment gives rise to the second lateral leaf, basiscopic in position. The branch-spiral is homodromous with the axis when the branch has arisen in an anodic segment-half, and antidromous when it has arisen in a kathodic segment-half.

In the *Microlepidozia* type the third branch-segment is ventral in position, and the branch-spiral is always homodromous with the axis because the branches of this type always arise in anodic segment-halves.

In the *Acromastigum* type the third branch-segment is ventral (just as in the *Microlepidozia* type), and the branch-spiral is homodromous or antidromous with the axis, according to whether the branch is situated in the anodic or the kathodic segment-half.

In the *Radula* type the first branch-segment is sometimes ventral, but usually lateral and basiscopic. The branch-spiral is usually sinistrorse on the left-hand side of a branching axis, and dextrorse on the right-hand side (when the shoot is viewed from the ventral surface), but subfloral innovations in the Lejeuneae sometimes show variations.

The leaves at the base of a terminal branch, especially one of the *Frullania* type, are more or less modified in form, in size, and in manner of

attachment, some of these modifications representing reversionary tendencies and others special adaptations.

Intercalary branches may be either lateral or ventral in position. Their spirals show little or no relation to the spiral of the branching axis, and there is nothing definite about the position of the first branch-segment. The modifications at the base of a branch are reversionary in character.

There is some evidence (derived from phylogenetic and ontogenetic considerations) that the *Frullania* type of branching was the first one to make its appearance, that this was followed by the *Radula* type, and that intercalary branches came afterwards. It is possible that this sequence appeared independently in different developmental lines. A tendency to delay in the process of branch formation was apparently an important evolutionary factor.

There is evidence also that there is a harmonious relation of some sort between vigorous vegetative development and terminal branching, and that there is usually an antagonism between vigorous growth and intercalary branching.

On a Palaeozoic Fern, the *Zygopteris Grayi* of Williamson.

BY

D. H. SCOTT, F.R.S., P.L.S.

With Plates I-V and one Figure in the Text.

INTRODUCTION.

THE species *Zygopteris Grayi* was founded by Williamson in 1888 (Williamson, '89) on some specimens in a nodule from Oldham, which, though imperfectly preserved, enabled him to recognize the chief points in the morphology of the plant. Williamson had previously recorded a stem of the same type under the name of *Anachoropteris Deccaisnii*, Renault (Williamson, '74, p. 699).

A much better specimen than any of those described by Williamson was found later by Mr. J. Lomax, who was also the discoverer of the type-specimens. Five sections of this stem are in Williamson's collection, but his intention of figuring it was never carried out.¹ Figures have since been published by myself (Scott, '00, Figs. 97, 98²), Dr. P. Bertrand ('09, Pl. XI, Fig. 78), and Dr. Kidston ('10, Figs. 1-4), but the specimen has never been fully illustrated.

In 1910 I received from Mr. Lomax a series of sections of a new specimen from a fresh locality—Shore, Littleborough, so well known for other interesting fossils with their structure preserved. The present paper is based primarily on the new specimen, with comparative references to the others and especially to the best Williamson specimen mentioned above. The question whether all known specimens can really be referred to the one species, *Z. Grayi*, will be discussed in the latter part of the paper.

It will be well to preface the detailed observations with a short summary of what is already known of the structure of the *Zygopteris Grayi* type.

¹ I know of eight sections (all transverse) of this specimen, namely 1818 A and 1919 A to 1919 D in the Williamson Collection (see p. 66), 308 in that of Dr. Kidston, R. 443 in the Manchester Museum Collection, and 184 in my own. The proper order of these sections will be given below (p. 52). The sections of the type-specimens in the Williamson Collection are: 1817-1843 (excl. 1818 A) and 1919.

² Figs. 115, 116 in the second edition, Scott, '08.

[Annals of Botany, Vol. XXVI. No. CI. January, 1912.]

The stem has a very characteristic transverse section, owing to the form of the stele, which represents a five-rayed star with the rays or arms of unequal length (Pl. II, Photos. 11–13); each arm of the stele corresponds to the insertion of a leaf-trace; the phyllotaxis is $\frac{2}{5}$, and the longest arm is that which is next going to give off a trace, while the shortest arm is that which has last done so. The most prominent arms are truncate, the broad end assuming a bicornute form. The main mass of the wood consists of a wide zone of large scalariform tracheides; this zone, the peripheral xylem, encloses a central mass of tissue, which, like the stele as a whole, is stellate, having narrow protrusions which pass out into the projecting arms. Up to 1900 this central tissue was described as a pith, with the tacit assumption that it constituted a mass of parenchyma. This, however, has been shown not to be the case (Scott, '00, p. 281, Fig. 98¹). The central tissue contains numerous tracheides, much smaller than those of the main zone of wood. They are accompanied by parenchyma and are ranged in an irregular ring round the centre of the stele: from this central ring radial tracts of small tracheides extend outwards, up the middle of each arm of the stele; it is among the internal tracheides of the arms that the protoxylem of the stem is situated. Groups of small tracheides also occur externally at the extremities of the more prominent xylem-arms; where the arm is truncate or bicornute they form two groups, one at each angle. The nature of these external groups of small xylem-elements will be discussed below; they are connected at certain points with the internal tracheides of the xylem-arms.

The phloem surrounds and follows the outline of the xylem. It contains a single or double band of large elements, no doubt the sieve-tubes, which, however, are for the most part limited to the bays of the stele, only extending round the xylem-arms where the latter are at their shortest, having just given off a leaf-trace.

Immediately surrounding the stele is a comparatively narrow zone of inner cortex consisting of thin-walled parenchyma; beyond this comes the broad and dense outer cortex, succeeded on the outside by a few layers of delicate hypoderma and the epidermis bearing multicellular hairs.

The stem bears appendages of four kinds: (1) the large foliage-leaves, of which only the bases are shown; (2) the 'axillary shoots' of Stenzel; (3) the small scale-leaves or aphlebiae; (4) the adventitious roots.

The bases of the foliage-leaves are of large size and have a marked effect on the outline of the stem; they are given off at short intervals. The whole form of the stele is, as we have seen, dependent on the course of the bundles supplying these leaves and their axillary shoots. The latter, the nature of which has been somewhat disputed of late (Kidston, '10), are a most characteristic feature, peculiar to the *Zygopteris Grayi* type among

¹ p. 309, Fig. 116 in the second edition.

known fossil Ferns, but finding a close analogue in recent Hymenophyllaceae. Where the trace of a foliage-leaf is to be given off the stelar arm broadens out at the end and acquires two prominent angles or horns (Pl. II, Photos. 11 and 12). At the same time the large-celled xylem becomes continuous across the arm, cutting off the peripheral part of the internal xylem, which now forms an island (Phot. 12). When the trace detaches itself from the stele the line of separation passes through the large-celled xylem, which thus forms a closed ring in the leaf-trace, while it also remains closed in the arm from which the trace has parted (Phot. 13). Nothing of the nature of a leaf-gap is formed; a real leaf-gap is of course out of the question, as there is no true pith.

The leaf-trace, immediately on leaving the stele, as shown in Williamson's later specimen, is approximately triangular in transverse section with the base of the triangle outwards (Pl. II, Phot. 13; Pl. IV, Fig. 12). At the two abaxial angles are the groups of small tracheides already mentioned, and in the middle of the strand is the island of internal xylem and parenchyma. The abaxial groups are destined for the foliar bundle, while the central island belongs to the axillary stele.

The phloem closes round the outgoing trace as soon as it becomes detached, so that the bundle assumes concentric structure from the first (Pl. IV, Fig. 12). It may be called the undivided trace, for it represents the common base of the foliar bundle and of the axillary stele. The separation between the two takes place where the trace is passing through the outer cortex, at a level where the base of the leaf is already prominent (Pl. II, Phot. 11). The abaxial part of the common trace separates, to form the foliar bundle, the line of separation passing through the large-celled xylem, so that here, as in the departure of the trace from the stele, no gap is left in the strand behind. The foliar strand, as it becomes free, begins to assume the H form, but at first the shape is rather that of a very flat W with the base of the letter outwards, for the adaxial are longer than the abaxial 'antennae' and diverge from one another towards the axis (Pl. II, Phot. 12; Pl. V, Fig. 13). The phloem at once completes itself around both foliar bundle and axillary stele; the latter at this level has an almost circular or slightly elliptical transverse section, the major axis in the latter case being tangential with reference to the parent stem (Pl. II, Phot. 10; Pl. V, Fig. 13); the island of internal xylem persists throughout. A little higher up, the stele passes into the cylindrical axillary shoot, where it becomes free. I adhere to the terminology of Stenzel, reserving all morphological questions as to the nature of the leaf-trace and branch for future discussion (p. 57).

The scale-leaves or aphyllae, discovered by Renault in 1869 in his *Zygopteris Brongniartii*, and by Stenzel in *Zygopteris scandens* twenty years later (Stenzel, '89), are seated both on the stem itself and on the base

of the leaf. They are quite distinct from the foliage-leaves and much more numerous. The small trace supplying each aphlebia traverses the cortex with a steeply ascending course. These bundles, unlike those of the true leaves, have no effect on the general morphology of the stele. On entering the aphlebia the vascular strand undergoes one or more divisions. In calling the scales 'aphlebiae' it is implied that they are of the same nature as the outgrowths borne higher up on the rachis of allied leaves. As Paul Bertrand has stated ('09, p. 109), their vascular strands in *Z. Grayi* and *Z. scandens* are given off from the leaf-traces 'avant même leur individualisation complète'.

Lastly, there are the adventitious roots; they are much less numerous than the aphlebiae and their steles pass out almost horizontally through the cortex, a fact which enables them to be easily distinguished. The roots, so far as observed, are diarch; the root-stele is inserted laterally on an arm of the main stele near its extremity (see Pl. V, Fig. 14).

The above description would apply almost word for word to the *Zygopteris scandens* of Stenzel as well as to Williamson's species. Williamson, indeed, when he first saw Stenzel's paper of 1889, was inclined to assume that the two species were identical (Williamson, '89, p. 157). We shall find that the new specimen from Shore presents some slight differences from the described specimens of both species.

The old genus *Zygopteris* of Corda, characterized by the H or double anchor-form of the foliar bundle, has been broken up in Dr. P. Bertrand's memoirs, and among the smaller genera created out of it are *Ankyropteris* (founded as a subgenus by Stenzel but redefined by P. Bertrand) and *Etapteris* (P. Bertrand, '09, pp. 206, 218). The distinction is based on the petiolar structure; the well-known species *Z. (Ankyropteris) bibractensis* and *Z. (Etapteris) Lacattii* may serve as types of each. Among the most important diagnostic characters of the two genera are:

Ankyropteris. Ramifications of the frond in two series, one on each side of the rachis.

Etapteris. Ramifications of the frond in four series, two on each side.

Ankyropteris. Peripheral loops of small-celled xylem permanently present on the flanks of the foliar bundle.

Etapteris. Peripheral loops absent.¹

Ankyropteris. Adaxial longer than abaxial antennae. Middle band of bundle often curved, with concavity outwards.

Etapteris. Adaxial and abaxial antennae of equal length. Middle band of bundle straight.

The question whether *Zygopteris Grayi* belongs to *Ankyropteris* or *Etapteris* is disputed. Dr. P. Bertrand takes the former view and suggests that the petiole may possibly be identical with *Ankyropteris bibractensis*,

¹ Except perhaps temporarily in *E. tubicaulis* (P. Bertrand, '09, p. 206).

var. *westphaliensis* (P. Bertrand, '09, pp. 106, 109). Dr. Kidston, on the other hand, identifies the petiole of *Z. Grayi* with *Z. di-upsilon*, Williamson, which is a typical *Etapteris* (Kidston, '10). As we shall see, the new specimen is an unquestionable *Ankyropteris*; as, however, it differs somewhat from those previously described, it does not by itself suffice to settle the point in dispute, and reference to the other specimens will be necessary.

Other questions on which the new specimen throws light are the morphology of the leaf-trace and axillary stele, the structure of the internal xylem, the position of the protoxylem, and the course of the bundles supplying the aphanlebiae.

THE SHORE SPECIMEN.

We will now go on to describe the Shore specimen. The specimen is from an ordinary seam-nodule and is accompanied by fragments of *Lyginodendron*, *Lepidodendron* leaves, and other familiar objects of the coal-balls. In this respect it resembles Williamson's later specimen (see above, p. 39) and the fragment originally described by him in 1874, while it differs from the specimens on which the species *Z. Grayi* was founded in 1888; the latter were contained in a roof-nodule and are accompanied by *Goniatite* shells.¹ This difference may raise a doubt whether all the specimens of the *Z. Grayi* type really belong to one species. The part of the Shore specimen from which my sections were cut was about two inches in length; this piece was cut into twelve transverse and ten longitudinal sections, the latter coming immediately below the former. The transverse series is very good for following the whole process of the emission of the leaf-trace,² but it does not show perfectly the separation between leaf-trace and axillary stele; the latter, however, is seen very well, both in transverse and longitudinal sections (Pl. IV, Figs. 9 and 10), while the form and structure of the foliar bundle are fairly exhibited, though in oblique section (Pl. I, Phot. 9).

The general structure requires no long description, as it is in all essentials of the *Zygopteris Grayi* type, as recapitulated above. The maximum diameter of the stem is about 18 mm., that of the wood about 6 mm.

The five-rayed, stellate wood is rather regular in outline, for even the shorter arms are well marked (Pl. I, Photos. 1-6). The longer arms, about to give off a leaf-trace, are more conspicuously bicornute than in some other specimens, as corresponds to the form of the leaf-trace itself. A glance at Pl. I, Photos. 4-6, shows that the leaf-trace has a very different form from that in the figured specimens of *Z. Grayi* or *Z. scandens*. In these

¹ In my review of Dr. P. Bertrand's *Études sur la Fronde des Zygoptéridées* (New Phytologist, vol. viii, 1909, p. 268) I erroneously stated that '*Z. Grayi* is a roof-nodule fossil'. This is only true of the type-specimens. The correction of this slip removes one objection to Dr. Bertrand's suggested identification of *Z. Grayi* with *Ankyropteris westphaliensis*; see, however, p. 57.

² A selection from the transverse series is shown in Plate I, Photographs 1-6, running from below upwards.

cases, as already mentioned, the undivided leaf-trace has a somewhat triangular transverse section, as shown in Pl. IV, Fig. 12; in the Shore specimen the section may be described as crescentic (Pl. I, Photos. 4-6, 8; Pl. III, Fig. 1) with the concavity outwards and the ends obliquely truncated. The bundle here, however, is obviously of the same nature as in the *Z. Grayi* type, for in Pl. I, Phot. 1 (*l.t., a.s.*), we see it in the act of dividing to form the axillary stele and foliar bundle, though the latter is imperfectly shown. The form of the undivided trace, though a striking feature of the new specimen, is not peculiar to it; a similar crescentic leaf-trace occurs in one of Williamson's type-specimens, as shown in Pl. II, Phot. 15, *l.t.* The $\frac{2}{5}$ phyllotaxis is obvious on comparing the successive sections (Photos. 1-6) and observing the position of the stelar arms from which leaf-traces depart. The phloem and inner cortex are badly or not at all preserved; in this respect the Shore fossil is inferior to the best Williamson specimen (see Pl. IV, Fig. 12; Pl. V, Fig. 13). The wide outer cortex has the same general character as in the latter, and is traversed by numerous aplebia-bundles. In both plants the epidermis bears great numbers of multicellular uniseriate hairs (Pl. IV, Fig. 7). The adventitious roots appear to be given off in the same way in all the specimens (see Pl. V, Fig. 14, from Williamson's later specimen).

Structure of the Stele.

The general ground-plan of the wood is not at all unlike that in the Williamson type-specimens (Williamson, '89, Pl. I, Figs. 1 and 2, and Pl. II, Phot. 15, in the present paper); the resemblance to his later specimen is not quite so exact (cf. Pl. II, Photos. 11-13). The central tissue ('mixed pith') has a diameter of little over 1 mm., and a pentagonal outline (Pl. I, Phot. 7). The internal system of tracheides forms an interrupted zone in the outer region of the mixed pith, enclosing a considerable amount of parenchyma (Pl. I, Phot. 7).

Pl. III, Fig. 3, is from a longitudinal section of the stele, cut somewhat tangentially, so that the plane of section coincides with one side of the zone of internal xylem, and several groups of internal tracheides are shown (*x.i.*).

From the central zone extensions of the internal xylem extend outwards, up each of the xylem-arms, forming the internal rays, the length of which varies according to the level at which the arm is cut. The internal rays are narrow in this specimen and the tracheides in them much compressed. The tangential diameter of the tracheides in the outer part of the internal ray ranges from 12 to 20 μ , the radial diameter from 18 to 60 μ . Some of these compressed tracheides show a spiral thickening, and no doubt represent the protoxylem of the stele.¹

¹ The protoxylem elements are best shown in the axillary stele. See Pl. IV, Fig. 10, *px.*

It is to be noted that the internal tracheides are of the normal elongated form and not short, as in the stem of *Diplolabis Römeri* described by Dr. Gordon ('11). The parenchyma accompanying the tracheides in the internal rays as well as in the central tissue consists of much-elongated thin-walled cells (Pl. III, Fig. 3).

The tracheides of the internal xylem-zone range from about $45\ \mu$ to $100\ \mu$ in diameter. The smallest, in the outer part of the zone, sometimes show a spiral thickening (Pl. III, Fig. 3).

The peripheral or main zone of wood consists entirely of large scalariform tracheides from $100\ \mu$ to $250\ \mu$ in diameter, the larger sizes predominating, if we leave the ends of the arms out of consideration. In the latter region the structure varies greatly according to level, as will be seen on examining any of the Photographs 1-6, Pl. I. A xylem-arm which has just given off a leaf-trace (arm 5, Phot. 5) shows practically no differentiation; the tracheides at the distal end are scarcely smaller than the others. On the other hand, an arm which is on the point of giving off a trace already has the characteristic leaf-trace structure in its distal part, which is about to become detached (arm 5, Phot. 3, and arm 4, Phot. 6). This structure consists essentially in the presence of peripheral loops, one at each extremity of the bicornute arm, and of an island of internal xylem on the median line (Pl. I, Phot. 8; Pl. III, Fig. 1). The intermediate arms show the various stages of transition from the undifferentiated to the differentiated structure, as will be explained in describing the process of emission of the trace.

Structure of the Leaf-trace.

The structure of the undivided leaf-trace is shown in Pl. I, Phot. 8, where it has just parted from the stele, Pl. III, Fig. 1, where it has already entered the cortex, and Pl. III, Fig. 2, at a point further out on its course. The trace passes out so gradually that it is seen practically in transverse section throughout. The changes in this part of its course consist in a slight broadening of the middle part of the trace and in a gradual lengthening of the 'antennae', the name given by Dr. Paul Bertrand to the extensions of the xylem forming the lateral bars of the H-shaped foliar bundle in the old genus *Zygopteris*. At the lowest level (Pl. I, Phot. 8) the antennae are scarcely present; the peripheral loops simply occupy the truncated ends of the lunulate bundle, facing obliquely outwards (cf. Photos. 4 and 5). At the level shown in Pl. III, Fig. 1, the antennae already form recognizable protrusions, especially at one end of the bundle; at a still higher level (Fig. 2) they are quite prominent; it will be noticed that at the level shown in Fig. 2 the abaxial is longer than the adaxial antenna, contrary to the usual condition in *Ankyropteris* (cf. Pl. V, Fig. 13).

The peripheral loop consists of a double or triple band of small

scalariform tracheides (forming the 'filament' of Dr. P. Bertrand) (Pl. I, Phot. 8; Pl. III, Figs. 1 and 2, *x.e.*). At the ends, this band turns round and is continuous with the xylem of the antenna. The narrow space enclosed by the loop is occupied partly by very narrow tracheides, partly by a few elongated parenchymatous cells. The narrow tracheides inside the loop are no doubt the protoxylem; I have detected ill-preserved spiral elements in this position in a longitudinal section. The protoxylem appears to form two groups, one near each end of the loop (*px.*, Figs. 1 and 2, Pl. III), probably with one or more intermediate groups as well.

On the inner side the loop is bounded by the ordinary xylem of the antenna, the tracheides in this position being only a little smaller than elsewhere. It will be seen that the structure agrees quite well with that of the peripheral loops in *Ankyropteris bibractensis*, var. *westphaliensis*, as described by Dr. P. Bertrand.¹ The agreement is especially evident where the antennae have become prominent, as shown in Fig. 2.

The external xylem-band or filament sometimes appears to be confluent with the antenna for considerable distances, the interior space of the loop then not being continuous (Fig. 2).

The stages where the leaf-trace is separating from the axillary stele are not well shown in the new specimen. A trace in the act of division is present at *l.t.*, *a.s.*, in the section represented in Pl. I, Phot. 1; the axillary stele is clear, but the foliar strand is much damaged.

In the longitudinal series a foliar bundle is shown in very oblique section (Pl. I, Phot. 9). This is seen some little way above its separation from the axillary stele, which is present in another section of the series (part of this stele is shown in Pl. IV, Fig. 10). The foliar bundle represented in Phot. 9 has, in fact, already entered the petiole. Its slender proportions and long antennae agree well with the structure of the bundle in Williamson's original specimens (cf. Pl. II, Phot. 16). The peripheral loop is quite evident, and at once identifies the bundle as that of an *Ankyropteris*. In the comparative straightness of the middle band ('apolar') and of the antennae the bundle differs widely from *A. bibractensis*, var. *westphaliensis*, P.B.; the original *A. bibractensis* of Renault is intermediate in these respects (Renault, '69, Pl. IX).

The swelling on the adaxial antenna, near its junction with the middle xylem-band, marks the presence of a lateral bundle, destined for a secondary rachis (Pl. I, Phot. 9), as is more clearly shown in an adjacent section (2529). So far as can be seen, the mode of emission of the secondary bundle agrees with that described by Dr. P. Bertrand, but the obliquity of the sections leaves the details obscure. At any rate it is clear that the lateral strands were given off singly as in *Ankyropteris*, and not in pairs as in *Etaopteris*.

¹ '09, p. 74, Pl. IX, Figs. 62, 63, &c.

Another characteristic feature of the undivided trace is the presence of a median island or strand of internal xylem, accompanied by parenchyma (Pl. I, Phot. 8; Pl. III, Figs. 1 and 2, *x.i*). The island has an irregularly elongated shape, and one or more smaller islets may be detached from it (Phot. 8). These, however, die out as the trace is followed upwards, and the median strand becomes more regular. This strand is destined to form the internal xylem of the axillary stele (Pl. I, Phot. 1, *a.s.*; Pl. IV, Fig. 9). I have found it continuous at all levels, both in the Shore specimen and in the best one of Williamson's (Pl. IV, Fig. 12; Pl. V, Fig. 13). The doubt expressed by Dr. Kidston ('10, pp. 452, 454) as to the presence of a 'pith' at the place where the axillary stele separates from the leaf-trace is evidently to be explained by defects of preservation, as he himself suspected. It must, however, be emphasized that in no case is a true pith present in *Zygopteris Grayi*, either in the main stele, the undivided leaf-trace, or the axillary stele. In all cases the central tissue contains numerous tracheides, as proved by longitudinal as well as transverse sections.

The whole form and structure of the undivided trace in the Shore specimen show that this organ is essentially a *leaf-trace* rather than the stele of a branch. It constitutes, as already stated, the common base of the foliar bundle and the axillary stele; in the Shore specimen the foliar bundle characters predominate, while in the Williamson specimens, at least those which have been figured, the stele characters are more obvious, so that the whole has been regarded as a branch (compare Pl. III, Fig. 1, with Pl. IV, Fig. 12). Such an idea would scarcely have arisen if specimens like that from Shore had first come under observation. The question will be more fully discussed later in the paper (p. 57).

Emission of the Leaf-trace.

The whole process can be followed in the Shore specimen.

If we start with that arm of the stele which has last given off a leaf-trace (e. g. arm 5, shown in Pl. I, Photos. 4 and 5) we find that it is short, with a rounded outline, and without any sign of the peripheral loops. The corresponding internal ray penetrates the arm for half its length or more. Otherwise there is little or no differentiation. At a slightly higher level the internal ray extends further outwards, and the tracheides external to its termination become markedly smaller than the rest. The extension of the ray is at first one-sided (see Phot. 1, arm 1; Phot. 2, arms 1 and 2; Phot. 6, arm 5). This is the first indication of a peripheral loop. Further up, a second branch of the internal ray appears, so that it becomes forked. The branches very nearly reach the surface, from which they are only separated by bands of small tracheides (Photos. 3 and 4, arms 1 and 2). The structure at this level is of much interest, as we here see continuity

established between the protoxylem of the stem contained in the internal rays and that of the leaf-trace enclosed in the peripheral loops. It must, however, be remembered that the approach of the protoxylem-rays to the surface of the wood is not only connected with the supply of the leaf-trace; continuity with adventitious roots has also to be established. Root-steles, for example, are given off from arm 1 at a level between that of Phot. 4 and Phot. 5.

The condition at a somewhat higher level, in a case not complicated by root-insertions, is shown in detail in Fig. 4, Pl. III.¹ Here the arm already has a squarer end than lower down. The internal ray (which is still continuous) is expanded, at the point where it forks, into a little triangular body, the first indication of the central strand destined for the axillary stele. Beyond this the two branches of the ray run out nearly to the surface.

Still higher up, the arm becomes cornute; the peripheral loops are lengthened and are here more evident as loops; they now become isolated, so far as the transverse section is concerned, by the closing up of the branch rays which connected them with the triangular body. This also becomes isolated by the closing up of the internal ray behind it, a change which may take place at a lower level. (See Photos. 3-5, arm 3; for the shutting off of the main ray at a lower level see Phot. 6, arm 1.)

The rest of the process may be followed rapidly in arm 5. At the bottom of the series (Phot. 1) this arm has long lobes, each of which is obliquely truncated and tipped by a peripheral loop; the loops are quite cut off from the median triangular strand, but the latter is still in connexion with the internal ray. Above this (Phot. 2) the ray is beginning to die out behind the strand, which is lengthening tangentially. At the next higher level shown (Phot. 3) the ray has completely closed up for a long distance and the median strand appears as an island, surrounded by the large-celled wood. The arm is here distinctly constricted about midway between the island and the end of the internal ray.

Here the trace separates from the wood, as seen in Phot. 4 and Phot. 8. The outward passage of the trace and the slight changes which it undergoes within the limits of the series require no further description.

From the facts observed it is clear that the peripheral loops are constituted by the two branches of the internal ray passing out nearly but not quite to the surface of the wood, the parts which enclose their termination becoming small-celled. The internal rays contain the protoxylem, which thus comes to lie inside the peripheral loops. The point of bifurcation of the internal ray supplies the median strand for the axillary stele. All these parts become isolated as we follow them further up. In other words, the 'undivided leaf-trace' receives three branches from the internal

¹ Arm 2, from the section next above that shown in Phot. 6.

xylem and protoxylem of the stem; the two distal branches pass into the peripheral loops; the proximal branch takes a median position and ultimately supplies the axillary shoot. Thus the whole organization of the leaf-trace is dependent on the internal xylem of the stem, for it is from this that its first-formed elements are supplied.

Structure of the Axillary Stele.

As we have seen, the axillary stele is represented in the undivided trace by the median adaxial bulge with its central strand of small tracheides and parenchyma (Pl. I, Phot. 8; Pl. III, Figs. 1 and 2). The bulge becomes more marked as the trace passes further out (Pl. I, Phot. 6; Pl. III, Fig. 2).

At the beginning of the series of transverse sections, the axillary stele seen far out in the cortex is just separating from the leaf-trace,¹ and its outline is already clearly defined, the line of separation passing through the thick abaxial xylem (Pl. I, Phot. 1, *a.s.*). It has a somewhat elliptical central strand at this level. The same stele at a rather higher level, after its complete separation, is shown in Pl. IV, Fig. 9. Allowing for slight damage, the stele is approximately circular in section; the central strand ('mixed pith') has a somewhat angular outline, possibly an indication of its ultimate stellate form. The internal xylem appears to form a solid, rather irregular mass, and has not assumed the annular arrangement characteristic of the main stele. The position of the protoxylem is not easy to determine; some of the smallest elements lie on the outside of the internal xylem, but it is not certain that they all do.

The longitudinal section (Pl. IV, Fig. 10) shows the structure of another axillary stele, no doubt that belonging to the next lower leaf-trace. The broad outer zone of scalariform tracheides encloses the strand of small elements forming the internal xylem, and in one part the spiral tracheides of the protoxylem (*px.*) are evident. They appear to be adjacent to the parenchyma of the central strand, and thus to lie on the outside of the internal xylem.

The axillary stele, in this part of its course, thus shows the stelar structure of the plant in its simplest form. The essential features—peripheral and internal xylem-systems—are present, but none of the complications of form and tissue-arrangement belonging to the fully developed stele have yet appeared.

Some further points connected with the axillary stele will be considered when we return to the Williamson specimens (see p. 54).

¹ This is the trace corresponding to arm 1 of the stem-stele.

The Aphlebiae.

Scale-leaves or aphlebiae are borne indiscriminately on the stem and the leaf-bases, unless indeed we regard the whole surface as covered with leaf-bases, an interpretation which the form of the transverse section scarcely seems to justify. The numerous aphlebia-traces which traverse the cortex give the best idea of the number of these appendages (Pl. I, Phot. 4).

The Shore specimen shows several aphlebiae in connexion with the stem, but not many after they become free. Fig. 7, Pl. IV, represents one just detached from the cortex, with which it is connected lower down in the series. There are two gaps in the tissue, symmetrically placed, in one of which a vascular bundle is contained; no doubt the second bundle has been lost. In another case an aphlebia contained three bundles, and there was some evidence of a lateral lobe having been given off. The extreme tangential extension of the bundle in the aphlebiae still attached to the stem (cf. Pl. III, Fig. 6) is no doubt preparatory to division; in some cases the fission had begun.

From the evidence of the Shore fossil and of the second Williamson specimen we may conclude that the aphlebiae were lobed bodies containing as many as three vascular strands—possibly more.

The origin of the aphlebia-trace has been investigated, confirming Paul Bertrand's statement that they are given off from the leaf-traces, even before the complete individualization of the latter. They spring from the arms of the stele below as well as above the point where these become free as definitive leaf-traces. Thus Plate III, Fig. 5, shows an aphlebia-strand just given off from, and still connected with, one of the peripheral loops of a leaf-trace (No. 5) just detached from the stele. The level of the section figured is immediately below that of Phot. 4, Pl. I. On the other hand, in Pl. III, Fig. 4, an aphlebia-strand is shown which has separated from an arm of the stele, still far below the point where the leaf-trace will be given off, and indeed at a level where the peripheral loops are not yet fully differentiated.¹ The strand is well preserved and appears to show some remains of phloem. Other cases of stele-borne, as distinguished from trace-borne, aphlebia-strands have been observed.

The course of the strand is steeply ascending, as is well shown in the longitudinal section (Pl. IV, Fig. 8), where such a strand can be followed almost the whole way from the stele through the cortex. Numerous aphlebia-strands are given off, in succession, from each leaf-trace or stelar arm. They form four series, two to each peripheral loop.

¹ The drawing is from the section next above that represented in Pl. I, Phot. 6, and the arm is No. 2.

The text-figure gives a rough idea of the arrangement of six aphlebia-traces, of which the course was actually followed. They are lettered (A-F) in the order in which they were observed to be given off from the leaf-trace 5, to which they all belong. Probably, however, two additional strands from the same end as C and E were missed, owing to local damage.

The aphlebia-strand first appears as a bulge of the peripheral loop. On first becoming free its xylem appears to be solid; where any differentiation can be observed, the smallest tracheides are in the middle. As the strand passes further out it becomes tangentially extended, ultimately to an extreme degree, as shown in Pl. III, Fig. 6 from the outer part of the cortex of the stem. In this condition the xylem appears to form a flattened

Diagram of stele, with the arms, numbered in cathodic order, the leaf-trace 5, and the aphlebia-strands (more crowded than in nature) given off from it (A-F).

ring, with the smallest elements in the interior; in a longitudinal section there was some indication of laxly spiral elements (protoxylem) in this position. It is often noticeable that the tracheides on the abaxial side are larger than those on the adaxial side of the ring, a point of some slight interest, as the same difference exists, in a more marked degree, in the secondary strands of the rachis of *Ankyropteris* (P. Bertrand, '09, p. 85; Pl. X, Figs. 73 and 74). So far as I have been able to make out, the aphlebia-strands are given off essentially in the same way as the secondary rachis-strands, as described by P. Bertrand, i. e. without any interruption of the external xylem ('filament'). There thus seems to be a considerable analogy between the scale-like aphlebiae and the ordinary pinnae of the leaf.

The conclusions as to the aphlebiae are—

- (1) that they are borne on all parts of the stem, without any special relation to the leaf-base ;
- (2) that their strands come off from the leaf-trace, both below and above its separation from the stele ;
- (3) that the protoxylem of the strand is central ;
- (4) that the strand divides into two or three branches when the aphlebia becomes free.

The Roots.

Adventitious roots are not very numerous in the Shore specimen ; they are better shown in the second Williamson specimen ; the illustration on Pl. V, Fig. 14, is from a section of this specimen from the Manchester Museum, kindly lent by Prof. F. E. Weiss. There appears to be no difference among the different specimens in the way the roots are borne. They spring laterally, as a rule, from the arms of the stele, the base of the root-stele occupying in some cases about half the length of the arm (Fig. 14). In the Shore specimen, where the peripheral loops are evident, it is seen that they contribute to the elements of the root-xylem (see above, p. 48).

The root-steles are given off on both sides of the stelar arm ; sometimes two roots are opposite, in about the same plane. They arise from the arms at different levels, but I have not found them in connexion with the leaf-trace when free from the stele. They pass out horizontally.

As regards the structure of the root the evidence is still imperfect, for I have not yet seen a root in transverse section showing its connexion with the stem. In the Shore sections there are two or three roots near the stem which probably belong to it. They are about 1 mm. in diameter and diarch, with a very bulky xylem-plate, elliptical in transverse section. The cortex, if complete, is rather narrow, and sometimes has a pentagonal outline. Quite similar roots are also associated with the second Williamson specimen.

THE WILLIAMSON SPECIMENS.

The general description of the structure given in the earlier part of the paper is based essentially on the later Williamson specimen, the most perfect known before the discovery of the Shore fossil, and superior even to the latter in certain respects.

The eight sections of this specimen which I have seen are enumerated on p. 39. I have taken some pains to determine their correct order, which, from below upwards, appears to be as follows :

1. (7) Williamson 1919 D.
2. (8) ,, 1919 B.
3. (1) ,, 1919 C.
4. (2) ,, 1919 A.

5. (3) Manchester R. 443.
6. (4) Kidston 308.
7. (5) Williamson 1818 A.
8. (6) Scott 184.

The only doubt is as to the position of sections 1919 D and B from the Williamson Collection ; it is possible that they should come at the end of the series instead of the beginning. I have given the alternative order in parentheses. No question of importance is involved ; the order of 6 of the sections is certain, and 1919 B clearly comes next above 1919 D (see Pl. II, Photos. 11 and 12).

The stem is considerably smaller than in the Shore specimen, having a diameter of about 12 mm. as against 18 mm., the wood measuring about 4 mm. as against 6 mm. The arms of the stele are rather shorter in proportion, and when a leaf-trace is detached only a slight protrusion is left (see Pl. II, Photos. 11-13, and compare with Pl. I, Photos. 1-6).

In the matter of preservation, the older specimen has the advantage as regards the phloem and the thin-walled inner cortex (see especially Pl. IV, Fig. 12, and Pl. V, Fig. 13). The row of dark cells in the figures cited is probably the endodermis. The outer cortex appears to have thicker walls than in the Shore specimen. On its outer border a few layers of periderm can be recognized in places. The main features of the anatomy need not be further described ; they are evident from what has been said above, and from the figures.¹

Williamson's second specimen is the typical example of that form of undivided leaf-trace which is approximately triangular in transverse section (Pl. IV, Fig. 12), thus differing widely from the Shore specimen with its crescentic trace (Pl. I, Phot. 8 ; Pl. III, Fig. 1). At one time I thought that this difference might be of specific value. I find, however, that among Williamson's type-specimens of 1888 both forms of leaf-trace occur. Thus, an approximately triangular trace is shown in the stem figured by Williamson ('89, Pl. I, Fig. 1), while in the stem of which a photograph is given in the present paper (Pl. II, Phot. 15) the trace (*l.l.*) is perfectly crescentic and agrees closely with those of the Shore plant. Hence, whatever the variation in form may mean, it is impossible to base a specific distinction upon it, for no one will suppose that Williamson's type-specimens, closely crowded together in the same block, belong to two different species. The form of the trace is, however, important, in so far as it has influenced the morphological interpretation of its nature. This question is discussed below (p. 57).

Returning for a moment to the later Williamson specimen, it may be worth mentioning that it differs from the Shore plant in the form of the

¹ The anatomy of the stele is shown in my *Studies in Fossil Botany*, 2nd ed., Fig. 116, p. 309. See also Bertrand, '09, Pl. XI, Fig. 78.

aphlebia-strands. In the latter, these bundles, as they pass out through the cortex, become, as we have seen, much flattened and tangentially extended (Pl. III, Fig. 6). The second Williamson specimen shows nothing of the kind; the aphlebia-strands are only slightly elliptical in section, however far out in the cortex they may be. It is possible that the difference may be exaggerated by accidents of preservation, the strands in the Shore plant having to some extent collapsed, but a real distinction, though probably not an important one, certainly remains.

The Williamson type-specimens of 1888 agree in this respect, as in others, with the Shore fossil. The preservation of the cortex is very imperfect; the parts that persist are generally the external margin, the inner margin of the outer cortex, and a margin round the various outgoing strands, including those of the aphlebiae (Pl. II, Phot. 15). It is, however, evident that the aphlebia-strands are much flattened in the outer part of their course.

The type-specimens appear to be of the same variety or form as the Shore fossil, though the former came from a roof-nodule and the latter from a seam-nodule. The largest stem in the type is about 22 mm. in diameter, with the wood measuring 6 mm. The form of the stele agrees very closely (compare Pl. I, Photos. 1-6, with Pl. II, Phot. 15); as we have seen, crescentic leaf-traces occur in both and the aphlebia-strands are alike. There can be no doubt on the evidence that the new specimen belongs to the true *Zygopteris Grayi*, as founded by Williamson on the 1888 specimens. His later specimen, as we have seen, is a little different in detail, but not, as it seems to me, sufficiently so to warrant specific distinction.

Williamson's later specimen shows some points of interest as regards the axillary stele. The mode of separation between this stele and the foliar bundle is rather different from that shown in the Shore plant. In the latter, as we have seen, the undivided trace is a massive structure, and when the adaxial bulge is to be cut off as the axillary stele the line of separation simply passes through the thick band of the abaxial xylem (Pl. I, Phot. 1, *l.t.*, *a.s.*). In the other, the xylem is narrow and has to be thickened up by the addition of more tracheides, before separation can take place (Kidston, '10, p. 452; Pl. XXXIV, Figs. 3 and 4). Thus the formation of a gap in the xylem-band is avoided. Further, the axillary stele bears a much larger proportion to the foliar bundle at the point of separation than in the Shore plant. The stele and bundle a little above their severance are shown in Fig. 13, Pl. V. The structure of the stele is the same as at the corresponding level in the Shore specimen, but the phloem is well preserved, forming a ring round the xylem, and conspicuous by its large sieve-tubes. So far there is no indication of lateral appendages.

In Phot. 10, Pl. II, the stele is shown further out in its course, where the axillary branch is nearly free. Here the internal xylem is

laterally extended, forming a band coincident with the major axis of the elliptical section, and tangential to the parent stem. The row of internal tracheides almost reaches the surface at either end of the band, while the main zone of xylem appears divided into two arcs; the large sieve-tubes are now limited to the adaxial and abaxial arcs, and are absent opposite the ends of the internal band. The structure strongly suggests that leaf-traces, distichously arranged, are about to be given off. The bilateral anatomy of the axillary shoot at this level presents the closest analogy with that of the stem in some recent Hymenophyllaceae, especially *Trichomanes radicans* and *T. reniforme* (Boodle, '00, Pl. XXVI, Figs. 22 and 24).

Unfortunately, in the section next above that from which Phot. 10 was taken, the axillary stele is destroyed; in the second section above, it is seen in oblique section and not quite complete;¹ it shows a relatively large 'mixed pith', with at least four prominent angles, and corresponding groups of internal tracheides; on the adaxial side, corresponding to one of the protrusions of the central tissue, there is a projecting arm or incipient leaf-trace, with an evident island of internal xylem near its end. It is thus clear that at this level the axillary shoot was already preparing to assume mature structure, with leaves in several series;² the distichous stage, indicated at a lower level, must have been passed through very rapidly. Intermediate conditions between that of the axillary stele (as seen at its base) and the normal stellate form have been previously figured by Williamson ('88, Pl. I, Fig. 5, see p. 157) and Stenzel ('89, Taf. VI, Fig. 53; see '96, p. 71).

ZYGOPTERIS GRAYI AN ANKYROPTERIS.

We have seen that the Shore fossil is clearly an *Ankyropteris*, as shown by the manifest presence of the peripheral loops, characteristic of that genus, on the leaf-trace, confirmed by such slight indications as we have of the arrangement of the pinnae on the rachis (see above, p. 46).

The question remains whether the *Ankyropteris* characters are common to all the specimens known. Dr. P. Bertrand includes the plant in *Ankyropteris*, and in his description, based immediately on the later Williamson specimen, he states that the leaf-trace has two poles, *interior to the wood*, on its posterior (abaxial) side, situated exactly at its extremities. He adds that, after the separation of the axillary strand, each of the poles divides into two, and that this division is the point of departure of the formation of two peripheral loops (Bertrand, '09, pp. 108, 109).

In a letter dated September 25, 1911, Dr. Bertrand informed me that

¹ The three sections are W. 1919 A, R. 443, and Kidston 308. See list above, p. 52.

² It is interesting to find that in this section (Kidston 308) the cortex of the axillary shoot contains several aplebia-bundles, which are absent from it at a lower level. Evidently, as soon as the first leaf-traces of the shoot began to be differentiated, the inevitable aplebia-strands appeared with them.

he had strong reasons for believing that Williamson's type-specimens also belonged to *Ankyropteris*. He sent me photographs of Williamson's section 1824, showing that a petiole of the plant had evident peripheral loops. I at once consulted the original section, and satisfied myself that this is the case. The section has been rephotographed by Mr. Tams, and is shown in Pl. II, Phot. 16. The petiole in question is a perfectly typical one of *Z. Grayi*, and, as Dr. Bertrand pointed out to me, is identical with the petiole of which another section is figured by Williamson ('89, Pl. I, Fig. 4). There is little doubt that this petiole belongs to one of the associated stems.

A glance at Phot. 16 will show that the band of small elements forming the external xylem (*x.e.*) of the peripheral loop is perfectly evident, especially on the left-hand side.

The proof that Williamson's type-specimens of *Zygopteris Grayi* belonged to the genus *Ankyropteris*, as now defined, is entirely due to Dr. P. Bertrand, to whom I am much indebted for calling my attention to the critical section.

The difficulty is greater in the case of the later Williamson specimen. The preservation of this specimen, good as it is for most purposes, is such as to render it difficult to make out the arrangement of the small external tracheides. When I described the structure of this stem in my 'Studies in Fossil Botany', I was inclined to regard these elements simply as protoxylem. On a careful re-examination of all the sections, I have observed cases where peripheral loops appeared to be present on the leaf-trace, but scarcely any were absolutely decisive, as it was seldom possible to distinguish with certainty between the supposed elements of the external xylem ('filament') and those of the protoxylem on the one hand or the inner phloem on the other.

The leaf-trace shown in Pl. II, Phot. 14, seems, however, fairly conclusive. The position of this bundle (*l.t.*) relative to the stele is shown in the general sketch, Fig. 15, Pl. V. One corner of the trace is obliquely truncated, recalling the leaf-traces of the Shore specimen. The truncated end is coated by a band of small elements, apparently tracheides (see Pl. II, Phot. 14, *x.e.*, and the slightly diagrammatic drawing of the same in Pl. IV, Fig. 11, *x.e.*). The appearance is remarkably like that of one of the peripheral loops of the Shore specimen, though of course less clear (cf. Pl. I, Phot. 8, and Pl. III, Fig. 1).

Taking the whole of the evidence into consideration, I feel no doubt that Dr. P. Bertrand was right in his interpretation, and that this specimen, like the others, has peripheral loops and is therefore an *Ankyropteris*. As we have seen, this conclusion is now established as regards the Shore fossil and the type-specimens of Williamson; I believe it may safely be extended to all specimens of the *Z. Grayi* type.

I think it probable, however, that there was a slight difference between the later Williamson specimen and that from Shore, the peripheral loops not becoming clearly differentiated so low down in the course of the leaf-trace in the former as in the latter. Dr. Bertrand's own description clearly points to a rather late differentiation in this respect.

The petiolar bundle of the type-specimens (Pl. II, Phot. 16) is almost identical in form with that of *Zygopteris di-epsilon* (Williamson, '80, Pl. XXI, Fig. 90), with which Dr. Kidston identified *Z. Grayi* (Kidston, '10). The resemblance is so striking that this conclusion appeared well founded at the time. Dr. Kidston, like myself, had not then recognized the presence of peripheral loops in *Z. Grayi*. *Z. di-epsilon* is a typical *Etapteris* (P. Bertrand, '09, p. 148; Pl. I, Fig. 6; Pl. XVI, Fig. 110), and, as such, has no peripheral loops and gives off four series of secondary strands from the foliar bundle. It cannot therefore belong to *Zygopteris Grayi*, which is shown to be an *Ankyropteris* by the presence of peripheral loops, and by there being (so far as the available evidence shows) only two series of secondary rachis-strands.

Dr. P. Bertrand ('09, p. 106) suggested, with much reserve, the possibility that the petiole of *Z. Grayi* might be identical with the well-known *Z. bibractensis*, var. *westphaliensis*. The differences in the form of the foliar bundle are obvious; the middle band of the xylem ('apolar') is straight in *Z. Grayi*, curved in *Z. westphaliensis*; the lateral bands (antennae) are long and but little curved in *Z. Grayi*, while in *Z. westphaliensis* they are strongly bent inwards towards the plane of symmetry; further, the antennae are of approximately equal length in *Z. Grayi*, while in *Z. westphaliensis* those on the convex (presumably adaxial) side of the median band are considerably longer than those on the concave (abaxial) side. Nothing has yet been observed to indicate that the one form passed over into the other, and there is a strong presumption that the species are distinct.

THE MORPHOLOGY OF THE LEAF-TRACE AND AXILLARY STELE.

There are two views of the nature of the organ which throughout this paper has been called the 'leaf-trace' or the 'undivided trace'. On the one view, which was that of Stenzel,¹ the first to observe the facts, this strand is essentially a leaf-trace, directly continuous with the foliar bundle, but modified, to a certain extent, by the presence of a branch, the stele of which is given off from the leaf-trace on its adaxial side and a little above its base. From its position the branch is consistently termed the axillary shoot, and its vascular strand the axillary stele.

On the alternative view, the meristele which we have called the leaf-trace is, from its base, of an axial nature, constituting the stele of a branch; the true leaf-trace is given off from it as a lateral appendage. On this

¹ '89, p. 35; '96, p. 31.

interpretation there is no 'axillary' organ at all; the branching is regarded as an unequal dichotomy, of which the main stem and the smaller (so-called 'axillary') shoot are the two limbs. The leaf associated with the smaller branch is the first appendage of that branch and not its subtending organ.

This interpretation was mentioned by me in 1908¹ as a possible one; I then regarded the data as insufficient to settle the question. Dr. Kidston ('10, pp. 451, 454) has adopted this view; he speaks of our 'undivided leaf-trace' as a 'branch', and describes the petiole trace as an independent organ arising from the periphery of the 'branch' (i. e. branch-stele).

The interpretation of the branching of *Z. Grayi* as a dichotomy is supported by the analogy of *Z. corrugata*, in which, to all appearance, a real and equal dichotomy of the stem and its stele occurs.²

After the investigation of the Shore specimen of *Z. Grayi*, I can no longer regard the question of the morphology of these organs as an open one. The evidence of that specimen seems to me decisive in favour of the view that the meristele, from its base upwards, is a leaf-trace. The peripheral loops are essential parts of the leaf-trace or foliar bundle; they have nothing to do with the stem or its branches. Now we have seen that in the Shore specimen the peripheral loops are already fully differentiated where the meristele first becomes free from the stele, and even at a considerably lower level. It is impossible any longer to contend that an organ with these characteristic foliar structures can be of the nature of a branch. The general form of the meristele further supports the obvious leaf-trace interpretation. What is true of the Shore specimen must moreover hold good for the other specimens also. In the type specimens, as we have seen, leaf-traces of the same form as those of the Shore fossil occur. In the later Williamson specimen the form of the meristele is different, and the peripheral loops perhaps differentiated later; they exist, however, where the meristele is still undivided; the relation of the meristele to the main stele on the one hand and to the axillary stele and foliar bundle on the other is the same as in the Shore plant.

It thus seems to be established that in *Z. Grayi* the meristeles given off from the arms of the stem-stele are leaf-traces, altogether homologous with those of *Z. corrugata* or *Diplolabis Römeri*. With the former plant especially, there is a close agreement in the mode of emission of the leaf-trace, if we allow for the difference in the form of the stele from which it is given off (P. Bertrand, '09, p. 110; Pl. XII, Figs. 87-9).

¹ Studies in Fossil Botany, 2nd ed., p. 318.

² This seems to be rare. I only know of one specimen (to be described fully in a forthcoming paper) which shows the branching in this species. Dr. Kidston's citation ('10, p. 454) of the brief reference to the fact in my Studies (p. 318) might be understood to imply that I regard the leaf-traces in *Z. corrugata* as of the nature of a dichotomy. This is not, of course, the case; the forking of the stem involves an equal division of the stele and has nothing to do with the well-known process of the emission of a leaf-trace.

The conception of the meristele as a leaf-trace keeps the *Zygopteris Grayi* type in line with all the other *Zygopterideae*, and is in agreement with all the facts, as, for example, with the $\frac{2}{5}$ phyllotaxis.

On the branch interpretation, the arrangement of the appendages would not be a phyllotaxis at all, but a caulotaxis—a system of dichotomies in which the successive smaller limbs followed a $\frac{2}{5}$ divergence—a strange phenomenon for which we should be puzzled to find an analogy. Also, the branch theory would compel us to assume that the main stem was leafless, or restricted to scale-leaves (like a *Pinus*), while the foliage-leaves were limited to the lateral branches or smaller limbs of the dichotomy. All these are sufficiently improbable assumptions where Ferns are concerned, and, even without the evidence of the Shore specimen, would almost drive us to accept the simple and intelligible view that the leaves are borne directly on the stem.

What then are we to make of the axillary branch? Although it certainly does not give rise to the leaf-trace it must undoubtedly have some effect on the structure of the latter in the basal region. In the case of Williamson's later specimen especially, the effect is very marked, disguising to a considerable extent the leaf-trace character of the meristele; it led to the whole organ being regarded as the stele of a branch. In the Shore specimen, on the other hand, as we have seen, the leaf-trace characters predominate throughout, and the presence of an axillary shoot is only indicated in the meristele by a slight adaxial bulge and by the median island of internal xylem. It is not even certain that the latter is *necessarily* connected with the axillary stele, for a very similar central island appears in the leaf-trace of *Z. corrugata*, which has no axillary stele (P. Bertrand, '09, Pl. XII, Fig. 88); in this case, however, it soon dies out.

We may, if we like, regard the axillary stele as 'adherent' to the adaxial side of the leaf-trace, but this is a mere phrase and throws no new light on the facts.

The analogy with the axillary branching of the Hymenophyllaceae has been often insisted on (see especially Boodle, '00, p. 487), and appears to be a very close one. In the recent family the axillary shoot is sometimes abortive (Chambers, '11), and possibly, as Stenzel thought, this may also occur in *Zygopteris*, though certainly not as a rule.

Axillary branching also takes place occasionally in Ophioglossaceae (*Botrychium*, Holle, '75, p. 313, Taf. III, Fig. 4; *Helminthostachys*, Gwynne-Vaughan, '02). Judging from sections kindly shown me by my friend Prof. W. H. Lang, F.R.S., there seems no doubt that here also there is a decided analogy with the fossil forms.¹ It is interesting that the axillary branching occurring in *Zygopteris* should find its parallel in two recent

¹ Professor Gwynne-Vaughan's suggestion that the axillary organs which he found in *Helminthostachys* were rudimentary branches appears to be fully confirmed by Professor Lang's observations.

families with which an affinity has been recognized by most investigators, from Renault onwards.

Though the branching of *Zygopteris Grayi* and its allies is not a dichotomy, it may have originated from a dichotomy, the association of the smaller branch with a subtending leaf being a derivative condition. On this view the equal dichotomy of *Z. corrugata* would be the more primitive state, as seems natural. On the other hand, it is not impossible that the case of *Z. corrugata* may be one of modified axillary branching. I hope to return to this question in a subsequent paper.

THE MORPHOLOGY OF THE APHLEBIAE.

Both Renault and Stenzel regarded the scale-leaves which they discovered in *Zygopteris Brongniartii* and *Z. scandens* respectively as abortive or reduced leaves, and therefore as comparable to the normal foliage-leaves of the plant. This view is no longer tenable. In *Z. Grayi*, as we have seen, the scale-leaves (aphlebiae) occur on the leaf-base as well as on the stem; their vascular strands are given off from the leaf-traces of the foliage-leaves and are not independent leaf-traces. Dr. P. Bertrand's view that the scales have the value of secondary petioles seems fully justified (P. Bertrand, '11, p. 53). Their vascular strands are included by him under the name 'sorties hâtives', i. e. they are secondary strands given off 'in a hurry' or below the point where the normal pinnation of the leaf begins. We have seen above that the structure of the aphlebia-strand is not unlike that of the secondary or tertiary rachis-strands in allied species, and that its mode of emission appears to be the same. The aphlebiae, then, are best regarded as modified pinnae of the leaf which have spread downwards on to the stem, but are always in definite relation, by their vascular strands, with the leaf-traces.¹ That they are modified is shown by the fact that their lamina contains two or three bundles (resulting from the division of the single supply-strand), while in all allied plants the normal pinnae are monodesmic. The function of the aphlebiae may have been a transitory one, the protection of the growing points and young leaves; in fact, they may well be analogous to bud-scales, which are often of the nature of stipules. The aphlebiae themselves might be described as multiple stipules.

Dr. Bertrand's observations appear to have cleared up the mystery which once hung about these curious organs; we need no longer feel tempted to interpret them as representing an ancestral form of foliage such as the phylloids of Lignier, which hypothetically once covered the thallus before its differentiation into stem and frond.

It is very interesting to find that aphlebiae have now been discovered

¹ It is true that the aphlebia-strands are given off in *two* rows from each peripheral loop of the trace (unlike the pinna-strands of the *Ankyropteris* leaf); no two aphlebia-bundles, however, appear to be given off *at the same level*.

by Dr. Margaret Benson ('11) in a species of *Botryopteris*, *B. antiqua*, in which they are found to be associated with the simpler monarch form of petiole, which in this species alternates with the larger diarch petioles. These remarkable organs were evidently very widely spread among the Primofilices; how far they were truly homologous with the aphlebiae, so well known in their external form on impressions of the frond in other Palaeozoic Ferns and Pteridosperms, can only be determined when the structure of the latter has been further investigated.

AFFINITIES.

There are two other species of the same type as *Zygopteris Grayi*, namely, the *Z. scandens* of Stenzel and the *Z. Brongniartii* of Renault. The former is so closely similar to our species that Williamson thought it the same, and no one has yet found thoroughly satisfactory distinctive characters, though the horizons are so far apart (Lower Coal Measures and Permian) that specific identity is improbable. Dr. Kidston ('10, p. 455) enumerates several points of difference, but some of these are only distinctive on the assumption that *Zygopteris* (*Etapteris*) *di-epsilon* is the petiole of *Z. Grayi*, which, as we have seen, cannot be the case, the latter being an *Ankyropteris*. From sections of *Z. scandens* in my possession I have not been able to find constant distinctions; possibly a reinvestigation of the type-specimens might lead to a more definite result. It appears to be commonly admitted that *Z. scandens* is an *Ankyropteris*; this is probably the case, though the evidence is much less direct than is now the case with *Z. Grayi*; here, again, a further investigation of Stenzel's plant is desirable, though the close agreement with Williamson's species leaves no real doubt as to the genus being the same.

Z. Brongniartii, Ren., differs from the other species in the form of the stele, in which the angles are not at all prominent (Renault, '69, Pl. III, Fig. 1). This seems a well-marked distinction, though Stenzel ('96, p. 31) thought that all three species might be referable to one. There appears to be no independent evidence to show whether *Z. Brongniartii* is an *Ankyropteris*. There is a probability that it is so, but at present this only rests on the general similarity to *Z. Grayi* in structure and mode of branching.

Zygopteris corrugata, on the other hand, is certainly a typical *Ankyropteris*, as Dr. Bertrand has shown, but differs from *Z. Grayi* in its cylindrical stele, dichotomous branching, and other points.

The stem of the Lower Carboniferous *Metaclepsydropsis duplex*, of which a full description by Dr. Gordon ('11²) has just appeared, bears a general resemblance to that of *Ankyropteris corrugata*, the tracheides of the internal xylem being here also associated with parenchyma. Another Lower Carboniferous plant, *Diplolabis Römeri*, of which Dr. Gordon has given an

exhaustive and admirable account (Gordon, '11), has a solid xylem without any parenchyma, but there is a marked differentiation between the inner and the outer xylem; the former consists of smaller elements, which are quite short, and presumably served for the storage rather than the conduction of water. The complex structure of the petiole shows beyond doubt that the plant is a *Zygopterid*; Dr. Gordon regards the stem-structure as the most primitive yet known in the family. So far as the solid xylem is concerned this may well be true; in the shortening of the internal tracheides, however, *Diplolabis* shows a differentiation not yet observed in *Ankyropteris*, where these elements are, usually at least, of the ordinary elongated form. Also, as Dr. Gordon has pointed out, *Diplolabis* and *Metaclepsydropsis* have quadriseriate pinnae, while in *Ankyropteris* they are biseriate. It therefore appears that these three genera cannot belong to the same direct line of descent. Dr. Gordon's suggestion (Gordon, '11²) that *Diplolabis* and *Metaclepsydropsis* led on to *Zygopteris Grayi* involved the assumption that the latter species is an *Etapteris*, whereas, as we have seen, it belongs to *Ankyropteris*. Of the stem of *Etapteris* we know nothing as yet.

I am inclined to agree with Dr. Gordon's general line of argument in deriving the stem-structure of *Zygopterideae* from a simple protostele like that of *Botryopteris*, though, as we shall see presently, Dr. P. Bertrand takes a totally different view of the relationships.¹

The most interesting comparison, perhaps, is that between *Ankyropteris Grayi* and *Asterochlaena*, a genus very imperfectly known until 1911, when Dr. P. Bertrand published a magnificent monograph on the Permian species *Asterochlaena laxa*, Stenzel. This fine fossil is on a much larger scale than our *Ankyropteris*, the stem (apart from the leaf-bases) reaching 50 mm. in diameter. The xylem, as is well known, is of the most extreme stellate form, with long spidery arms. The number of xylem-arms at the periphery of the star ranges from eight to thirteen; they anastomose towards the centre. There is, however, no relation between the form of the star and the phyllotaxis, for each xylem-arm gives off two or three series of leaf-traces; the arrangement of the bi- and tri-lobed arms is irregular; a unilobed arm has only once been observed with certainty. The number of orthostichies ranges from twenty to twenty-seven; in some specimens the phyllotaxis is whorled, in alternating verticils of ten or eleven members; in the others it is described as 'subverticillate', the number of orthostichies being uneven.

In spite of these striking differences from *Ankyropteris*, many equally remarkable points of agreement exist. There is a 'mixed pith' at the centre of the star, and from this, median protoxylem-bands radiate, passing up the middle of each arm; where the arm forks the protoxylem-bands

¹ The discussion of the curious stem of *Zygopteris Kidstoni* (P. Bertrand, '11, p. 55), which is described as having a stellate solid xylem, will be best postponed till fuller information is available.

form a triangle. Dr. Bertrand believes that the median protoxylem-bands are in connexion with the protoxylem which passes out in the peripheral loops of the leaf-traces, though the connexion is often obliterated. The true protoxylem elements are accompanied by narrow scalariform tracheides, exactly as in *Ankyropteris Grayi*. There is, however, a difference in the fact that short, globular tracheides are also present in the 'mixed pith' of *Asterochlaena*; I have not found these in our plant.

Roots are inserted laterally on the leaf-trace, just where it leaves the stele, but they also occur on other parts of the xylem-arms. The structure of the roots exactly agrees with that of the roots associated with *Ankyropteris Grayi*.

The outgoing leaf-trace gives off numerous lateral strands, which pass out in advance of the trace itself. Dr. Bertrand ('11, p. 53) points out the manifest agreement with the strands in *Ankyropteris* which supply the scales (aphlebiae). In both cases the organs thus supplied have the value of secondary petioles.

Asterochlaena might be described as a multiple *Ankyropteris*, for it differs most essentially from such a plant as *Ankyropteris Grayi* in the fact that each arm of the stele supplies two or three vertical series of leaf-traces instead of one.

Dr. Bertrand, it is true, does not recognize so close an agreement between the two genera as seems to me to exist. He states (p. 50) that the *Asterochlaenas* are the only known Ferns which possess a system of protoxylem-bands proper to the stem. It seems clear that *Ankyropteris Grayi* and its allies are precisely in the same position. He also gives an interpretation of the *Ankyropteris* vascular system which separates it from *Asterochlaena*. In *A. Grayi* he regards the wood as constituted of five curved plates, concave outwards, the five 'réparatrices', each of which represents the left-hand 'demi-réparatrice' of one xylem-arm and the right-hand 'demi-réparatrice' of the next ('11, p. 52, Fig. 8; see also the text-fig. in this paper, p. 51). These 'réparatrices' alternate with the 'génératrices foliaires' (vertical lines of leaf-traces). On this view each leaf-trace is supposed to be supplied by the two xylem-bands lying to the right and left. In *Asterochlaena*, on the other hand, the simple 'réparatrices' are placed directly behind the 'génératrices' in the same radial plane (p. 53). Personally I can see no distinction in this respect, except that the xylem-arms are longer in *Asterochlaena*.

This whole conception of the *Ankyropteris* stele seems to me defective, for it ignores the internal xylem, which here, just as in *Asterochlaena*, 'represents, as it were, the skeleton of the xylem-star' (P. Bertrand, '11, p. 36).

The object of Dr. Bertrand's somewhat artificial interpretation of *Ankyropteris* structure appears to be to bring it into line with the vascular

system of Osmundaceae; probably, however, the relation is too indirect for any such detailed comparison to be admissible.

Finally, some reference must be made to Dr. Bertrand's theory of the general course of evolution of the Zygopterideae.

Asterochlaena, though complex in the structure of the stem, has a simple form of petiolar bundle, the xylem forming a curved band, concave towards the stem, with a peripheral loop, containing the protoxylem, near each end, and slightly towards the abaxial surface. The only simpler foliar bundle of this group is that of *Clepsydropsis*, which is straight, and is thus symmetrical about two planes, while the bundle in *Asterochlaena* is only symmetrical about one plane (the radial).

Dr. Bertrand ('08) believes that *Clepsydropsis* is the petiole of *Cladoxylon*, though the two have not been found in connexion, and the proof is still incomplete. *Cladoxylon* has a very peculiar polystelic structure, the steles having, on the whole, a radiating arrangement. Dr. Bertrand holds that the xylem-star of *Asterochlaena* was probably derived by condensation from the dispersed xylem-system of *Cladoxylon*. A greater condensation, he adds, would clearly give rise to a solid or annular mass of wood with a circular contour ('11, p. 54). Both in *Diplolabis Römeri* and *Ankyropteris corrugata* he derives the circular xylem from a stellate xylem by condensation.

He appears, however, to regard the *Ankyropteris Grayi* type not as an intermediate stage of condensation, but rather as a specially high form of differentiation (see p. 56). He supposes that phenomena of condensation have occurred simultaneously in all the parallel series of the family. The more highly differentiated members may be expected to show—

- (1) a solid xylem,
- (2) a continuous xylem-ring, or
- (3) a xylem-ring differentiated into alternate reparatory and leaf-generating regions, this being the highest type of all.

In the more primitive members of the family, on the other hand (i. e. those nearest to *Clepsydropsis*), we shall be likely to find a stellate vascular mass. Dr. Bertrand enumerates *Diplolabis*, *Tubicaulis* (which has a proto-stele), and *Ankyropteris* among the advanced Zygopterideae, *Asterochlaena* and *Zygopteris Kidstoni* among the primitive forms.

I do not propose to discuss this interesting theory in detail; a better opportunity may be found in a future communication. It is necessary, however, to point out that two opposite views are held: Dr. Bertrand's theory of condensation from a primitive polystelic structure, and Dr. Gordon's theory (shared, I believe, by most palaeobotanists) of the gradual elaboration of an undifferentiated protostele. Dr. Bertrand's view really depends on the truth of his attribution of the simple petiole *Clepsydropsis* to the complex stem *Cladoxylon*; it will scarcely command general assent until this identification has been placed beyond doubt.

In the meantime it seems to me to be established that a somewhat close affinity exists between the genera *Ankyropteris* and *Asterochlaena*. We cannot of course derive one from the other; *Ankyropteris* has advanced along the line of high differentiation of the petiolar strand, while *Asterochlaena* is distinguished by the complexity of the vascular structure in the stem.

SUMMARY.

1. *Zygopteris Grayi* is a member of the genus *Ankyropteris*, as shown especially by the presence of peripheral loops on the leaf-trace. The resemblance of the petiole to *Zygopteris* (*Etapteris*) *di-epsilon* is therefore illusory.

The opinion of Dr. P. Bertrand is thus confirmed.

2. The protoxylem of the stem is situated in the internal rays of the xylem-arms, and passes out thence into the peripheral loops of the leaf-trace, which are differentiated before the trace leaves the stele.

3. The protoxylem of the axillary stele is likewise directly continuous with that of the internal rays of the main stele.

4. The undivided leaf-trace or meristele is, from its base upwards, of the nature of a foliar strand and not of a branch-stele. Its structure is, however, affected to a varying extent by the presence of the axillary stele.

5. The branching is rightly described as axillary rather than as dichotomous.

6. Internal xylem is always present, both in the main and the axillary stele. There is at present no evidence for the existence of a true pith, without internal tracheides, in any member of the *Zygopterideae*.

7. Aphlebiae occur abundantly both on the stem and the leaf-base. Their strands are given off from the leaf-traces both below and above their departure from the stele.

8. The aphlebiae are modified basal pinnae of the leaf, as shown by the structure and mode of origin of their vascular strand. The free aphlebia, however, contains two or three vascular strands, which are branches of the original one.

9. *Ankyropteris*, and especially *A. Grayi*, shows a close affinity with the genus *Asterochlaena*, the latter differing from the former chiefly in the presence of more than one series of leaf-traces in connexion with each arm of the stele.

10. The vascular system of *Ankyropteris* is regarded as probably a highly elaborated protostele, rather than as a condensation of a polystelic structure.

For the loan of sections or photographs I am indebted to my friends Dr. R. Kidston, F.R.S., Prof. F. E. Weiss, and Dr. P. Bertrand, to whom I wish to express my warm thanks.

The photographic illustrations are for the most part the work of Mr. W. Tams, but some were taken for me long ago by my friend Mr. L. A. Boodle.

The drawings reproduced in Plates III to V are partly by Mr. G. T. Gwilliam, partly by Miss G. C. Harrison.

To all these collaborators I am greatly obliged for their aid.

APPENDIX.

It may be of interest to reproduce Williamson's MS. description of the sections of his later, unpublished specimen. The original notes are accompanied by rough sketches to which the letters refer. I am indebted to Dr. F. A. Bather, F.R.S., for a copy of this passage, from the Williamson Catalogue, preserved in the British Museum (Natural History):

'1818 A. *R[achiopteris]* Grayii. The most perfect section yet obtained. To be figured. Oldham. Lomax.

1919 A. *Rach. Grayii*. Trans. Section of a second specimen free from the abnormal mineralization of the specimens previously described. Structure of its secondary branches distinct. Oldham. Lomax.

1919 B. *Rach. Grayii*. Trans. A second section of 1919 A, showing some marked features. The extremity of each of the five radii on the transverse section of the axial bundles is square, *a*. In another radius this square end is detached, *b*; in another ray this latter section seems to have divided into two, the "Axilspross", *c*, and the Zygopteroid petiole, *d*. It is thus evident that these two structures spring from the main vascular axis of the stem as a single bundle, *a* and *b*, but that they divide as they ascend into *c* and *d*. Stenzel says it is so with his *Zygopteris scandens*, but he thinks that the primary bundle is a Zygopteroid one from which the "Axilspross" is a secondary branch. This is *not* the case in my specimen. He also thinks that the "Axilspross" is an abortive bud. I doubt this. Oldham. Lomax.

1919 C. *Rachiopteris Grayii*. Trans. A third section of the same with one secondary branch entirely free and a second one just separating from the central axis. Oldham. Lomax.

1919 D. *Rachiopteris Grayii*. Trans. A fourth section from the above specimen. Lomax.'

EXPLANATION OF PLATES I-V.

Illustrating Dr. Scott's paper on *Zygopteris (Ankyropteris) Grayi*.

The Photographs in Plates I and II often need to be examined with a lens.

PLATE I.

(Photographs by Mr. W. Tams.)

Shore specimen.

PHOTS. 1-6. Selections from the transverse series of sections, from below upwards. PHOTS. 1, 2, 3, 5, and 6 show the stele and surrounding tissues. Phot. 4, on a smaller scale, shows the whole stem.

Phot. 1. (Reversed, as compared with PHOTS. 2-6.) The arms of the stele are numbered 1-5, following the phyllotaxis in cathodic order. The leaf-trace, *l.t.* (incomplete), and axillary stele, *a.s.*, are shown in the outer cortex. × 8. Scott Coll., 2511.

Phot. 2. The arm 5 is spreading out laterally and its internal ray becoming interrupted. × 8. Scott Coll., 2512.

Phot. 3. The end of arm 5 is about to separate as a leaf-trace. × 8. Scott Coll., 2514.

Phot. 4. Complete section. The leaf-trace 5 has now separated (see Phot. 8). Numerous aphaniblasts are seen in the cortex. × 4. Scott Coll., 2516.

Phot. 5. The leaf-trace 5 has now entered the cortex. × 8. Scott Coll., 2518.

Phot. 6. The leaf-trace 5 has passed out further into the cortex and is assuming a stouter form. The arm 4 is preparing to detach its leaf-trace. × 8. Scott Coll., 2520.

Phot. 7. Middle part of stele, showing irregular ring of internal xylem, *x.i.*, with the five internal protoxylem rays. × about 30. Scott Coll., 2516.

Phot. 8. Leaf-trace 5 (see Phot. 4). *x.e.*, peripheral loops formed by the small-celled external

xylem; *x.i.*, median island of internal xylem, destined for the axillary stele. \times about 30. Scott Coll., 2516.

Phot. 9. Foliar bundle, in oblique section, from the base of a petiole in connexion with the stem. *x.e.*, peripheral loop; *s.v.b.*, base of a secondary vascular bundle belonging to a pinna. \times 8. Scott Coll., 2530.

PLATE II.

(Photographs 10–13 by Mr. L. A. Boodle, F.L.S.; 14–16 by Mr. W. Tama.) Photographs 10–14 from Williamson's later specimen.

Phot. 10. Axillary stele, from the transverse section figured as a whole in Scott, '08, Fig. 115. *x.i.*, band of internal xylem, tangential to the parent stem; *ph.*, phloem; *i.c.*, inner cortex of the axillary shoot. \times 34. Williamson Coll., 1919 A.

Phot. 11–13. General transverse sections.

Phot. 11. Leaf-base prominent. *st.*, stele of stem; *l.t.*, leaf-trace in the act of separating from the axillary stele; *aph.*, aplebieae, two in connexion with the leaf-base, and the third in connexion with the stem. The strands of other aplebieae are seen in the cortex. \times about 4. Williamson Coll., 1919 D.

Phot. 12. Here the foliar bundle, *l.t.*, and the axillary stele, *a.s.*, have already separated. For details see Pl. V, Fig. 13. \times about 4. Williamson Coll., 1919 B.

Phot. 13. (Reversed, as compared with Phot. 11 and 12.) *Pet.*, petiole, in oblique section, with the axillary shoot, not yet quite free, between petiole and stem; *a.s.*, axillary stele; *l.t.*, another leaf-trace, diverging from the former by $\frac{3}{4}$, just leaving the stele. \times about 4. Williamson Coll., 1919 C.

Phot. 14. Undivided leaf-trace in the outer cortex. *x.e.*, small tracheides of a peripheral loop. The position of this trace is shown in the diagram, Pl. V, Fig. 15, *l.t.* \times 35. Scott Coll., 184.

Phot. 15 and 16 from Williamson's type-specimens.

Phot. 15. Transverse section of a stem, showing the stele and surrounding tissues (imperfectly preserved). *l.t.*, crescentic leaf-trace, as in the Shore specimen; *aph.b.*, aplebia-bundle (several shown); *r.*, root passing out through cortex. \times 7. Williamson Coll., 1824.

Phot. 16. Transverse section of the vascular bundle of the petiole and adjacent tissues. *x.e.*, small-celled external xylem of the peripheral loops. \times 26. Williamson Coll., 1824.

PLATE III.

Figs. 1, 3, and 5 by Miss G. C. Harrison. Figs. 2, 4, and 6 by Mr. G. T. Gwilliam.

Shore specimen.

Fig. 1. Undivided leaf-trace, after entering the cortex (level of section between that of Phot. 5 and 6). *x.*, large-celled xylem; *x.e.*, small-celled external xylem of the peripheral loops; *px.*, probable positions of protoxylem; *x.i.*, island of internal xylem, destined for the axillary stele; *ph.*, remains of phloem; *i.c.*, band of inner cortex between leaf-trace and stele. \times about 40. Scott Coll., 2519.

Fig. 2. Leaf-trace further out in cortex. Rather more than half is shown (level two sections above Phot. 6). Note the increased width of the middle part of the trace, in preparation for the detachment of the axillary stele. Lettering explained under Fig. 1. \times 50. Scott Coll., 2522.

Fig. 3. Longitudinal section of the stele of the stem passing tangentially through the 'mixed pith', and showing the internal xylem, *x.i.*, at several places. *pp.*, parenchymatous cells; *x.x.*, inner edges of the outer, large-celled xylem-zone. \times 100. Scott Coll., 2525.

Fig. 4. Transverse section of arm 2 of stele (level immediately above Phot. 6). *x.i.*, internal protoxylem ray, the forks nearly reaching the surface of the xylem; *aph.*, aplebia-strand, given off from the arm of the stele. \times 65. Scott Coll., 2521.

Fig. 5. Part of leaf-trace, just detached from arm 5 of the stele (level between Phot. 3 and Phot. 4), showing one of the peripheral loops and an aplebia-strand just given off and still in connexion. *x.e.*, external xylem of peripheral loop; *ph.*, remains of phloem; *aph.*, the aplebia-strand. \times 120. Scott Coll., 2515.

Fig. 6. Aphlebia-strand, *v.b.*, in the outer cortex. The strand is much extended tangentially. $\times 40$. Scott Coll., 2516.

PLATE IV.

Fig. 9 by Miss G. C. Harrison; the others by Mr. G. T. Gwilliam. Figs. 7-10, Shore specimen.

Fig. 7. Aphlebia detached from cortex of stem, *c. v.b.*, one of the vascular bundles of the aphlebia; the other is only indicated by a gap in the tissue; *h.*, multicellular hairs of the stem. $\times 30$. Scott Coll., 2516.

Fig. 8. Somewhat diagrammatic longitudinal section of stem. The cross-hatched area is the outer cortex, *st.*, stele, cut rather obliquely so that the 'mixed pith' is seen below, and two of the internal rays, passing out from it, above. *aph.*, aphlebia-strand, passing out through the cortex. $\times 5$. Scott Coll., 2525.

Fig. 9. Transverse section of an axillary stele (the same as shown in Phot. 1, but two sections higher up). *x.i.*, internal xylem; *p.*, parenchyma of the 'mixed pith'; *x.*, large-celled xylem-zone; *c.*, part of cortex; \rightarrow *S.*, direction of main stele of stem. $\times 44$. Scott Coll., 2513.

Fig. 10. Longitudinal section of another axillary stele, passing through the 'mixed pith'. *x.i.*, internal xylem; *px.*, protoxylem, consisting of spiral tracheides; the parenchyma of the 'mixed pith' is shown above; *x.*, large-celled xylem-zone. $\times 70$. Scott Coll., 2527.

Figs. 11, 12. Williamson's later specimen.

Fig. 11. Undivided leaf-trace in the outer cortex, the same as shown in Pl. II, Phot. 14, and in the diagram Pl. V, Fig. 15, *l.t.* *x.e.*, small-celled external xylem of a peripheral loop. \times about 50. Scott Coll., 184.

The Water-balance of Desert Plants.

BY

D. T. MACDOUGAL, PH.D., LL.D.

Director, Department of Botanical Research, Carnegie Institution of Washington.

With Plates VI-X.

THE conducting tissues of seed-plants are closely connected with morphologically distensible tracts of medullary and cortical tissue which have an appreciable capacity for the retention of water in plants of even the strictest habit and stature. As the ascending current passes from the absorbent elements to the transpiratory surfaces, some of it may go into such masses of cells constituting reservoirs, in the roots, stems, or leaves. This accumulated supply may be drawn out to the transpiring cells when the pressure of the solution in the cell-sap is overcome.

All plants with massive stems may thus carry a large balance of water, and this stored solution may play a very important part in the life of the individual. The relatively largest balances are carried by some of the species characteristic of the arid regions of the south-western and southern parts of North America, some parts of South America, and the southern part of Africa, while Northern Africa, Asia, Australia, and arid regions in high latitudes everywhere have but few plants with a large water-balance.

The author began some work on the water-balance of desert plants in 1908, and the earlier results obtained have already been published.¹ A few of the plants survived the original tests, and these with other living specimens have yielded evidence upon phases of the subject not discussed in full in the earlier paper.

The Tucson region, in which the observations were made, has a winter rainy season and a wet midsummer, with a hot dry fore-summer and arid after-summer. The total average annual precipitation is about 12 inches. The extremest arid effects are seen in June and early July, when the humidity falls as low as 6 per cent. with midday temperatures of 110° and 112° F. Some of the material was observed in the open, and other specimens were kept in a shaded laboratory room in which the extremes of temperature were not reached by ten or fifteen degrees.

[*Annals of Botany*, Vol. XXVI. No. CI. January, 1911.]

ECHINOCACTUS WISLIZENI.

This species is native to the Tucson region, being found on rocky slopes between 500 and 900 metres elevation. The globose or cylindrical stems attain a length of 1.5 metres and a diameter of half or even two-thirds the length in some instances. The root-system is horizontally disposed.¹ The stems may have a weight of 80 to 100 kg., and the long axes are generally parallel to the axis of maximum illumination, which accounts for a slight leaning to the southward in a perfectly open country. The southern side has the folds more closely drawn together, while the cortex of the shaded side will be more heavily developed with the external ridges of the stem widely separated. The extra weight on the shaded sectors of the plant counterbalances the tendency to fall towards the southward. (See Pl. VI.)

About twenty individuals of various ages were examined during a period of four years. It will be necessary to summarize briefly some of the data already published in order to interpret the newer facts presented.

Echinocactus No. 1. A large plant weighing 42.743 kg. was taken up March 4, 1908, and placed on a suitable support on a platform in a shaded room. The rate of loss at the beginning was 17 g. daily or one part in 2,500, which rose to 29 g. daily in the arid fore-summer, dropped to 14 g. during the summer rains, rose to 18 g. in the dry after-summer in September, and then fell irregularly to 1 g. daily in December. This rate of one part in 40,000 is the lowest recorded for any plant that came under observation. The highest daily rate, one part in 1,100, was observed in May, 1908. A year later, when the plant had lost about 4 kg. or 10 per cent. of its original balance out of a total weight of nearly 43 kg., the daily rate was but one in 2,500 of the total weight. With reference to the amount of the water-balance, the daily rate was one in 1,300 in May, 1908, and one in 2,000 in May and June, 1909, at which time the weight was about 38 kg.

Echinocactus No. 2 was taken up November 5, 1908, and placed in the room with No. 1, weighing 5.136 kg. The midwinter rate of loss was as great as that of No. 1, but it soon fell to 0.6 g. daily. This was equivalent to one part in 8,056. The plant was placed in an equable temperature room in mid-February in which the thermometer showed a rise from 56° F. to 71° F. in midsummer, and the humidity ranged from 80 to 90 per cent. The rate under such circumstances rose to 0.7 g., seemingly independent of humidity, with a direct relation to the temperature at first, but the rate continued to increase despite the falling temperature until it reached 1.3 g. daily in October. A decrease now ensued parallel to the falling temperature which carried the rate down to 0.27 g. daily, or one part in 18,000.

¹ See Cannon, W. A.: The Root-habits of Desert Plants. Publication No. 131, Carnegie Institution of Washington, 1911.

Late in February, 1910, the plant was removed to the open and the rate immediately rose to 6 g. daily, and with the coming of the arid fore-summer rose to 21 g. daily, or one part in 150 of the weight at the beginning of the period taken into account. The rate now fell to 7 g. in the rainy season, 3 g. in October, 1910, 1 g. in November, and 0.5 g. in December to February, 1911, or one part in 5,000 of the total weight. The loss in December to February, 1908-9, was one part in 3,000 of the water-balance and about one part in 4,000 of the water-balance two years later (1910-11). The weight on March 20, 1911, was 2.220 kg., showing a loss of 2.916 kg. or 56.5 per cent. of the original weight in the total period of desiccation extending over thirty months.

A chemical analysis of the plant made in April, 1911, showed total solids of 8.097 g. per 100 c.c. of sap, and 3.149 g. of ash, with an average osmotic activity of 2.3 atmospheres at 25° C. This plant, as well as No. 3, may be supposed to have reached the limit of endurance, and disintegration had set in, although a high concentration of the sap contents had not been reached.

The record of this plant includes some data of importance as bearing on the capacity of such plants to absorb moisture through their aerial surfaces. The weight in the open on February 28, 1911, after a drizzling rain lasting through the night, was 2.430 kg., which was 8 g. more than on February 20, 1911. The loss during the eight days would have been about 4 g., so that an estimated absorption of 12 g. by the spines and external structures must have taken place. The plant showed no adhering drops or films of water, and the weighing was done at noon on the 28th.

Echinocactus No. 3 was taken from the soil on March 6, 1908, and placed on a base of loosely-piled black volcanic rocks in the open, its estimated weight being 5.480 kg. It weighed 3.893 kg. when brought into the laboratory on November 5, 1908, and during the next month gained 14 g., which may be attributed to absorption of water vapour by the dead and dried spines. The daily rate of loss was 0.8 g., or one part in about 5,000 in the period from November to February.

The plant had now been deprived of a water-supply for a year, and when placed in the soil exhibited the usual phenomena of growth and flower formation during the summer of 1909. The roots were embedded in soil in a suitable box and the preparation set under a glass shelter without sides, an arrangement which would allow desiccation to proceed as usual. The plant was freed from the soil on November 5, 1910, cleaned, and the roots cut away to simulate the conditions in November, 1908, and the weight was found to be but 4 kg., showing that practically all accretion of dry material had been used in the construction of roots, although some expansion of the head had taken place in 1909. Still supported under the shelter, but separated from its roots and soil, the rate of loss was 1.6 g. daily from

November, 1910, to February 3, 1911, or one part in 2,500, the glass shade having been removed. Its weight was 3.855 kg. on February 28, 1911, and after a rain of 0.19 inch in the form of a slow drizzle throughout the night, the same weight was found. Estimating the total loss at the rate in the preceding period, it must have amounted to 40 kg. in twenty-five days, and this amount appears to have been balanced by the absorption on the part of the dried spines and other external parts. It may not be asserted that any of the above absorption was carried on by living tissue, nor does it appear that the water taken up might be of use to the plant.

The chemical analysis of the sap in April, 1911, showed 9.512 g. solid matter per 100 c.c. of sap and 3.864 g. of ash, the average of over a dozen determinations giving an osmotic pressure of 2.2 atmospheres at 25° C. The total solid and ash were thus about five times the minimum shown by a turgid plant (see p. 76). The concentration of the sap was greater than that of any plant previously examined, yet it is notable that the osmotic activity was scarcely more than half that of any other specimen examined. This would seem to indicate that actual disintegration had begun, and that this individual might not have been able to recuperate if supplied with soil moisture.¹ The total loss was 2.075 kg. or 36.2 per cent. of the original weight in three years.

Echinocactus No. 4 was taken from the soil, the root-system cut away, and placed on a base of loosely piled volcanic rock in the open on March 5, 1908. The estimated weight was 1.192 kg., which was reduced to 795 g. on November 5, 1908. A slight gain in weight was noted, as in No. 3, when this plant was brought into the shaded laboratory. The rate of loss was 0.5 g. daily in the 164 days ending May 21, 1909. This was equivalent to one part in 1,500. The rate was 0.6 g. in August, then fell to 0.4 g. and to 0.2 g. in November, and then during the midwinter period fell to 0.13 g., or one part in 5,300. A gain of 2 g. in weight ensued when the plant was placed in the humid dark room for seven days. The humidity was 62 per cent. with a temperature of 58° F. Upon being taken out the rate rose to 0.4 g. in March and 0.6 g. in May, which was practically equivalent to the rate at the corresponding period of the previous year. A rate of 0.4 g. was maintained from July to November, when it fell during the period of November to February to 0.11 g., or one part in 5,000, which, with corrections for variation in periods of observation, is not materially different from the rate of the year before.

The room in which this plant was placed was heated during February so that the rate rose to 0.24 g. daily and the weight fell to 549 g. on February 28. It was now placed outside for four days, its final weight on March 5, 1911, being 549 g. It was then set on the parapet wall of

¹ See MacDougal and Cannon : The Conditions of Parasitism. Pub. 129, Carnegie Institution of Washington, p. 33, 1910.

the laboratory. The high temperatures and intense sunlight soon killed it, however. (See Pl. VII.)

Echinocactus No. 6 was taken from the soil November 7, 1908, and after being freed from roots was mounted on a stand in the laboratory. The initial net weight was 28.573 kg., and the rate of loss during the first month was 13 g. daily, which was about one part in 2,200 of the total weight. The rate during the winter fell to 0.6 g. daily, or one part in 5,000, and rose in the hot fore-summer to 10 g. daily. By October, 1909, the rate had fallen to 8 g. daily, and to 2.5 g. daily in November, which was one-fifth of the rate of the previous year. The rate in January was 1.7 g. daily, or one part in 16,000. Observations now showed 2.2 g. in March, 4.6 g. in April, 6 g. in May, 7.2 g. in June, 7.7 g. in July, 5.8 g. in August, 5 g. in November, and 2 g. daily in the period extending into February, 1911, a rate of one part in over 12,000, which was greater than that of the previous year, but was still less than the rate of loss during the first year of observation. The rate increased to 2.6 g. daily during February as the room was heated daily during that time. The rate of loss during the first seventeen days of March was nearly 4 g. daily, and 2.3 g. daily during the twenty-four days ending April 10. The entire loss during twenty-nine months was 3.713 kg., or nearly 13 per cent. of the original weight. No noticeable growth had taken place, but sixteen greenish-yellow fruits were retained. It is to be seen that the changes in the form of this plant would be such as to maintain fairly constant transpiratory conditions, and the variations from year to year are to be ascribed to other causes than variations in temperature, air currents, &c.

Echinocactus No. 7 was taken from the soil November 7, 1908, freed from its roots, and set on a metal support in the laboratory. The net weight was 35.818 kg., and the rate of loss during the first month was 18 g. daily, or about one part in 2,000, which was slightly more than that of No. 6. The rate during the winter was 10.5 g. daily, or one part in about 3,500, which was higher than in No. 6. The rate ran very irregularly, falling to 8 g. daily in June, 9 g. in August, and decreasing to 4 g. in November, which, like that of No. 6, was much less than in the previous year. The winter rate did not fall below this, however, and amounted to one part in over 8,000, which was double the rate of No. 6. The loss rose to 9.8 g. daily in June, fell to 6 g. in August to October, to 4 g. daily in October, while the midwinter rate, 1910-11, was 2.1 g. daily, or one part in 15,000, less than that of No. 6 and slightly less than its own rate of the previous year. The rate from February 3 to February 28 was 1.6 g. daily, a notable decrease and less than that of No. 6 during the same period. The erratic record from February to April was found to be due to errors caused by a mouse's nest built among the arms of the balance. During the next seventeen days the rate rose to 2 g. daily, and to 3.3 g. daily during the twenty-four days ending April 10, 1911.

The weight was now 31.570 kg., the total loss during the entire period of the experiment extending over twenty-nine months being but 42.48 kg., or less than 12 per cent. of the original. During this time some apical growth had ensued and eighteen fruits were retained. This plant, with No. 6, was set up for further observation.

Echinocactus No. 10 was taken from the soil November 7, 1908, freed from its roots, and set on a tin box near the south side of the laboratory in the open. Its net weight was 14.588 kg. and it lost 61.6 g. daily during the first month, or one part in 220, about ten times the rate of plants in a shaded room. The rate during the next six months was 30 g., the total being 4.860 kg., out of the original noted above. This rate was one part in 430, which is about five times that of Nos. 6 and 7 during the same period in the shade.

The analysis of the expressed juice of the sap of the cortex gave the following data :

Specific gravity	1.035
Acidity calculated as H_2SO_4 per 100 c.c.	0.1064
Total solids per 100 c.c. of sap	7.060
Ash content of sap per 100 c.c.	3.009

A similar analysis of a turgid plant taken up on September 9, 1909, gave the following :

Specific gravity of sap	1.0095
Acidity calculated as H_2SO_4 per 100 c.c. of sap	0.0887
Total solids per 100 c.c. of sap	2.092
Ash content of sap per 100 c.c.	0.792

Echinocactus No. 13 was taken from the soil and freed from its roots on February 18, 1910, after which its net weight was found to be 49.390 kg. It was now mounted on a base of loosely piled black volcanic rock near a *Carnegiea* taken up at the same time. Definite points were located for calibration, and the greatest length was 585 mm. and the greatest diameter 413 mm. The rate of loss was 150.5 g. daily from February to May, this being one part in over 300 total weight. The total loss of 12.490 kg. up to May 12, 1910, was accompanied by a decrease in length of 25 mm. and of diameter amounting to 43 mm. The rate of loss fell to 102 g. daily in July, some new spines being formed and flower buds developed at this time. The rate fell to 33 g. daily by October 3, 1910, at which time the total loss was 12.845 kg. This rate amounted to one part in 873. Although the plant had lost over one-fourth of its total water-balance, eighteen flowers had been formed and eight small fruits matured. The length had decreased to 500 mm., a further shrinkage of 60 mm. in length and of the diameter to 325 mm., a loss of 45 mm. The lowest rate, 9.3 g. daily or one part in nearly 2,900, was found in the period of thirty-five days ending November 9,

1910. The rate rose to 14 g. daily during the period ending February 6, 1911, and the external dimensions remained unchanged from the measurement of October 5, 1910. During this period of eighty-nine days the external measurements did not follow the transpiratory loss.

The final weight, taken on March 20, 1911, was 25.540 kg., indicating a total loss of 455 g. in forty-two days at the rate of nearly 11 g. daily. The total loss in thirteen months amounted to 23.850 kg., or 48.3 per cent. of the total weight. The total solids in the sap amounted to an average of 3.7 g. per 100 c.c., the ash being 1.4 g. per 100 c.c. The average of a large number of freezing-point determinations gave an osmotic activity of about 3 atmospheres at 25° C. These results show a different aspect from anything previously examined. The plant seemed alive as indicated by its osmotic pressure, but the soluble matter in the sap had been reduced to a minimum.

Some interesting relations appear when the amount of loss is contrasted with the degree of succulency. Turgid specimens of *Echinocactus* contain 90 to 95 per cent. of their total weight in water, and this plant may be estimated to have contained about 45 kg. of water at the beginning of the experiment. The cylindrical body, with its fluted surface, offers about twice the transpiratory area of a plain cylinder of the same measurement, which would amount to about 15,000 sq. cm. The degree of succulence would, therefore, be about 3 or 3 g. of water present to each sq. cm. of surface. This is to be compared with 10 g. in leaves of *Suaeda* as determined by Miss Delf.¹ In this condition the plant lost in the open one part in 300 on the average during a period when daily temperature ranged from 32° to 90° F., and in the full blaze of the desert sunlight.

The total loss in weight up to May 12, 1910, was 12.490 kg., which may be taken as being principally water, the total amount remaining now being about 32.5 litres. The surface had shrunk to 14,000 sq. cm., but the succulence had also decreased to about 2.3. These conditions, together with the higher relative humidity prevalent in July, were seen to result in a lessened rate of loss during the summer. At the end of the dry after-summer, the surface showed a further estimated decrease to about 3,000 sq. cm., and as but small loss had ensued since the last observation, the total now being 12.485, the remaining water may be estimated to have been about 32,000 litres, which indicates a succulency of 2.4 g. per 100 sq. cm. of surface, which is slightly greater than that shown in midsummer, although the rate of loss was much lower. Other factors may be taken as contributing to this result. The approximated position of the folds and the cooler night temperatures would both tend to lessen the rate of total loss. Next it is to be seen that as soon as the transpiratory loss was not taken up by the changes in external dimensions, the rate increased even under the retarding

¹ See Transpiration and Behaviour of Stomata in Halophytes, *Ann. of Bot.*, vol. xxv, 1911, pp. 485-505.

influence of seasonal factors least favourable to transpiration. Nothing may be safely said as to the cause of this rise. It is to be noted in this connexion, however, that the amount of dissolved solids in this plant, instead of being about seven or eight parts per hundred, as shown by other desiccated specimens, was about half this amount, not very much more than the proportion shown by a turgid specimen. The disintegration of certain substances in the walls of the cells or membranes may have altered their permeability and permitted a more rapid water loss.¹

The Tree Cactus *Carnegiea gigantea*, Britton and Rose, or Sahuaro forms a trunk 25 to 50 cm. in diameter with a heavy cylinder of woody tissue, enclosing a medulla of a diameter amounting to 8–10 cm. in some instances. The cortical layer of colourless cells is also very thick, the outer layers of this tissue being chlorophyllose. Externally the trunk presents a series of longitudinal folds or ridges, separated by furrows which vary in depth much more widely than similar structures in the various species of *Echinocactus*. The older portions of the trunk may become so distended as to eliminate the folding or plaiting. The trunk may reach a height of 12–15 metres and bear many heavy branches. The total weight of the larger plants might be estimated at 2–4,000 kilos, 85–90 per cent. of which may be taken as water. The water-content may, however, undergo a wide variation, as is well illustrated by the following paragraphs.

The root-system penetrates the soil more deeply than those of the *Echinocactus*, and even these organs are thick, soft, and contain a great amount of fluid.

Carnegiea No. 1 was taken up May, 1908, and freed from soil and roots, after which it was set in a perpendicular position on a base of loosely piled rocks in the open. Its estimated weight was about 40 kg. November 5, 1908, the weight was 32.518 kg. It was now brought into the laboratory with the *Echinocacti* already described. Water was lost at a rate of 62 g. daily during October, and at the rate of 23 g. daily during the next six months, which amounted to one part in 1,700 of the weight at the beginning of the period. The analysis of the expressed juice obtained from the terminal portion of the trunk gave the following results:—

Specific gravity	1.0355
Acidity calculated as H ₂ SO ₄ per 100 c.c. of sap	0.103
Total solids per 100 c.c. of sap	9.622
Ash content of sap per 100 c.c.	2.754

Carnegiea No. 1a was taken up, freed from soil and roots, October 22, 1909, when it weighed 45.325 kg. It was suitably mounted in the laboratory, and lost weight at the rate of 114 g. daily during November. This

¹ The transpiratory mechanism of *Echinocactus* has been described by Cannon. See Biological Relations of Certain Cacti, American Naturalist, vol. xl, Jan. 1906, p. 27.

rate fell to 8 g. in January, 5.5 g. in February, and rose to 67 g. daily when removed to the open in May, June, and July. The rate fell to 6 g. daily in October, 1910, and to 3.8 g. in the period of 89 days ending February 6, 1911. The loss during a part of February, 1910, was one part in over 8,700, while in the corresponding period of a year later it was but one part in over 9,300. The last calculation was made for a longer period, and the actual minimum may have been much lower.

The total weight of the plant was reduced from 45.325 kg. to 34.810 kg., a total loss of 10.535 kg., or 23.3 per cent. of the original weight. The chemical analysis made in April, after some further loss had been undergone, showed the following :—

Total solids in juice per 100 c.c.	10.44 g.
Ash content of sap per 100 c.c.	1.83 g.

Three determinations of the osmotic activity by the freezing-point method gave 10.15, 9.64, and 9.72 atmospheres, the average being 9.84 atmospheres at 25°C.

Three analyses of growing plants previously reported¹ show total solids in the juice ranging from 3.4 g. to 5.9 g. with an ash content of 1 to 1.7 g. per 100 c.c. of sap.

The desiccation of this plant, which had progressed without any repletion of the water-balance for over 16 months, may be taken as representing about the limit of endurance of the species without water, both as to time and amount of loss. It is of interest to note also that determinations of the osmotic activity of the sap of individuals rooted in moist soil by the freezing-point method gave pressures of 6.78 atmospheres, although some as low as about 4 atmospheres by plasmolytic methods are on record.² It is to be seen from this that the range of variation with regard to this condition is as 1 to 2.

The desiccation of *Carnegiea* was not found to cause any noticeable reduction in length, a fact that may be readily understood when the heavy woody cylinder is seen to be well formed to within a few centimetres of the upper end of the trunk. The shrinkage in the cortex would result in some decrease in diameter, but this would be accomplished by contraction of the folds without any great decrease of the outer surface. Turgid trunks consist of over 90 per cent. water, but their slender cylindrical form would operate to give them a relatively lower succulence than *Echinocactus*. Furthermore, the degree of succulence would be much lowered during desiccation by the maintenance of the surface area as suggested. Transpiratory loss seemed to be more or less closely correspondent to the succulence, and to be

¹ In Publication No. 141, Carnegie Institution of Washington, 1910, p. 47, 1911.

² See MacDougal and Cannon : Conditions of Parasitism in Plants. Pub. 129, Carnegie Institution of Washington, 1910, p. 25.

affected by the seasonal changes in an obvious manner. No changes of mode or discontinuity in the rates of loss, such as were seen in *Echinocactus*, were recorded. The extremest stages of desiccation were accompanied by highly increased total solids and ash content of the sap.

Carnegiea seedlings. Twenty young plants, seven months old, were taken from the flat in which the germinations had taken place, and put in a dish in the laboratory, November 4, 1910. The net weight of the lot was 27.244 g., and the loss during the first three days was 6.865 g. at the rate of 2.286 g. daily, this being one part in 12 of the total. Much of this may be attributed to the desiccation of the exposed root-surfaces, although all of the finer branches had been removed. The rate of loss was 0.5 g. daily, or one part in 40 during the next nine days, while in the next 79 days ending February 3, 1911, the rate was 0.85 g. or one part in 30, an increase for which no adequate cause may be given. February 24, 1911, the net weight was 12.499 g., the loss in the preceding 21 days having been 0.055 g. indicating a rate of one part in 46. The total loss was 14.745 g. or 54 per cent. of the original weight. Four of the seedlings were wilted beyond revival, and as many more were in a doubtful condition, the above may be taken as roughly representing the average resistance of the seedlings. From this it may be seen that the seedling loses water at such a rapid rate during even the cooler season as to exhaust its effective balance in about 100–120 days. The death of some of the individuals ensues when something less than 54 per cent. of the total water-balance is lost. This is, however, a greater degree of endurance than that exhibited by adult plants, as may be seen by reference to page 79. The older individuals are not able to withstand a loss greater than about 23 per cent. of their original turgid weight.

Thirty-six resting corms of a native *Brodiaea* were taken from the soil on October 30, 1910, and brought into the laboratory to obtain data which might be of interest in comparison with those furnished by the seedlings of *Carnegiea*. The net weight of the lot was 46.7 g., and the loss during the first 24 hours was 4.9 g., which was one-eleventh of the total. This doubtless represents the desiccation of the outer dried coating of the bulbs. The loss during the following day was 0.78 g. or one part in 53. During the next week, ending November 9, 1910, the loss fell to 0.31 g. daily or one part in 130. The loss during the week ending November 16, 1910, was 1.680 g., 0.24 g. daily, or one part in 200. The total loss was 18.425 g. or 39.5 per cent. of the original weight during 96 days. During the latter part of this period young corms were developed, and the contents were slowly withdrawn from the older ones. The desiccation of the other structures described in this paper resulted in depletions in water-balance followed by shrivelling and contraction of the affected members. The reaction of *Brodiaea*, however, is seen to consist in the formation of new smaller corms which are plump and turgid, although each one contains but the fraction of

the water of the larger member from which it originated. The repetition of this action might result in the survival of the species through several arid seasons by the seasonal development of a series of diminishing size (Pl. IX, D).

IBERVILLEA SONORAE.

The indurated tubers of this plant are irregularly globose or flattened, and lie on the surface of the ground. A network of small fibrous roots is formed during the summer rainy season and serves to take in a supply of solution which is added to the enormous balance already present. The growing points which are distributed irregularly over the surface of the tuber awaken at the same time, and produce vines which may reach a length of two to three metres, quickly maturing flowers and fruits (Pls. VIII and X). The rhythm of the plant is such that this activity ensues for many seasons after the plant has been separated from the substratum, as has already been described.¹

A tuber of a plant which had been established at the Desert Laboratory in 1906 was taken up October 22, 1909, and when cleaned and freed from roots and dead vines, weighed 530 g. The loss was 0.4 g. daily during the first 15 days, or one part in 132, 0.16 g. daily in the next 12 days, and in the 51 days ending January 8, 1910, the loss was but 0.08 g. daily or one part in 6,500. The rate fell to 0.04 g. daily in the latter part of January and February, which was but one part in nearly 13,000, but rose to 0.11 g. daily during the 55 days ending April 21, 1910.

The rising temperature stimulated the formation of green stems in May, the rate of loss rising to 0.3 g. daily, or one part in 1,500. The rise continued until the rate was 0.08 g. daily in July, which was one part in 573, this being the greatest transpiratory activity exhibited at any time. A decrease now began which brought the rate to 0.05 g. in the period ending October 3, 1910, and to 0.3 g. in November, after the vines had died. The rate during the following 91 days was 0.09 g. daily, or one part in nearly 4,500, which it may be seen is in excess of the rate during the corresponding period of the previous year. The room containing this plant was warmed in February so that the rate increased to 0.16 g. daily, the weight being 389 g. on the last day of the month. The rate during the first 20 days of March was less than 0.1 g. daily, decreasing slightly during the next 21 days, but rising again to exactly 0.1 g. daily during the 20 days ending May 1, 1911, slightly less than the rate of loss during the corresponding period in 1910.

May 26, 1911, the weight was 387 g., indicating a daily loss of 0.12 g. during May, an increase commensurate with the higher temperatures prevailing.

¹ MacDougal, D. T.: Botanical Features of North American Deserts. Pub. No. 99, Carnegie Institution of Washington, 1908, p. 20.

The total loss from this plant in 19 months was 143 g. or 27 per cent. of the total weight. This included the material used in the construction of stems and leaves in the summer of 1910. In addition to the increased transpiration from these stems, some marked loss would be attributable to respiration and to the falling away of dead stems and branches. (See upper right-hand figure in Pl. X.)

Ibervillea Nos. 4 and 5 were received as freshly collected tubers from Dr. J. N. Rose, who was in the field near Guaymas, Sonora, in March, 1910. The tubers were cleaned and freed from roots, then placed on suitable supports in a shaded laboratory. The weight of No. 4 was 1.452 kg. on March 17, 1910. The loss during the first five days was 25.6 g. daily, which was about one part in 520. Much of this accelerated loss was due to the transpiration from cut surfaces and bruised tissues. With the closure of such places the rate fell to 1.3 g. daily in April, and 0.85 g. in May, although the rising temperature would have tended to increase the rate, which continued to fall until it was but 0.36 g. in June, which was one part in nearly 3,700. The development of a number of branching stems caused the rate to rise to 0.66 g. daily in July, which fell to 0.5 g. in the period ending in early October, when the stems were dead. A decrease continued which brought the rate to less than 0.2 g. daily in late October, and to 0.04 g. daily in the period ending February 3, 1911, which was but one part in 30,000. The room was warmed to 18° C. for a few hours daily during February, and the rate of No. 4 rose to 0.3 g. daily in March, but fell to 0.05 g. daily in the 20 days ending April 10, but rose to 0.35 g. in the 21 days ending May 1.

May 26, 1911, the weight was 1.260 kg., indicating a daily loss of 0.16 g. in May, which was less than that in April, although green stems were being formed. A similar decrease in the rate of loss was recorded for the corresponding period of 1910 as noted above. No explanation may be offered for the erratic behaviour of this plant, which was kept within a few centimetres of the other tubers used.

The total loss in 14 months amounted to 192 g. or but 13 per cent. of the original weight, although many branches and small leaves were produced in the summer of 1910. (See left-hand figure in Pl. X.)

Ibervillea No. 5 weighed 1.006 kg. on March 17, 1910. The rate of loss during the following days was but 3.6 g., which was probably less than that of No. 4, largely by reason of the small amount of damaged surface. The rate fell to 0.9 g. in April, and to 0.5 g. in early May. The rising temperatures failed to accelerate the loss, but the rate rose only when green stems were formed. These brought the loss to 0.6 g. later in May, 0.9 g. in June, and to 1.5 g. with the fullest development of the leafy stems in July. The gradual death of the stems brought the rate down to 1 g. daily in the 68 days ending October 3, 1910, 0.9 g. in November, and to 0.15 g. daily in

the 91 days ending February 3, 1911. This minimum was equivalent to one part in over 5,000, which was much in excess of the loss displayed by No. 4. The excessive loss is to be attributed to the greater development of green stems, five of which remained alive. The room was warmed to 18° C. for a few hours every day in February, but the rate of loss rose to only 0.16 g. daily. The rate was 0.2 g. daily during the first 20 days of March, 0.2 g. daily during the next 60 days, and 0.32 g. daily in the period of 25 days ending May 1, when a number of rapidly elongating stems were being formed. (See lowermost figure in Pl. X.)

TUMAMOCA.

Tumamoca is a relative of *Ibervillea*, native to the region about the Desert Laboratory, and having similar habits. The tuberous formations which retain the balance of food-material and water, however, are formed underneath the surface of the soil, and the outer layers are not so impervious to water. One of these structures taken from the soil and cleaned, November 2, 1910, weighed 125 g. Upon being placed on a suitable support in the laboratory it lost 1.3 g. daily during the first two days, or one part in 93, although care was taken not to damage the outer layers. This high rate continued, being 1.37 g. during the next five days, although it fell to 0.3 g. daily during the 86 days ending February 3, 1911. Its net weight at this time was but 90 g. and the minimum loss was one part in 400, which is greatly in excess of that of its relative *Ibervillea*, under the same conditions. (See uppermost figure in Pl. X.)

The total loss from this plant amounted to 258 g. or about 25.5 per cent. of the original weight, which was greater than that shown by any other plant of this species. The excess is probably attributable to the greater number of green stems formed.

GROWTH ACTIVITIES OF DESICCATING PLANTS.

In addition to the observations made on the growth or quiescence of plants with a water-balance during a period of depletion recorded in the preceding pages, the unpublished results of a study of the formation of stems from desiccating tubers of *Dioscorea alata*, which were made in the New York Botanical Garden, by the author in 1902, are of interest in connexion with the subject under discussion.

Mature tubers produced by vines in the conservatories were placed in shallow glass dishes on tables within two or three metres from large windows in January of that year. The illumination did not differ greatly in intensity from that of the glass houses. Growth soon began and two or three buds awakened on each tuber, and the stems produced extended at an extremely slow rate during the following 20 months, with the result that an extension* of 10 to 15 cm. was reached (Pl. IX, c). A

comparative examination was made of this material with stems of vines in the conservatories and of the young stems sent out by tubers in the propagating houses. The work of Duchartre upon *D. Batatas*, Dcsne., was found of great interest in connexion.¹ Duchartre placed tubercles in a dry chamber where they would be compelled to sprout without a supply of soil moisture, in a manner similar to that noted above. He noted that the stems developed were 50 to 80 cm. long, composed of elongated internodes, and that the leaves remained extremely small with diminutive laminae, entirely lacking from lower internodes, and showed a lack of mechanical tissues, from which he points out the resemblances to etiolation as exhibited by some plants. The bases of the stems remained green, but the remainder of the epidermal structures were of a reddish brown colour. He also noted that the base of the stem became the seat of the formation of a tuberous swelling which must have been the beginning of the large tuber usually formed by these plants underground. No stomata were found on the reduced leaves, the starch was not all converted, and the unequal thickenings were not seen in the layer of cells usually becoming collenchymatous. (See Pl. IX, A and B.)

Miss Dale performed similar cultural experiments with *Dioscorea sativa*, although no reference is made by her to the previous experiments of Duchartre.²

In this case also elongated stems were formed which measured as much as six or eight feet. The formation of buds at the bases of the stems was noted, but no comparisons of the lengths of internodes with those of the normal were made. Tuberous structures were seen to develop in the axils of the leaves, and the branches remained very short. The formation of adventitious roots around the bases of the stems, with a scaly epidermis, was noted.

The stems in my cultures of *D. alata* did not seem capable of reaching the lengths described by Duchartre and by Dale in the two species named, but this deficiency may be accounted for in part by the smallness of the tubers and correspondingly small supply of food-material available. The stems consisted of two to five internodes, and were angular, reddish brown, and bore numbers of trichomes and glandular structures. The internodes were of a length less than that of the normal in every instance. The bases of the stems underwent a tuberous swelling from which arose numbers of short thick adventitious roots (Pl. IX, C).

The leaves were extremely small, and were in the form of narrow reddish brown scales, with no differentiation into lamina and petiole. The axillary buds showed an activity similar to that of the main buds of the

¹ Duchartre, P. : Influence de la sécheresse sur la végétation et la structure de l'igname de Chine *Dioscorea Batatas*, Dcsne. Bull. Soc. Bot. de France, vol. xxxii, 1885, p. 156.

² Dale, E. : On the Origin, Development, and Morphological Nature of the Aerial Tubers in *Dioscorea sativa*, Linn. Ann. of Bot., vol. xv, 1901, p. 491.

tubers, and the bases of the primary branches were expanded into tuberous formations in the same manner as the primary stems, but the adventitious roots formed did not progress beyond the form of papillate outgrowths. In no instance did the branches attain a length beyond a centimetre.

An examination of my material showed that the xerophilous stems had attained a degree of differentiation of the tissues much less than the normal, which may be attributed directly to the lack of formative material, including water. The pericycle might not be distinguished, and the cortical tissue was composed of cells of greater angularity of outline. Despite the lack of development in the stelar elements, the sub-epidermal parenchymatous elements showed marked collenchymatous thickenings, not seen in normal stems, while the outer walls of the epidermis were much heavier and were distinctly cutinized. (See Pl. IX, A and B.) It is thus to be seen that, despite the lack of nutritive material and the capacity for photosynthesis, the small resources of the shoot were directed towards the formation of elements which would operate to husband the minute supply of water and diminish transpiration. The differences in structural reaction in *D. Batatas* and *D. alata* may be accounted for chiefly by the fact that the tuberous formations of the first are thickened roots, while those of *D. alata* are undoubtedly stem structures.

GENERAL DISCUSSION.

The vegetation of almost all desert regions usually includes a number of rapidly maturing forms, indigenous or of ancient or recent introduction, which carry out their entire cycle of existence during regular or irregular periods of rainfall, and are physiologically mesophytes. Other forms that require much moisture are to be found along streamways.

The specialized forms not affected by the streamways and more or less active during the dry seasons comprise two types, viz. the sclerophyllous and the succulent. The first includes a large number of woody and spinose herbs and shrubs with reduced branches, restricted spread of leaves, and indurated surfaces. These xerophytes have a very small water-balance, and the cell-sap may show extreme concentration. Determinations of the osmotic pressure of the sap of a number of such types at Biskra,¹ in Africa, by Fitting, gave pressures of 100 atmospheres and over. The roots of such plants are usually in continuous absorptive contact with soil particles from which some moisture may be withdrawn, and sclerophyllous forms are notably difficult to transplant, since they wilt so quickly when removed from the soil. Mesophytic plants, when grown under arid conditions, simulate sclerophylls to some extent, although the extremes of osmotic pressure of the sap are probably not approximated.

¹ See Fitting, H.: Die Wasserversorgung und die osmotischen Druckverhältnisse der Wüstenpflanzen. Zeitschr. f. Botan., vol. iii, 1911, p. 209.

Morphogenic reactions of a xerophytic character are well illustrated by the structural features of *Dioscorea* described in this paper.

The specializations exhibited by sclerophyllous forms are therefore of a direct physiological character and entail the least morphological change. This group is represented in American deserts by a large number of leguminous trees and shrubs, such as *Prosopis*, *Acacia*, *Calliandra*, *Parkinsonia*, *Cercidium*, *Olneya*, &c., and by *Covillea* (*Larrea*), *Fouquieria*, *Lycium*, *Koehberlinia*, *Condalia*, *Zizyphus*, *Manzanita*, *Quercus*, *Aster*, *Encelia*, *Franseria*, *Fatoupha*, *Sapindus*, *Vauquelinia*, &c.

Succulents display most of the external features of the spinose xerophytes, which may be carried to their extreme limits. This is well exemplified by the Cacti, in which the entire shoot may be reduced to a short cylindrical or globose form. In addition to these reductions secondary morphological changes have ensued, which have resulted in exaggeration of the medullary or cortical tissues in roots, stems, or leaves, which may contain large balances of water. The sap of succulents generally shows a comparatively low osmotic pressure. Three to five atmospheres are usually found in *Echinocactus Wislizeni* when turgid. *Carnegiea* shows 6–8 atmospheres, and *Opuntia* 10–12; *Agave* slightly more; and the pressure in all of these may increase greatly with desiccation. The greater number of succulents in South-Western America are to be found in the regions in which the rainfall occurs regularly within well-defined seasons. This is true of the plants used in the experimental work described in the preceding pages. The root-systems of such plants are generally horizontally disposed within a few centimetres of the surface, and are in a position where the moisture is most available during the rainy seasons. The cessation of the rains is soon followed by a low water-content of the surface layers of the soil, and the passage of water from the soil to the plant is reduced to a minimum. The finer rootlets perish, and the plant stands self-contained until the next rainy season, when new absorbing branches are formed.

The actual physiological value of large water-balances varies widely, as may be seen by an examination of the experimental data given in this paper. The great Tree Cactus, or Sahuaro (*Carnegiea gigantea*), may survive a year or perhaps two, under certain circumstances, without receiving additional water from the soil. The formation of flowers in the arid fore-summer, however, will not take place unless the plant has received its supply during the previous winter rainy season. Neither would apical growth ensue in midsummer unless the summer rains were available. The death of a plant from the base upwards may sometimes result in the development of flowers on isolated branches which have received no water for a year, but this must be taken as a special case in accord with many experiences that approaching death stimulates reproduction.

Echinocactus was seen to exhibit both root development and apical growth of the stem after one or two years of depletion of the water-balance, and showed some capacity also for flower formation. Individuals exposed to the full intensity of the Arizona sunlight might not survive for more than a year, although even the slightest amount of shade would greatly enhance the value of the enormous water-balance. Plants in an ordinary room were in good condition after three years of deprivation of water.

Repeated observations show that the flattened *Opuntias* may exist for extended periods, perhaps two or three years, without a water-supply, and may carry out seed-formation during this period. New joints may be formed, but generally at the expense of the older ones, which are destroyed during the process.

Ibervillea has a great balance of food material as well as water, which is accumulated in woody tubers with heavily indurated outer tissues. These plants have been seen to be capable of developing the thin shoots for many years with a small rate of depletion. One individual has been under continuous observation for ten consecutive seasons. The intensity of the illumination and temperature, of course, figure largely in the matter.

The corms of *Brodiaea* respond to seasonal stimuli by the development of smaller new and turgid corms in prolonged periods of desiccation. The older corms are emptied and destroyed in the process, which may be repeated a few times.

No notable morphogenic departures were seen in the phenomena of growth and reproduction as exhibited by *Echinocactus*, *Opuntia*, and *Ibervillea* with a depleted water-balance, except that the new structures were generally of a minimum size. The stems of *Dioscorea* developed under such conditions, however, showed some notable departures towards a sclerophyllous habit. (See pp. 83-5.)

All of the plants examined showed a high rate of water loss immediately upon removal from the soil, due to evaporation from moist outer surfaces and from abraded tissues, regardless of the season. Next it was found that the curve of transpiration was lowest in the cool months of November, December, and January. At this time the daily rate of *Echinocactus* was between one in 40,000 of the total weight and one in 8,000 in a well lighted room, while individuals in the open showed a rate of one part in 5,000 to one part in 2,500, and even one part in 300 in a single instance. The maximum rate during the hot, dry fore-summer with relative humidities between 6 and 20 per cent. and midday temperatures as high as 90° F. indoors and 112° F. in the open, varied between one in 800 and one in 4,000 in a well lighted room, while it rose to one part in 300 for the entire period of February to May, and must have been double this rate in May.

The minimum daily rate of loss in *Carnegiea* (adults) was about one part

in 9,000 of the total weight in a shaded room in winter, and the maximum in the open was one part in 640 after the plant had suffered several months' depletion. Seedlings of this plant lifted from the soil in November lost weight at the rate of one part in 12 daily for three days, the average during the next nine days being one in 40, which then rose to one part in 30 in midwinter, and fell later to one part in 227 in the period when some of the individuals were dying. This expected high rate of loss by desiccation would contribute to the enormous mortality of seedlings in the open. Germination takes place in the summer rains in July, and the tender plantlets must then endure a period of four months of extreme aridity, but with falling temperatures.

The resting corms of *Brodiaea* lost one part in 11 by evaporation from the dead outer coats the first day after removal from the soil in November, and this rate fell at once to one in 53, then to one part in 164, and finally to one part in 200. The latter rate was calculated for the period including the formation of new corms. This rate of loss is probably greater than that which would be exhibited by corms *in situ* in the soil.

The minimum rate of loss of *Ibervillea* during the relatively humid cool winter season was one part in 4,500 to one part in 32,000. The maximum in a well lighted room during the arid fore-summer was one part in 573 to one part in 2,000. This applies to the period in which new stems were being formed.

The behaviour of a plant in successive seasons with especial relation to the state of depletion of its water-balance of succulency was a matter which received some attention. *Echinocactus* No. 1 showed a maximum rate of 29 g. daily in 1908, and 15.6 g. a year later, after it had lost but 3 kg. or 7 per cent. of its weight. The minimum rate in March, 1908, was 10 g. daily, while a year later, in the corresponding season, it was less than 4 g. after a loss of but 3 kg. or about 7 per cent. of its weight.

Echinocactus No. 6 lost at the rate of 0.6 g. daily during 155 days including the winter of 1908-9, and 3.7 g. daily during a corresponding period of 173 days a year later, after it had decreased 1.370 kg. or 3.8 per cent. of its earlier weight. A year later the rate was 2.8 g. for a period of 188 days after a loss of but 1.600 kg. more. The maximum rate in June, 1909, was 10 g. daily, and in June and July, 1910, 7 and 7.7 g. daily, after a loss of 1.865 kg. or less than 7 per cent. of its total weight. *Echinocactus* No. 7 lost 9 g. daily in 56 days in midwinter of 1908-9, while the rate was 2.3 g. daily for 109 days in the corresponding period of 1909 and 1910, after a loss of 2.653 kg. or 7.5 per cent. of the earlier weight.

The above data were taken from plants kept in the laboratory, in which corresponding seasons would be fairly equalized.

Echinocactus No. 13 lost at the rate of 150 g. daily during 83 days ending May 12, 1910, and 10 g. daily in the 42 days ending March 20, 1911,

after its weight had decreased nearly 50 per cent. This plant was exposed in the open.

An *Ibervillea* tuber lost at the rate of 0.8 g. in May, 1910, and at the rate of but 0.12 g. daily in May, 1911, after the weight had decreased 15 per cent. Green stems were present, and the conditions fairly equivalent in the two periods.

Ibervillea No. 4 lost at the rate of 0.8 g. daily in 15 days ending May 26, 1910, during which time new stems were starting, and at the rate of 0.16 g. daily under equivalent conditions in 1911, after the weight had decreased 15 per cent.

Ibervillea No. 5 lost at the rate of nearly 0.7 g. daily in 15 days ending May 26, 1911, under equivalent conditions, after the weight had decreased 22 per cent.

The green stems were especially vigorous in No. 5, and to their activity must be attributed the excessive total and high rate shown in May, 1911. An inspection of these data shows that a total loss of 15 per cent. in weight was followed by a decrease of 85 per cent. in the rate, a loss of 8 per cent. in weight by a decrease of 80 per cent. in the rate, a loss of 22 per cent. in weight by a decrease of 56 per cent. in the rate, in tubers of *Ibervillea*. The significance of these measurements is partly obscured by the activity of newly developing green stems, but it is evident that the major variation in the transpiratory loss with progressive depletion of the water-balance (which in turgid individuals would be 60–80 per cent. of the total weight) is not to be attributed to climatic variation, or the activities of stems formed, although the influence of the last-named feature is obvious.

The evidence furnished by the individuals of *Echinocactus* free from the influence of factors which would prevent a fair comparison affords some further illustration of the matter.

Echinocactus No. 1 lost water at the rate of 109 g. daily in March, 1908, and at the rate of 3–5 g. daily in March, 1909, a decrease of 50–66 per cent. in rate with a lessening of the water-balance of about 7.7 per cent. The maximum rate in May, 1908, was 29 g. daily, in June, 1909, 15.6 g. daily, a decrease of nearly 47 per cent. in rate with a loss of 7.2 per cent. in weight.

Echinocactus No. 4, which had already been exposed in the open for eight months, lost at the rate of nearly 0.45 g. daily in 182 days ending May 21, 1909. The loss during the 209 days ending May 13, 1910, was at the rate of about 0.24 g. daily, a decrease of nearly 50 per cent. in rate after a total decrease of about 7 per cent. of the earlier weight.

Echinocactus No. 6 lost at the rate of 6 g. daily for 155 days ending May 12, 1909. In 177 days ending May 13, 1910, the rate was 3 g. daily, a decrease of 30 per cent., although the weight had fallen but 4.7 per cent.

The rate was but 2.3 g. in 157 days ending April 10, 1911,

a decrease of 23 per cent. in the rate although the weight had fallen but 3.5 per cent.

Echinocactus No. 13 lost at the rate of 150.5 g. daily in 83 days ending May 12, 1910, and after a decrease of 28.6 per cent. of the remaining weight, the rate was less than 11 g. daily, a decrease of 92.6 per cent.

Five possible causes which might have influenced the rate of transpiration of a desiccating succulent present themselves. These are as follows: 1st, the increased concentration of the cell-sap, which was of such degree in the experiments as to increase osmotic pressures from 4 or 5 to 10 or 12 atmospheres, might retard evaporation from the cell-membranes; 2nd, a diminution of the degree of succulence, or proportion of water per unit area of surface present might lessen evaporation; 3rd, desiccation may result in alterations in the character of the outer membranes, or of any of the transpiring walls of the plant; 4th, desiccation may stimulate the formation of new tissues or the alteration of existing cells in such manner as to close openings through which water vapour might pass; and 5th, the positions of the surfaces might be shifted in such manner as to vary the exposure and lessen transpiration.

Livingston has recently pointed out that a concentration of the sap, even if carried to a point where an osmotic pressure of 100 atmospheres was exhibited, would not give a retardation of more than 10 per cent. from the rate afforded by a pure water surface.¹ It is evident, therefore, that this factor is negligible in the present discussion, as the increases found were not more than 5 or 6 atmospheres.

The records of the observations are not sufficiently complete to permit any accurate integration of the influence of succulence upon the rate of transpiration. The course of events in the behaviour of *Echinocactus* No. 13 shows a fair correspondence between the two in the course of rapid desiccation in the open air. The rate of loss diminishes so much more rapidly than the estimated degree of succulence in slowly desiccating individuals that it is impossible to escape the conclusion that other agencies are operative. Thus, *Echinocactus* No. 1, weighing over 42 kg. in March, 1908, may be safely estimated to have contained at least 92 per cent. or 39 kg. of water, and by comparison with No. 13 would have a relative succulence of 3 and a surface of 13,000 sq. cm. The rate of transpiration was 10 g. daily. A year later the degree of succulence after a loss of 3 kg. may be estimated at 2.76, with no allowance for diminished external area. The rate of loss, however, was 5 g. daily, a decrease of 50 per cent., although the succulence had fallen but 8 per cent. If an allowance were made for the shrinkage of external area, the disproportion would be greater, as the

¹ Livingston, B. E.: The Relation of Osmotic Pressure in Plants of Arid Habitats. *Plant World*, vol. xiv, 1911, p. 153.

actual decrease in succulence was probably not more than 5 per cent. Data from *Echinocactus* No. 6 for longer periods are equally interesting. This plant contained about 27 kg. of water December 8, 1908, and with a succulence of 3 would offer a surface of 9,000 sq. cm. The rate of loss for the 155 days ending May 12, 1909, was 6 g. daily. November 18, 1909, a further loss, 2.335 kg., had ensued and the succulence was then 2.7 daily. In the 178 days to May 13, 1910, the rate of loss was but 2.8 g. daily. The succulence had decreased 10 per cent. and the transpiration rate 53 per cent. The annual growth and consequent accelerated loss in *Ibervillea* makes the data from these plants ineligible in the present connexion.

The approximation of the ridges or folds in *Echinocactus* would operate to diminish the angle of exposure to the sun and the consequent transpiratory loss. A detailed examination of *Echinocactus* has not been made, but the corky outer layer of the tubers of *Ibervillea* is being added to at intervals, and changes of this character would lessen the water loss.

The total losses from various plants in which the course of desiccation was not disturbed is given below :—

Name.	Original weight.	Total loss.	Proportion.	Period.	Remarks.
<i>Echinocactus</i> .					
„ No. 1.	42.743 kg.	4.583 kg.	11%	15 mo.	In shaded room. Died.
„ No. 2.	5.136 kg.	1.724 kg.	33%	18 mo.	Shade and open air. Living.
„ No. 4.	1.192 kg.	0.643 kg.	54%	36 mo.	Died.
„ No. 6.	28.573 kg.	3.713 kg.	13%	30 mo.	Shade. Living.
„ No. 7.	35.818 kg.	4.248 kg.	11%	30 mo.	Shade. Living.
„ No. 13.	49.390 kg.	23.850 kg.	48%	13 mo.	Open. Living.
<i>Carnegiea</i> .					
„ No. 1.	40.000 kg.	11.250 kg.	28%	12 mo.	Open air and shade. Living.
„ No. 1a.	45.325 kg.	10.535 kg.	23%	16 mo.	Open air. Living.
20 seedlings.	27.244 g.	17.745 g.	54.7%	102 da.	Shade. 4 dead.
<i>Brodiaea</i> .					
36 resting corms.	46.700 g.	18.425 g.	39.5%	96 da.	Shade. Young corms formed.
<i>Ibervillea</i> .					
„ No. 0.	530. g.	143. g.	27%	19 mo.	Shade. Sending up shoots annually.
„ No. 4.	1.452 kg.	164. g.	11.5%	14 mo.	Shade. Annual shoots.
„ No. 5.	1.006 kg.	278. g.	27%	14 mo.	Shade. Annual shoots.
<i>Tumamoca</i> .					
Tuber	125. g.	34.4 g.	17.5%	4 mo.	Shade. Died.

No special attention was given to the matter of absorption of water or water vapour by the plants which were used in the experimental work. The results of the weighings, however, disclose the fact that small individuals of *Echinocactus* made a net increase in weight when placed in a dark room with a relative humidity of 80–90 per cent., after removal from a room with a humidity of 15–30 per cent. Other specimens made similar gains when

brought into a shaded room from the open air. Still another specimen showed a distinct gain in the open during a night of drizzling rain. As these plants are provided with a dense armature of long curved spines (see Pl. VII) which are hygroscopic, their dead tissues dry out under arid conditions and appear to take up water or aqueous vapour, as any bit of dry wood might do it. The bases of these spines are made up of heavy-walled tissues through which water might pass with difficulty. It is probable, therefore, that the changes in weight of *Echinocactus* due directly to humidity do not affect the succulence of the living tissues, and concern the dead spines only.

The actual behaviour of the spines with regard to atmospheric moisture was tested in July, 1911. The spines from two ridges of a plant 50 cm. in height were detached and sent to the acclimatization laboratory at Carmel, California. The lot was placed upon a suitable sheet of paraffin paper and found to weigh exactly 20 g., in a sunny place, at noon on July 8. After exposure to the humid air in the open throughout the night, the weight was found to be 20.400 g. at 9.15 a.m. on the 9th, after some drying out had taken place. Desiccation occurred as before and the spines were again placed in the open and sheltered from precipitation, at 7 p.m. on the 10th. The night was foggy and misty and the spines absorbed so much that the weight had increased to 20.745 g. at 7 a.m. on the 11th. The lot of spines was practically equivalent to those clothing *Echinocactus* No. 4, and was about one-tenth of the whole number on the plant from which they were taken. The total weight variation on such a plant due to imbibition and desiccation of the spines might, therefore, be about 7 or 8 g. daily, and on the largest individuals two or three times this amount. The proportion of weight variation due to such causes would be large in small plants.

The conditions presented are different from those studied by Spalding,¹ Schönland,² and Marloth.³ Marloth³ detected positive absorption of water and water vapour by the hairs of *Mesembryanthemum* and *Crassula*, and the structure of one type of trichome in the younger stage is such as to permit the passage of water into the living cells. Lloyd found that water absorbed by the loose bark of *Fouquieria* passed into the living tissues, and that the consequent increase of the water-balance was followed by the unfolding of new leaves in stems, quiescent at the beginning of the experiment.⁴ Miss Delf demonstrated that water in liquid form as well as a vapour might pass the epidermis of the green parts of *Suaeda maritima* and *Sal-*

cornia annua, when the water-balance was low, and that absorption through immersed surfaces was exhibited by many plants.¹

Purpose and adaptation may be easily read into such action. This kind of an interpretation seems forced, however, when it is considered that a capacity for absorption depends upon physical qualities, the primary significance of which relates wholly to other features of the activity of the plant.

MACDOUGAL—DESERT PLANTS

The Weeds of Arable Land in relation to the Soils on which they grow. II.

BY

WINIFRED E. BRENCHELEY, D.Sc., F.L.S.

Lawes Agricultural Trust, Rothamsted.

DURING the season of 1910 an investigation was carried on in certain parts of Bedfordshire to determine the relation between the weeds of arable land, the crop grown, and the soils upon which they grow.

It was recognized at the outset that the results must be regarded as tentative in nature until confirmatory evidence was obtained from similar work carried out in other parts of the country, on soils both of the same and different geological derivation. Consequently in 1911 the field of investigation was transferred to certain parts of Wiltshire and Somerset, to districts round Warminster (Upper Greensand), Shrewton (Chalk), and Bath (Clay). In that part of the country a large number of geological formations crop out within a comparatively short distance, but attention was confined to two or three main types of soil.

In the area investigated no sand was available to compare with the Lower Greensand of Bedfordshire, the soils of the Upper Greensand being generally rather heavy. In place of the Oxford and Gault clays (here only represented by pasture), which are non-calcareous in nature, the calcareous clays of the Oolite and Lias series came under consideration.

The working plan adopted was the same as in 1910; the areas were characterized by the comparative absence of hedges, which greatly facilitated the work.

The relative prevalence of the weeds was again noted as:—

- (1) Dominant.
- (2) Sub-dominant.
- (3) Distributed.
- (4) Occasional.
- (5) Scarce or rare.

During the season's survey 106 species of weeds were met with, representing 74 genera. Of these 29 species, representative of 26 genera, were

each seen once or twice only. As in the previous investigation, attention was confined to those weeds growing in among the crop, the weeds of the surrounding hedgerows being left out of consideration. The classification of the soils did not present so much difficulty as in the case of the Bedfordshire work. The areas dealt with were much larger, and adjoining fields did not show the sudden change in the nature of the soil that occurred so frequently in the eastern county. In the chalk areas rather more subdivision had to be made this year. The presence or absence of lime in the various soils was frequently tested for with dilute hydrochloric acid.

The seasons in the two years of investigation were of totally different character, that of 1910 being wet and cold, with a deficiency of sunshine, while that of 1911 was characterized by an excessive amount of sunshine and by high temperatures, coupled with a low rainfall, so that conditions of drought prevailed. This radical difference may have influenced the relative occurrence of certain species, so that it is quite probable that some of the diversity in results may be due to seasonal variation rather than to the actual differences in the nature of the soil.

The chief species of weeds, with their habitats and dominance, were as follows :—

Ranunculaceae. *Ranunculus acris*. Found on clay and sand. Absent from chalk. Never dominant.

Ranunculus arvensis. Chiefly found on clay, once on chalk. Never dominant. (Rarely seen in this district; far less frequent than in Bedfordshire.)

Ranunculus repens. Most frequent on chalky soils; also seen on clay containing a fair proportion of lime. (N.B.—It is possible that in the Bedfordshire districts *R. repens* occurred in some instances, but was not separated from *R. acris*.) Never dominant.

Papaveraceae. *Papaver hybridum*. Only occasionally seen, then on chalky soil. Never dominant.

Papaver Rhoeas. Characteristic of chalky soils; hardly seen elsewhere. Occasionally dominant. (Many observations of poppies were made when the plants were too small to permit the species to be identified. These usually occurred on chalky soils, with one record (dominant) from sand.)

Fumariaceae. *Fumaria officinalis*. Chiefly on chalky soils, but fairly frequent on loam. Several records from clay, but then it was usually occasional or scarce in distribution. Occasionally dominant on chalk or loam.

Cruciferae. *Brassica alba*. Practically confined to chalk and brashy loam (limestone). Frequently dominant; one instance of dominance on clay, which proved to contain much limestone.

Brassica Sinapis. Chiefly on chalk and red land; also much on clay

and loam. No record from ordinary sand. Frequently dominant on all types of soil, including 'bake'. (This plant is perhaps more widely distributed in area than in Bedfordshire, but as it is not so abundant in quantity in the West Country, it is consequently less in evidence.)

Capsella Bursa-pastoris. Practically confined to clay and loam. Never dominant.

Resedaceae. *Reseda lutea*. Characteristic of chalk, but only occurring in very small quantity.

Violaceae. *Viola tricolor*. Practically confined to chalky soils. Very rare on clay. Never dominant.

Caryophyllaceae. *Arenaria serpyllifolia*. Occasionally found, usually on chalky soils. Never dominant.

Cerastium vulgatum. Distributed on various types of soil, but seldom seen and never very prevalent.

Lychnis Githago. Confined to chalk. Once dominant.

Lychnis vespertina. Chiefly on chalky soils, sometimes on clay and loam. Of frequent occurrence as an occasional or scarce weed.

Silene Cucubalus. Chiefly on chalky soils ; occasionally on clay, where it was once dominant.

Stellaria media. Universally distributed. Occasionally dominant on any soil.

Rosaceae. *Potentilla anserina*. Occasionally seen on chalky soils and clay. Once dominant on chalk.

Umbelliferae. *Daucus Carota*. Generally found on pure chalk, sometimes on chalky loam. Never dominant, usually only occasional.

Heracleum Sphondylium. Characteristic of chalky soils. Never dominant.

Scandix Pecten. Characteristic of chalky soils. Very occasional elsewhere. Once dominant on red land.

Rubiaceae. *Galium Aparine*. Generally distributed. Rarely dominant or sub-dominant, though of very frequent occurrence.

Sherardia arvensis. Rarely seen, but then chiefly on chalk in very small quantities.

Valerianeae. *Valerianella olitoria*. Confined to chalk. Rarely seen.

Dipsaceae. *Scabiosa arvensis*. Characteristic of chalk soils. Never dominant.

Compositae. *Anthemis sp.* Chiefly on clay or loam, but distributed over other soils. Once dominant on clay.

Carduus arvensis. Universally distributed and very common. Dominant on any soil.

Centaurea nigra. Chiefly found on chalk and red land ; only occasionally recorded from other soils. Never dominant.

Senecio vulgaris. Universally distributed, but by no means so frequent in occurrence as in Bedfordshire. Never dominant.

Sonchus arvensis. Generally distributed, but chiefly on chalk and clay. Frequently dominant on chalk, also dominant on clay and sand.

Taraxacum dens-leonis. Recorded most frequently from chalky soils, but also occurs on all other types. Never dominant.

Tussilago Farfara. Chiefly on clay, but frequent on other soils. Dominant on clay and chalk.

Primulaceae. *Anagallis arvensis*. Distributed over various types of soil but rarely in any quantity. It does not seem to appreciate chalky soils. Never dominant; once sub-dominant on 'bake'.

Convolvulaceae. *Convolvulus arvensis*. Universally distributed as to soil and dominant anywhere. One of the most commonly occurring weeds.

Boraginaceae. *Lithospermum arvense*. Characteristic of chalky soils. Never dominant.

Myosotis arvensis. Confined to chalky soils. Never dominant.

Orobanchaceae. *Orobanche minor*. Only recorded from one district on chalky soils. Never dominant.

Scrophulariaceae. *Bartsia Odontites*. Practically confined to chalky soils; very occasional on clay. Never dominant.

Linaria spuria. Occasionally recorded from the lighter soils—loam and red land. Never dominant.

Linaria vulgaris. Characteristic of chalky soils. Never dominant.

Veronica agrestis. Found on all types of soil. Never dominant.

Veronica hederæfolia. Recorded from all types of soil, but only dominant in one place, on chalk.

Labiatae. *Mentha arvensis*. Chiefly found on clay soils; probably characteristic of heavy land. Never dominant, once sub-dominant on clay.

Plantagineae. *Plantago lanceolata*. Practically confined to chalky soils. Never dominant.

Plantago major. Recorded from all types of land, but chiefly found on clay and chalky soils. Never dominant.

Plantago media. Confined to clay; never seen on chalk. Never dominant.

Illecebraceae. *Sceleranthus annuus*. Only seen on 'bake'.

Chenopodiaceae. *Chenopodium album*. Universally distributed both as to soil and dominance.

Polygonaceae. *Polygonum aviculare*. Chiefly found on chalk and clay. Often dominant on both types.

Polygonum Convolvulus. Chiefly on clay and chalky soils. Never dominant.

Rumex Acetosella. Only seen on 'bake'. (Characteristic of acid sandy soils.)

Rumex crispus. Most frequent on chalky soils, but often seen on clay and other types of land. Occasionally dominant on sand and red land.

Euphorbiaceae. *Euphorbia exigua*. Chiefly on clay, but frequent on other soils. Never dominant, but occasionally sub-dominant on clay.

Euphorbia Helioscopia. Fairly well distributed, but most frequent on chalky soils and loam. Never dominant, usually only occasional or scarce.

Liliaceae. *Ornithogalum pyrenaicum*. Characteristic of heavy clay soils in the Bath district. Rare.

Gramineae. *Alopecurus agrestis*. Occurred on various types of soil. Occasionally dominant on chalk.

Arrhenatherum avenaceum var. *tuberosum*. Distributed as to soil. Once dominant on 'black gravel'.

Bromus arvensis and *B. sterilis*. Very seldom seen, then only on chalk.

Lolium perenne. Only on chalk and clay. Never dominant.

Poa annua. Chiefly on clay, but also found on other soils. Never dominant.

Poa pratensis. Only recorded from chalk. Once dominant.

Poa trivialis. Universal in distribution. Once dominant on clay.

Triticum repens. Universal in distribution. Dominant on heavy land.

Equisetaceae. *Equisetum arvense*. Universally distributed as to soil, but not very frequent in occurrence. Once dominant on clay.

Analyses of the data have been made showing the distribution of the various weeds on the different soils. It must be remembered that a weed that is 'absent' from any particular soil may occur in isolated instances in that very habitat, in which case it is usually only occasional or very rare in distribution.

A. Clay and Heavy Brashy Soils.

In the districts round Inglescombe and Inglesbatch, near Bath, the land is of an exceptionally heavy nature, being a very sticky clay, which needs special care and methods to farm it properly. During the hot weather it bakes very badly and opens out into deep cracks. This soil is derived from three geological formations which crop out in succession up the hillsides, and it is characteristically calcareous on account of the limestone which occurs with it, in contradistinction to the non-calcareous clays worked in Bedfordshire.

1. Inferior Oolite; soil very reddish in colour and generally brashy in nature. Contains much limestone.

2. Fuller's earth; an argillaceous deposit between 1 and 3. Below the surface this appears as a very sticky yellow clay.

3. Bath or Great Oolite; clay and limestone.

In the Wilmington district, on the further side of the valley from the above, the soil is derived from—

1. Lower Lias; clay and limestone.

2. Inferior Oolite.

[In both these districts there is an outcrop of the Midford Sands, but this is generally either wooded or under pasture, and so does not affect the investigation in hand.]

The derivation of the soils does not appear to affect the varieties of plants occurring, as the different species of clay weeds were found indiscriminately on land derived from all the four geological formations, all being calcareous in nature.

The number of species occurring was relatively less than those found on chalky soils, and the majority of the plants were such as occurred on any type of soil, hardly one appearing to be *symptomatic* of clay. A very few species, however, were chiefly associated with clay, though occurring on other types of soil as well, and one, *Plantago media*, appears to be confined to clay in this district.

Plantago media—practically confined to clay.

Capsella Bursa-pastoris—also recorded from loam.

Mentha arvensis

Poa annua

Ranunculus arvensis

Tussilago Farfara

} chiefly found on clay, but also
seen on other soils.

Ranunculus acris—also on sand.

Brassica alba

Euphorbia exigua

Plantago major

Polygonum aviculare

„ *Convolvulus*

Potentilla anserina

} also on chalk.

B. Chalk.

The chalk districts investigated were chiefly on the Wiltshire Downs in the neighbourhood of Shrewton and Stonehenge, a radius of some four miles being worked. Data were also obtained from the chalk at Heytesbury and Sutton Veny, not far from Warminster. The whole of the soils were derived from the chalk formation, though for convenience of working and classification they were subdivided into—

(a) *Chalk*, where the soil was white or very light in colour.

(b) *Red Land*, lying above (a), rather darker in colour and perhaps a little heavier in texture.

(c) *Chalky loam*, very light calcareous soil, but slightly heavier than the above.

The noticeable feature of the weed flora is the large number of species occurring, many of which are essentially characteristic or even symptomatic of chalk. In both these respects the flora is in marked contrast to that of the clay soils.

Bromus arvensis	}	confined to chalky soil.
„ sterilis		
Campanula hybrida		
Daucus Carota		
Linaria spuria		
„ vulgaris		
Lychnis Githago		
Myosotis arvensis		
Poa pratensis		
Reseda lutea		
Centaurea nigra	}	very characteristic of chalk, but occasionally seen on other soils.
Heracleum Sphondylium		
Lithospermum arvense		
Papaver Rhoeas		
Plantago lanceolata		
Scabiosa arvensis		
Scandix Pecten		
Sherardia arvensis		
Viola tricolor		
Arenaria serpyllifolia	}	chiefly on chalk, sometimes on clay.
Bartsia Odontites		
Brassica Sinapis		
Fumaria officinalis		
Lychnis vespertina		
Papaver sp.		
Ranunculus repens		
Silene Cucubalus		
Brassica alba	}	equally abundant on clay.
Euphorbia exigua		
Plantago major		
Polygonum aviculare		
„ Convolvulus		
Potentilla anserina		

C. 'Bake.'

This is a thin layer of soil, often only a few inches thick, overlying the chalk on the top of some of the Downs. Instead of being calcareous, this layer is destitute of lime, and is indeed sandy and acid in nature, of a red colour. The local theory is that for some reason or other the lime has been entirely washed out from the soil and carried down, leaving a non-calcareous residue. The peculiar nature of the soil is reflected in the flora, the abrupt change from the typical chalk flora being quite startling in its suddenness. Unfortunately very little of the land was accessible. The number of species was relatively few, and the quantity of weed was comparatively scanty.

The actual weed flora may prove of interest :

Brassica Sinapis	} dominant in places.
Geranium sp. ¹	
Scleranthus annuus	
Anagallis arvensis	—sub-dominant or distributed.
Carduus arvensis	} occasional.
Rumex Acetosella	
Poa trivialis	} scarce.
Scandix Pecten	
Spergula arvensis	

The presence of *Rumex Acetosella* and *Spergula arvensis* is most significant, as these are unfailing indicators of an acid soil. The prevalence of *Anagallis arvensis* is also noteworthy, as on the chalky soil very few plants of this species are to be seen.

While so many species are more or less definitely associated with particular soils, others are universally distributed, and occur on various types of soil, on any of which they may be dominant. A few plants, while universal, are more particularly associated with chalk.

Weeds of universal occurrence.

Alopecurus agrestis	Galium aparine
Anthemis arvensis	Lolium perenne
„ cotula	Poa trivialis
Arrhenatherum avenaceum var.	Senecio vulgaris
tuberosum	Sonchus arvensis
Carduus arvensis	Stellaria media

COMPARISON OF THE WEED FLORA OF THE WILTSHIRE AND SOMERSET
DISTRICTS WITH THAT OF EAST BEDFORDSHIRE.

A. Weeds of clay soils.

The general aspects of the weed floras are fairly comparable, both as regards the distribution and variety of the species. Certain differences are however evident, of which the following are the most striking :

	<i>Bedfordshire.</i>	<i>West Country Districts.</i>
<i>Bartsia Odontites</i>	Typical and practically confined to clay. Never seen on chalk	Chiefly on chalk ; scarce on clay
<i>Matricaria inodora</i>	Very plentiful	Totally absent
<i>Plantago media</i>	Scarce ; distributed on various soils	Fairly frequent ; practically confined to clay
<i>Capsella Bursa-pastoris</i>	Scarce on clay	Chiefly on clay
<i>Tussilago Farfara</i>	Universal in distribution	Chiefly on clay
<i>Euphorbia exigua</i>	Scarce ; only one record on clay	Frequent ; chiefly on clay

B. Weeds of chalk soils.

The West Country chalk soils exhibit many species of plants, of which a large proportion are definitely characteristic of the chalk. The Bedfordshire soils, on the contrary, have relatively few distinct chalk weeds, of which still less can be called definitely characteristic.

	<i>Bedfordshire.</i>	<i>West Country Districts.</i>
<i>Lychnis Githago</i>	No record	Confined to chalk
<i>Silene Cucubalus</i>	Symptomatic of chalk	Also occurred on clay
<i>Campanula hybrida</i>	One record ; sand and clay	Symptomatic
<i>Linaria spuria</i>	„ „ heavy clay	„
„ <i>vulgaris</i>	„ „ chalk and clay	„
<i>Myosotis arvensis</i>	Universal in distribution	„

	Bedfordshire.	West Country Districts.
<i>Poa pratensis</i>	One record; gravelly loam	Symptomatic
<i>Daucus Carota</i>	„ „ on chalk	„
<i>Reseda lutea</i>	„ „ „	„
<i>Chenopodium album</i>	No record from chalk	Frequent on chalk
<i>Heracleum Sphondylium</i>	Not recorded	Very characteristic of chalk
<i>Lithospermum arvense</i>	„ „	„ „ „
<i>Papaver Rhoeas</i>	Seldom recorded from chalk	„ „ and frequent
<i>Plantago lanceolata</i>	Universally distributed	Characteristic of chalk
„ major	Scarce	Frequent on chalk
<i>Scandix Pecten</i>	Universally distributed	Characteristic of chalk
<i>Euphorbia exigua</i>	Designated as 'Calcifuge'	Frequent on chalk
„ <i>Helioscopia</i>	„ „ „	„ „ „
<i>Potentilla anserina</i>	No record on chalk	Occasionally seen on chalk

C. 'Calcifuges.'

Of the various so-called 'Calcifuges' of the Bedfordshire districts *Poa annua* is the only species which retains that character in the West Country. All the others are more or less associated with chalk.

Bedfordshire Calcifuges.

Occurrence in West Country.

<i>Alopecurus agrestis</i>	Recorded several times on chalk; dominant in one field.
<i>Anagallis arvensis</i>	Frequently recorded from chalk, but usually very scanty.
<i>Euphorbia exigua</i>	Frequent on chalk. ¹
„ <i>Helioscopia</i>	„ „ „
„ <i>peplus</i>	„ „ „
<i>Veronica arvensis</i>	Only three records, but all from chalk.
„ <i>hederaefolia</i>	Several records from chalk, with one of dominance.

¹ In Bedfordshire all species of *Euphorbia* are apparently absent from chalk, while certain of the species are frequent in that habitat in the West Country. It has been criticized that 'it is therefore a mistake to call them "calcifuge", as it can only mean that there is some other factor, commonly present with chalk in Bedfordshire, which determines absence'. Strictly, this criticism is quite just, but for the purpose of this investigation the word 'calcifuge' is used in a restricted local sense, in default of a better term, to indicate the absence of any species from chalk soils in a particular locality. Future work will probably sort out the true calcifuges from the local calcifuges.

An examination of the above analyses and of the available data shows:—

1. Many of the differences between the two floras are simply differences in quantity, which change the balance of the distribution of the weeds on the different types of soil.
2. Several plants which occur on various soils in Bedfordshire are definitely associated with chalk soils alone in the West Country.
3. Other plants which are calcifuges in Bedfordshire are more or less frequently observed on chalk in the West.
4. A few weeds are recorded from each district which are totally absent from the other. The number of such species, though, is far less than might have been expected, considering the distance between the two localities, involving some difference in climate and in soil.

Points of Interest.

1. While the association of particular weeds with certain soils is so well marked, the correlation between the weeds and the crops with which they occur is much less definite. The great majority of species occur indiscriminately with any kind of crop, whether cereals, roots, or 'seeds', the nature of the soil being the determining factor of their occurrence. Still, a few plants do show some correlation with the crop, and to a large extent the West Country results tally with those of Bedfordshire in this respect. The 'seed' crops were chiefly clover, vetches, and a mixture of Italian ryegrass and clover. A very few species were almost entirely confined to such crops, but a larger variety of plants were noticeable on account of their rarity or absence among seeds. Also a very few plants were exclusively associated with cereals.

Weeds only associated with cereal crops.

<i>Campanula hybrida</i>	<i>Poa trivialis</i>
<i>Lamium amplexicaule</i>	<i>Potentilla reptans</i>
<i>Lapsana communis</i>	<i>Ranunculus arvensis</i>

Weeds only associated with seed crops.

<i>Arenaria serpyllifolia</i>	<i>Geranium dissectum</i>
<i>Cerastium vulgatum</i>	„ <i>molle</i>
<i>Geranium columbinum</i>	<i>Sherardia arvensis</i>

Weeds absent or very rare in seed crops.

<i>Arrhenatherum avenaceum</i> var.	<i>Plantago media</i>
<i>tuberosum</i>	<i>Poa annua</i> (though once dominant among seeds)
<i>Heracleum Sphondylium</i>	
<i>Lolium perenne</i>	<i>Triticum repens</i>
<i>Mentha arvensis</i>	<i>Veronica hederaefolia</i>

A number of species which were absent from seed crops in Bedfordshire frequently occurred in association with them in the West Country. This may partly be due to the fact that a large proportion of the clover and rye-grass crops had only recently been seeded, and had made little growth owing to the long drought. In consequence the weeds had not suffered so much from the overshadowing effect of the leafy crop. Under the circumstances the occurrence of such weeds in conjunction with seed crops lends support to the hypothesis that their absence, when it occurs, is due to the starvation of light or air by the crop rather than to any inherent antagonism between the two plants, weed and crop. It is noticeable that the number of absentee species in the West Country records is only nine, as against twenty-one in the Bedfordshire lists.

2. *Couch or Twitch* was frequently noted as a troublesome weed, but as a general rule only two species were designated as such, instead of the half-dozen met with in other places.

(a) *Triticum repens*—the true Couch.

(b) *Arrhenatherum avenaceum* var. *tuberosum*—the 'Onion Couch', or 'Knotty Couch'. This is one of the worst of weeds when it occurs in any quantity, as it easily spreads and is most difficult to eradicate on account of its swollen tuberous stems, each joint of which will develop into an independent plant if detached.

3. In one instance the most pestilent weed was *Avena fatua* or Wild Oat, which existed side by side with the 'Onion Couch'. This weed is particularly troublesome, as

(a) it spoils the crop ;

(b) it spoils the sample of corn ;

(c) it gets into the thrashing-machine parts and clings together by its hairs until it blocks every outlet.

4. *Equisetum* and *Coltsfoot* did not occur in company so frequently as they did in Bedfordshire. The Coltsfoot was more often associated with clay soils, but as before the distribution of both weeds was general. It has been suggested that the presence of Coltsfoot is an indication of the nearness of underground water, and that the plants can only thrive if they can send down their long roots to tap it. This idea, however, needs confirmation.

5. Two plants are totally different in their habitat in the two districts :

(a) *Bartsia Odontites*, which is a clay weed and calcifuge in Bedfordshire, is practically absent from clay and is very frequent on chalk in the West.

(b) *Chenopodium album*, which is never recorded from chalk in Bedfordshire, is noted more frequently from that habitat than from any other in the West.

6. *Rhinanthus Crista-galli*, Yellow Rattle, was very prevalent in some places in the West. Generally this is a weed of pasture land, but in one case observed the barley crop was full of it and was utterly ruined by it. Some seasons are far more favourable to the growth of this weed than others, though in both 1910 and 1911 large quantities have occurred in this particular district.

7. The total absence of Mayweed, *Matricaria inodora*, was very noticeable. A small amount of *Anthemis* sp. occurred in places, but the plants rarely attained any size, and so a very conspicuous feature in the weed flora of Bedfordshire was missing in that of the West Country, on similar soils.

8. Where two or more species of the same genus occur as weeds, it frequently happens that the species differ among themselves in their distribution, being associated with different types of soil ; e.g.—

<i>Euphorbia exigua</i>	chiefly on clay
„ <i>Helioscopia</i>	„ „ chalk
<i>Plantago lanceolata</i>	chalk only
„ major	chalk and clay
„ media	clay only
<i>Poa annua</i>	chiefly on clay
„ <i>pratensis</i>	chalk
„ <i>trivialis</i>	distributed
<i>Ranunculus acris</i>	clay and sand
„ <i>arvensis</i>	clay
„ <i>repens</i>	chiefly on chalk
<i>Rumex Acetosella</i>	acid sandy soil
„ <i>crispus</i>	chiefly on chalk

SUMMARY.

1. In each district investigated a definite association exists between the species of weed plants and the soil on which they grow. This association may be either—

(a) *Local*. When a weed is symptomatic of a certain soil in one district but is not so exclusively associated with it in another.

(b) *General*. When a certain species is symptomatic or characteristic of the same type of soil in different districts.

2. In most cases there is no association between the weed and the crop, though a few species do show a relationship. The weeds usually found in 'seed' crops appear to be constant, and certain other plants exhibit

the same association with particular types of crop in Bedfordshire and in the West Country.

3. The relative prevalence of the weeds varies somewhat in the different districts, certain species which are more or less common in one place being practically absent or very scarce in another, on similar soils.

In conclusion I wish to tender my thanks to Mr. E. S. Beaven, who has given me every possible assistance, both by putting me into touch with various farmers, and by the personal interest that he has taken in the work, together with much friendly advice and criticism. Also I must express my indebtedness to all those whose land came under investigation, for their unfailing kindness and readiness to facilitate the work.

The Root-nodules of *Myrica Gale*.

BY

W. B. BOTTOMLEY, M.A.

Professor of Botany in King's College, London.

With Plates **XI** and **XII**.

THE discovery by Hellriegel and Wilfarth in 1886, that the root-nodules of leguminous plants are able to assimilate atmospheric nitrogen by means of the Bacteria present in the cortical cells, directed attention to the possibility of certain non-leguminous root-nodules having a similar function. The earlier observers failing to demonstrate the presence of Bacteria in the nodules they investigated, but finding the nodules, especially the older ones, filled with hypha-like threads, considered them instances of 'Wurzelsymbiosen' caused by mycorrhizal filaments.

In 1896 Hiltner demonstrated the presence of Bacteria in the root-nodules of Alder and *Elaeagnus*, and showed that young Alder plants without nodules would not thrive in a nitrogen-free soil. When, however, these starved plants were inoculated with organisms from Alder tubercles, nodules were produced and growth was normal. He also demonstrated that the poorer the soil in available nitrogen, the greater is the number of root-nodules developed on the Alder roots, provided the necessary organisms are in the soil. Hence under conditions of nitrogen deficiency the number of nodules on the roots becomes a measure of the nitrogen assimilating activities of the plant.

In 1899 Nobbe and Hiltner reported that the root-nodules of *Podocarpus* were active agents in the assimilation of nitrogen. A *Podocarpus* plant possessing root-nodules was grown for five years in nitrogen-free sand, thriving well during the whole period.

In 1907 the author demonstrated the presence of nitrogen-fixing organisms in the root-nodules of *Cycas*.

Hitherto, these four groups of non-leguminous plants—Alder, *Elaeagnaceae*, *Podocarpus*, and *Cycadaceae*—have been the only ones recognized as possessing root-nodules concerned with the assimilation of atmospheric nitrogen.

MYRICA GALE.

The peculiar nodule formations on the roots of *Myrica Gale* were first described and figured by Brunchorst in 1886. He states that the nodules are caused by an endotrophic fungus with septate hyphae and terminal spores, and considered them simply disease formations.

Möller in 1889 confirmed Brunchorst's observations, and, without adequate reasons, placed the fungus in the group *Frankia*, naming it *Frankia Brunchorstii*, considering it to be closely related to a similar fungus said to occur in Alder nodules.

Marshall Ward in 1889 mentions *Myrica* nodules as possible instances of symbiosis as yet unexplained.

Tubeuf in 1896 speaks of the Mycodomatia of *Myrica*. He says the nodules 'may increase to very large tubers with surfaces resembling a bunch of grapes. In the large cells of the middle layers of the primary root-cortex of these growths, coils of very fine fungus-threads are sheltered; these extend year after year into the younger parts of the enlarging tubercles, and gradually disappear in the older parts. What may be the significance of these structures for plants possessing chlorophyll and furnished with normal roots is as yet unknown.'

In 1902 Shibata stated that the inhabiting fungus is found exclusively in a peripheral sub-cork layer of parenchymatous tissue one to three cells thick, whilst the remaining parenchymatous cells of the rind are filled with starch bodies. Because of the peculiar ray branching of the fungus and its club-shaped spores he considered it to belong to the group *Actinomyces*.

Peklo in 1910, working on material from plants grown in a greenhouse, supported Shibata's views.

External Structure of the Nodules.

For the purpose of this investigation root-nodules of *Myrica Gale* were obtained from plants growing wild in Wales, Ireland, and the North of England, and from cultivated plants in the Chelsea Physic Gardens. The roots of all the plants were found to possess nodules of varying sizes. The young nodules (Pl. XI, Fig. 1) are visible first as tiny swellings on the sides of the roots. These grow until they are from 2–3 mm. long and 0.8–1 mm. broad. In this stage they resemble the single nodules found on *Vicia sativa*. This primary nodule then ceases to clongate, but from the distal end a thin hair-like rootlet grows out, and around this rootlet, from the body of the primary nodule, three secondary nodules arise. These secondary nodules grow to the size of the primary nodule and then each again gives rise to a rootlet and three tertiary nodules. These again repeat the process until by repeated branching the characteristic 'cluster' nodules (Fig. 2), with their fringe of radiating rootlets, are formed. When the branches become

closely crowded together sometimes only two branches arise from the end of the nodule, instead of the normal three, owing to lack of space for development.

The branching is apparently associated with the outgrowth of lateral roots, and is not due to dichotomy of the apical meristem of the nodule as in the case of the branched nodules of Alder, *Elacagnus*, and *Cycas*.

Internal Structure of the Nodule.

A transverse section of a single nodule (Fig. 3) shows a central tetrarch stele like that of the normal root, and indicates that the nodule itself is a modified root. The stele is surrounded by an endodermis characterized by neither radial dot nor thickened walls, but by the cells being filled with oil drops. Outside the endodermis are several layers of cortical parenchymatous cells covered on the outside by a definite small-celled cork layer. In mature nodules this cortical tissue is characterized by the presence of (1) somewhat enlarged cells filled with Bacteria, (2) cells filled with oil drops. In sections cut from material fixed in alcohol and stained with Kiskalt's amyl-gram stain the Bacteria can be seen *in situ* in the enlarged cells as small rods. In transverse sections cut near the apex of the nodules zoogloca threads of Bacteria are seen passing from cell to cell. These are comparable to the 'infection threads' seen in leguminous nodules.

In a median longitudinal section of a nodule (Pl. XII, Fig. 6) four fairly well defined areas can be distinguished :

1. *Meristem zone*. An apical mass of meristematic cells beneath the outer protective cork layer. This crowns the end of the stele and extends some distance down the sides (Figs. 4, 5, 6, *m.*).

2. *Infection zone*. A zone of cells in which the infection threads are seen passing from cell to cell. In a young nodule some of the cells contain starch grains (Fig. 8).

3. *Bacterial zone*. This area includes the bulk of the cortical tissue of the nodule and consists of parenchymatous cells. The majority of the cells are enlarged and crowded with Bacteria. Amongst these are scattered cells containing reserve food material in the form of oil drops (Fig. 3, 4, 5, 6, *b.* and *o.*).

4. *The basal zone*. In this region the bacterial cells are few in number, and in fully matured nodules are quite absent, but the oil-containing cells are numerous.

As the individual nodule matures and branches, the seat of bacterial activity is transferred to the branch nodules, and the Bacteria gradually disappear from the bacterial zone.

True fungal hyphae are often found ramifying through the cells of the basal zone, and in the old nodules they may sometimes be seen filling the majority of the cortical cells. These fungal hyphae were considered by the

earlier investigators of *Myrica* to be the cause of the formation of the nodules. This view, though now seen to be erroneous, was quite natural before the bacterial nature of the nodule was demonstrated, and it is possible that these hyphae, whilst not the cause of nodule formation, may be of a mycorrhizal nature and benefit the *Myrica* plant.

Origin of the Nodules.

The nodules evidently arise as modifications of lateral roots. The method of infection has not yet been observed, but it is presumably similar to that of leguminous plants. The Bacteria enter a root-hair and pass into the cortical cells as an 'infection thread'. It is possible that the presence of these Bacteria in the cortical cells stimulates the stele to produce a lateral branch at this point, for every nodule possesses a well-defined tetrarch stele. The cortical cells become enlarged by the growth of the infecting Bacteria, and a short swollen nodule is formed instead of a typical lateral root.

The tip of the nodule is rounded and does not possess a root-cap, for the stele of the lateral root does not break through the surrounding cortex until later.

When the nodule has reached its mature size further expansion ceases, but the stele, which up to this stage has remained completely within the nodule, ending a short distance below the apex, now grows on and out through the apex, and forms a thin hair-like rootlet (Fig. 6, *r.*) with a typical tetrarch stele (Fig. 7) surrounded by a few layers of cortical cells, but possessing no definite root-cap.

Around the rootlet three secondary nodules or branches arise from the primary nodule in a similar manner to the formation of the primary nodule from the root. These secondary nodules repeat the growth and branching of the primary nodule, a rootlet and three tertiary nodules arising from each. By repeated branching in this manner the peculiar 'cluster' nodules are produced.

Bacteria—Isolation and Cultivation.

Small nodules were removed from the roots and sterilized by being placed for two minutes in the sterilizing fluid used by Harrison and Barlow in their investigations on leguminous nodules. This fluid consists of hydrochloric acid 2.5 c.c., mercuric chloride crystals 1 grm., distilled water 500 c.c. After removal and washing in distilled water one of the nodules was crushed on a slide. The exuded matter adhering to the slide was then air-dried under sterile conditions and stained with Ziel's carbol fuchsin. On microscopic examination numerous small rod-shaped Bacteria were seen. These were evidently similar to *Pseudomonas radicola*, the organism found in the root-nodules of the Leguminosae. They further showed the characteristic staining reaction with Kiskalt's amylo-gram stain, the aniline gentian

violet being removed by ethyl alcohol, but retained when treated with amy alcohol. Harrison and Barlow consider this a special differentiating stain for *Pseudomonas radiculicola*.

Pure cultures were also obtained by plating out some of the expressed matter from a sterilized nodule on to nutrient agar plates.

The nutrient material consisted of maltose 1 grm., potassium phosphate 0.5 grm., magnesium sulphate 0.02 grm., ammonium phosphate 0.5 grm., agar 1 grm., and 100 c.c. distilled water.

The inoculated plates, after incubation for two days at 28° C., showed numerous colonies which were round to lenticular in shape, raised, entire, viscous, and 0.75 to 1 mm. in diameter. These colonies corresponded in all respects to the characteristic colonies of *Pseudomonas radiculicola*. Microscopic examination of the colonies showed the typical rod-shaped Bacteria.

Estimation of Nitrogen Fixation by the Bacteria.

Cultures of the Bacteria were made in Erlenmeyer flasks of 300 c.c. capacity containing a nutrient solution consisting of 100 c.c. distilled water, 1 grm. maltose, 0.5 grm. potassium phosphate, and 0.02 grm. magnesium sulphate. Some of the flasks were inoculated with a loop from the colonies on a nutrient agar plate; others were left uninoculated and formed controls. All the flasks were incubated at 25° C. for seven days. During this time the contents of the uninoculated flasks remained clear, but the inoculated flasks became cloudy.

Kjeldahl nitrogen determinations of the contents of the flasks gave the following average results:

Control flasks	.	.	.	0.53 mg. N per 100 c.c.
Inoculated flasks	.	.	.	2.58 " "

showing a fixation of nitrogen of 2.05 mg. per 100 c.c. of culture.

Effect of Nodules on Growth of *Myrica* Plants.

To ascertain the effect of the presence of nodules on the growth of *Myrica* plants attempts were first made to strike *Myrica* cuttings in sand watered with nutrient solution, but all ended in failure.

Excellent results were, however, obtained with young *Myrica* plants procured from Heysham Moss last spring. Some of these plants possessed small nodules on their roots; others appeared to be quite devoid of nodules. Six of each were planted out in a greenhouse, in pots containing sterilized soil deficient in nitrogen. All the plants with nodules flourished well. Of the six plants without nodules, two made no growth for some time, but afterwards began to shoot. On examining their roots a few nodules were found. Evidently these were already infected with Bacteria, but the nodules had been too small to see, when they were planted out. The remaining

four made no fresh growth, and after a time showed evident signs of starvation. At this stage two of these starved plants were watered twice, at an interval of seven days, with a liquid culture of *Myrica* nodule organisms. Soon these plants commenced active growth, and caught up and surpassed the two plants possessing root-nodules. By the end of the summer they were larger than any of the *Myrica* plants in the greenhouse. The two starved plants, which were not inoculated, lingered on for a time and were quite dead by the end of June.

It is evident from these results that the root-nodules of *Myrica* are definitely concerned with nitrogen assimilation, and the Bacteria in the bacterial zone of the nodule are the active agents in nitrogen fixation.

SUMMARY.

1. The root-nodules of *Myrica Gale* are modified lateral roots.
2. The young primary nodules give rise by branching to the characteristic 'cluster' nodules, surrounded by rootlets which grow out through the end of each branch.
3. Three branches or secondary nodules arise from the end of each primary nodule, and, like it, are modified lateral roots. After the formation of these branches the stele of the primary nodule elongates and grows through the apex of the nodule, giving rise to the hair-like rootlet.
4. In each mature nodule four zones can be distinguished :
 - (a) The apical meristem ;
 - (b) The 'infection thread' area ;
 - (c) The 'bacterial' zone, which includes most of the cortical tissue of the nodule, and consists chiefly of the enlarged cells containing Bacteria ;
 - (d) The basal zone. The lower end of the nodule, devoid of bacterial cells, but containing numerous cells filled with oil drops.
5. After the nodules have branched and reached their full size the Bacteria disappear from the cells of the bacterial zone, and the basal zone gradually encroaches upon and finally replaces all the other zones.
6. In old nodules, and sometimes in the basal zone of younger nodules, mycorrhiza filaments are found.
7. Pure cultures of the Bacteria from the 'bacterial' cells were made, and on examination were found to be identical in structure and growth with *Pseudomonas radicola*, the organism of the root-nodules of the Leguminosae.
8. Nitrogen determinations of liquid cultures, incubated for 7 days at 25° C., showed a fixation of 2.05 mg. of nitrogen per 100 c.c.
9. Young *Myrica* plants grown in sterilized nitrogen-poor soil did not flourish unless they possessed root-nodules. Plants devoid of nodules, after inoculation with a culture of *Myrica* nodule Bacteria, developed root-nodules and grew well.

The Morphology of the Root Tubercles of *Alnus* and *Elaeagnus*, and the Polymorphism of the Organism causing their Formation.

BY

ETHEL ROSE SPRATT, B.Sc., A.K.C.

Demonstrator in Botany at King's College, London.

With Plates XIII and XIV.

AMONGST the earlier investigators in the domain of the utilization of atmospheric nitrogen by plants, Hiltner stands out prominently, and in his work of 1899 the roots of *Alnus* and *Elaeagnus*, two non-leguminous plants, were shown to possess root tubercles which were associated with the assimilation of atmospheric nitrogen. These observations have been amplified more recently by Bottomley, who isolated a bacillus from the internal tissue of these nodules, and with a pure culture of this organism inoculated some *Vicia sativa* seedlings, upon the roots of which characteristic tubercles containing *Pseudomonas radicola* were subsequently produced. From this experiment it was inferred that the tubercles of *Alnus* and *Elaeagnus* contained *Pseudomonas radicola*, and infection of the roots by this organism was regarded as the probable cause of their formation. The literature concerning the tubercles of both these plants has greatly increased during recent years, and the various authors all find within the nodules a spore-producing hyphal-fungus, which has been placed in the group Hyphomycetes, but they do not appear to agree with one another in the detailed structure of this parasite, and its effect upon the host plant. The present communication is an account of some investigations which entirely support the original view, put forward by Hiltner and upheld by Bottomley, that there is a symbiotic relationship between these two plants and the organisms causing the tubercle formation.

Nodules have been obtained, at various seasons of the year, from plants of *Alnus incana*, *Elaeagnus edulis*, and *Elaeagnus rhamnoides*, growing at Chelsea, Sevenoaks, and North Wales. The material used for sectionizing was fixed in either Flemming's or Bouin's fixative or absolute alcohol, the latter having the advantage that only in this case is the oil which is present in large quantities in the tubercles of *Elaeagnus* removed by

subsequent treatment with xylol. Microtomed sections were almost exclusively employed, as the details could not be satisfactorily determined with certainty from the freehand sections which have been recommended by some writers. A large variety of stains were used, the principal being Flemming's triple, Heidenhain's iron haematoxylin, Ehrlich's haematoxylin, Löffler's blue, methyl green and fuchsin, methyl violet and fuchsin, carbol fuchsin, and Kiskalt's amyl gram. The last named proved the most satisfactory, since it is a good nuclear stain and also one by means of which *Pseudomonas radiculicola* can be differentiated.

In order to ascertain whether these root tubercles were connected with the presence of organisms possessing the power of assimilating atmospheric nitrogen, an attempt was made to isolate any such Bacteria from their internal tissues. For this purpose a medium of the following composition was utilized:

1 grm. saccharose,
0.5 grm. acid potassium phosphate,
0.02 grm. magnesium sulphate,
100 c.c. distilled water.

Into each of three Erlenmeyer flasks, 300 c.c. capacity, 50 c.c. of such a medium was placed, and then submitted to a temperature of 140° C. and a pressure of two and a half atmospheres for ten minutes in an autoclave. They were then neutralized with sodium hydrate and allowed to cool. Some of the tubercles were removed from the roots of both *Alnus* and *Elacagnus*, thoroughly washed, and then placed in a sterilizing fluid composed of:

2.5 c.c. concentrated hydrochloric acid,
1 grm. mercuric chloride,
500 c.c. distilled water.

They were allowed to remain in this solution for two minutes, when they were removed with sterile forceps and washed in distilled water contained in a sterile vessel. These nodules were then crushed with previously sterilized instruments, and the *Alnus* nodules were put into one of the above flasks, the *Elacagnus* into another, and the third was left untouched. All were then incubated at a temperature of 25° C.

After two days the solutions into which the nodules had been placed were quite cloudy, whilst the other one had remained unchanged. A drop of the cloudy liquid was placed on a slide, air-dried, then stained with carbol fuchsin, and examined microscopically. In both cases it was a pure culture of rod-shaped organisms, many of which contained two or three small round densely staining bodies, and were apparently very characteristic *Pseudomonas radiculicola* (Pl. XIV, Fig. 9). Another slide was prepared, and aniline gentian violet employed as a staining reagent, and this was found to be immediately

withdrawn from the organisms by absolute ethyl alcohol, but was retained by them when amyl alcohol was used as a dehydrating agent; which reactions clearly indicated that they were *Pseudomonas radicola*, according to the investigations of Harrison and Barlow.

Exactly the same results were obtained when maltose or glucose replaced saccharose in the above culture medium. Solid media were also prepared by adding 2 per cent. agar-agar to the above media, boiling, and then pouring into sterile Petri dishes and allowing to cool. These media were inoculated with very dilute crushed nodular tissue, prepared as above, by means of a sterile platinum loop, and incubated at 25° C. Very characteristic colonies were produced on the agar media, which were ovoid to circular in shape, with an entire margin, slightly raised above the surface, translucent, shining, and mucilaginous. They increased in size from 0.5 mm. diameter in one day to 1.5 mm. diameter in three days.

Streak and stab methods of cultivation produced equally typical growths. The streak produced an abundant, translucent, shining, mucilaginous growth, along the line of infection, with an entire margin, increasing in opacity, size, and viscosity from day to day. The stab induced the formation of a large typical colony on the surface of the agar, and a filiform growth along the stab in the medium.

The colonies embedded in the agar medium were very small, translucent, and disc-shaped or lenticular.

All the above cultures, after a period of incubation lasting four days or upwards, revealed on microscopic examination the presence of some larger organisms, tending to become ovoid in shape, amongst the characteristic rod-shaped *Pseudomonas radicola* (Fig. 10). These larger organisms also contain the densely stained round bodies which were present in the rods, their larger size being caused by an increase in the enveloping capsule. Division takes place so that one organism contains only one of the small bodies, which then grows until it fills the surrounding capsule, and the whole structure becomes spherical in shape and appears to have a very definite cell-wall (Fig. 11).

When the larger bodies are present in the colonies on the solid media, a white opaque appearance is assumed. The agar media were very favourable to the production of the larger spherical form, whilst in liquid cultures their appearance seems to be correlated with depletion of the medium of its carbohydrate, their source of energy, and probably also with the accumulation of the products of their own metabolic activities. That they are better able to resist the influence of the external environment than are the actively motile bacilli was demonstrated by boiling two cultures for ten minutes, one of which contained only the small rods, whilst the other contained only the larger spherical bodies, and subsequently inoculating freshly prepared culture media with them, and incubating

for two days, at the end of which period a normal healthy culture had been produced only in the medium inoculated from the culture containing the larger spherical organisms. These bodies appear to be analogous with the so-called 'bacteroid' forms produced by other species of *Pseudomonas radiculicola*, since by inoculating freshly prepared media with them the small typical bacilli are formed, which subsequently give rise to them again.

The above data indicate that the organisms living inside the root tubercles of these two non-leguminous plants are morphologically identical with *Pseudomonas radiculicola*, which inhabits the tubercles of leguminous plants. An attempt was made to determine also their physiological capabilities with regard to the assimilation of atmospheric nitrogen in the following experiments:

Into each of two Erlenmeyer flasks, 400 c.c. capacity, was placed 100 c.c. distilled water, 1 gram. saccharose, 0.5 gram. potassium hydrogen phosphate, 0.02 gram. magnesium sulphate. To one of these flasks, the control, was added 2 c.c. of a culture obtained from *Alnus* as described above. Both were then autoclaved and subsequently neutralized with sodium hydrate. The other flask, after cooling, was inoculated with 2 c.c. of the same culture as the control, and both were incubated at 25° C. for ten days. During this period the control remained apparently unaltered, but in the one containing the living organisms there was a visible change as described above.

The nitrogen content of both flasks was determined by the Kjeldahl method of analysis.

The following results have been obtained with cultures from *Alnus* and *Elaeagnus* respectively:

	Nitrogen found in control.	Nitrogen found in culture.	Gain in Nitrogen due to organisms.
<i>Alnus</i>	0.47 mg.	3.96 mg.	3.49 mg.
	0.62 "	3.85 "	3.23 "
<i>Elaeagnus</i>	0.45 "	3.07 "	2.62 "
	0.82 "	3.32 "	2.5 "

The increased nitrogen content can only have been produced by the growth of the living Bacteria introduced, and must have been derived by them from the atmosphere. Every precaution having been taken to exclude all other organisms except those derived from the tubercles, these experiments demonstrate that the root tubercles of *Alnus* and *Elaeagnus*, like those of leguminous plants, assist in the assimilation of atmospheric nitrogen, and this explains how, as Hiltner observed, the plant benefits from the presence of these tubercles on its roots.

The root tubercles of *Alnus* and *Elaeagnus* are usually present in clusters (Pl. XIII, Figs. 1 and 2), which may in *Alnus* attain a diameter of three inches or even more, but in *Elaeagnus* they are rarely more than an inch

and a half across. The tubercles are enabled to grow in clusters of such dimensions by their perennial habit and the repeated bifurcation which occurs when they are from a quarter to half an inch in length and about an eighth of an inch in diameter. In some cases, particularly when the tubercles occur in isolated positions on the roots, trifurcation occurs.

Transverse sections of the tubercles of both plants (Figs. 3 and 13) immediately reveal the fact that they are modified lateral roots, each possessing a well-defined central stele, and the increased diameter is caused by the enlargement of the cortical cells owing to their infection with the Bacteria. The organisms penetrated the root-hair, and entering the cortical cells caused them to hypertrophy, and this arrested the growth in length of the stele, so that a short swollen structure is produced instead of a typical lateral root. The tip of the nodule is occupied by a meristematic zone (Figs. 7 and 16), by means of which it grows, not only during one season, but also from year to year, growth being renewed each spring, when both meristematic apex and central stele branch (Figs. 7 and 16). The vascular tissue in the tubercles of *Elaeagnus* is in the form of a triarch stele (Fig. 13), possessing a relatively large amount of phloem, two or three layers of pericycle, and a distinct endodermis which is always closely packed with reserve food material, usually in the form of oil, but in some of the tubercles gathered in the spring there was a large proportion of starch. The xylem is composed of annular and spiral vessels and parenchyma. Towards the base of the older nodules a considerable amount of secondary vascular tissue is produced, and amongst this xylem there are scalariform vessels. In the tubercles of *Alnus* the central stele varies from triarch to hexarch (Figs. 3, 4, and 5). In the older regions there is a solid central mass of xylem (Fig. 5), whilst at the tip the centre of the stele is occupied by parenchyma, and the protoxylems are arranged round this (Fig. 4). Here also secondary thickening occurs, a considerable quantity of phloem is present, surrounded by two or three layers of pericycle and an endodermis, the cells of which are filled with reserve food material in the form of definite structures usually somewhat spherical in shape and giving very definite proteid reactions.

In the roots the phellogen has its origin in the pericycle, and forms a few layers of periderm externally, and several layers of secondary cortex on the inside. The tubercles are always surrounded by a few layers of periderm (Figs. 3, 7, 13, 16), which are formed by the continued growth of the original phellogen of the root to keep pace with the growth of the tubercle. In the spring the periderm near the tips of the tubercles in *Elaeagnus* frequently becomes very irregular, large masses being split off at various places, giving rise to small excrescences on the surface which are sometimes visible to the naked eye. This is caused by the inability of the phellogen to divide sufficiently rapidly to keep pace with the

rapid expansion and growth of the nodular tissue when reawakened to activity.

In the tubercles of *Elacagnus* the cortical cells situated immediately behind the meristematic zone appear to contain a protoplasmic network, while those a little further back are often somewhat abnormally enlarged and are filled with densely staining spherical bodies. This appearance suggests the idea which has been held by Woronin, Brunchorst, Shroter, and others, that the tubercles are produced by one of the Plasmodiophoraceae. When, however, the sections are stained with Kiskalt's amyl gram it becomes evident that the cortical cells contain the nitrogen-fixing organism *Pseudomonas radicola* (Fig. 8).

The apparent network is then seen to be a zoogloea thread in which are embedded the small rod-shaped Bacteria (Fig. 8, *b*, *z*). This is further demonstrated by applying a little ethyl alcohol, when the stain is instantly removed from the network, remaining only in the nuclei of the host cells. This condition always prevails in the youngest cells inhabited by the Bacteria, and is undoubtedly the form in which the organism passes from cell to cell, being exactly comparable with the so-called 'infection threads' produced in leguminous tubercles, and, as in them, seems to be attracted by the host nucleus around which it twines. The contents of the slightly older, enlarged cells are also very clearly defined by Kiskalt's amyl-gram stain, as distinct spherical bodies, having a definite wall and a strong resemblance to the organisms obtained in the old cultures and on the plates (Fig. 8, *c*). Detailed examination of a large number of sections of nodules of various sizes and ages, at different seasons of the year, showed that these spherical organisms are produced from the zoogloea after it has attained certain dimensions with regard to the host cell, and consequently has reached a particular stage in its development. In addition to the cells containing only the small rods in the zoogloea, others were examined in which there were a number of larger structures in the slime thread, and amongst these some very definite spherical bodies, the number of which evidently increases in proportion, until the host cell contains only these, the network being at first masked, but afterwards entirely used up as the bacilli assume the coccoid form (Fig. 8). The nuclei of the host cells under the influence of the zoogloea frequently assume a somewhat amoeboid form, become very vacuolate, may have several nucleoli, and in some cases appear to disintegrate (Fig. 8).

In order to ascertain the connexion between the two structures described above, the following methods of cultivation were tried. Part of the internal nodular tissue was crushed and put into a hanging drop so that it could be watched under the microscope, or incubated as desired. Some of these preparations were subsequently dried and stained. Thin hand sections were treated in the same way. The most satisfactory method

of cultivation, however, was to take a nodule, the outside of which had been sterilized, and cut it into three or four pieces, in order to expose some of the cortical cells directly to the influence of external agencies, and then place them in liquid culture media and incubate them at 25° C. The media used were those described above for the cultivation of the isolated organisms. The influence of adding a trace of ammonium phosphate or asparagin was also investigated. The pieces of nodule were incubated for periods varying from 12 hours to 6 days, when they were removed from the culture medium, fixed in Bouin's fixative, embedded and microtomed, and the sections stained with amyl gram or carbol fuchsin. In every case there was a steady increase from day to day in the proportion of bacilli present, and a corresponding decrease in the spherical bodies until after the fourth day, when all the latter forms had disappeared. The coccus forms were seen to divide, leaving a clear area across the centre, which always remained unstained (Fig. 14). Each half then divided again (Fig. 14), and the resulting bodies each produced a typical bacillus. In some cases there appeared to be more than four rod-shaped organisms produced from the one coccus, but the spherical body very soon loses its identity, especially when they are not too crowded together. All these stages are very evident in freshly gathered nodules, especially in the spring. These observations, like those in connexion with the isolated organisms, point to the conclusion that the amount of available carbohydrate present is one of the factors determining the production of the coccus form. It is extremely probable that the twining of the zoogloea round the nucleus of the host cell, as well as the activities of the Bacteria in these cells, impairs to a large extent the metabolic processes of the latter, and consequently renders it more difficult for the Bacteria to obtain the carbohydrate, their source of energy, and they consequently undergo a morphological change which renders them more resistant to the influence of their environment, and in this condition they rest. In the tubercles themselves, they become much more abundant in the autumn, in the winter appear to be the only form of organism present, and in the spring, when food material is once more available and fresh cortical cells are being formed in the nodule, they divide and once more assume the active bacillus form. The greater resistant power of the cocci was illustrated by moving some of the pieces of tubercle which contained none of this form from one culture medium to another, when it was found that in 12 hours the formation of a large number had been induced by this sudden change in the constitution of the environment. The two forms are clearly polymorphic of the same organism, which is a species of *Pseudomonas radicola*.

The tissue at the base of the tubercles contains an abundant supply of reserve food material, which consists mostly of oil, but in the spring a good deal of starch is present. In the older nodules this tissue becomes some-

what compressed laterally, and here and there are little colonies of Bacteria (Fig. 15) which have not migrated to the younger tissue nearer the tip of the tubercle, although they assume the rod-shaped form in the spring.

The cortical cells of the tubercles of *Alnus* also clearly contain organisms of two forms—small bacilli, undoubtedly *Pseudomonas radiculicola*, and larger coccus forms (Fig. 6). These forms are evidently analogous to the same forms in *Elacagnus*. Cells are frequently met with also, which contain a mixture of these two forms in varying proportions (Fig. 6), and in some tubercles the spherical bodies are seen to be in a state of division, so that they clearly produce rods again (Fig. 6, d). *Alnus* tubercles were subjected to the cultural methods described above for *Elacagnus*, which revealed the same polymorphic nature of the organism inhabiting it, the only difference being that the *Alnus* bacillus does not form such an evident zoogloea in the cells of its host. Probably correlated with this, the nuclei of the cortical cells do not appear to undergo any definite changes. In *Alnus*, too, the bacteroidal cells traverse the complete length of the nodule, and between them, in zones more or less concentric with the endodermis, are cells containing chiefly reserve food material in the form of oil and proteid globules.

The entire absence in all the tubercles examined of any filaments or hyphae in *Alnus*, and only the very narrow zoogloea threads being present in *Elacagnus*, together with the inability of the spherical bodies, which appear to have been called 'spores' by some authors, to germinate after the manner of a spore, seems to preclude the possibility of the tubercles being produced by the parasitism of a spore-producing hyphal-fungus. The present series of investigations entirely support the idea that the root tubercles of *Alnus* and *Elacagnus*, although morphologically different, are physiologically analogous to the root tubercles of the Leguminosae, which have been shown to be actively concerned in the fixation of atmospheric nitrogen, thus rendering this vast store available to the leguminous plant. This is done for *Alnus* and *Elacagnus* by a species of *Pseudomonas radiculicola*, which, in one of its forms, is morphologically identical with the organism found in leguminous nodules, but like the latter it is polymorphic and assumes a comparatively large spherical form, which does not usually occur in other species.

In conclusion, my heartiest thanks and gratitude are due to Professor W. B. Bottomley, in whose laboratory the investigations have been pursued, for his kindness, sympathy, and advice.

SUMMARY.

1. The root tubercles of *Alnus* and *Elacagnus* are modified lateral roots. They are perennial, dichotomously or trichotomously branched structures.

2. The tubercles are produced by the infection of the root with a species of the nitrogen-fixing organism *Pseudomonas radiculicola*.
3. The bacillus enters the root and afterwards propagates itself in the cortex of the nodule as a rod-shaped organism. In *Elaeagnus* it produces a very definite zoogloea.
4. The further development of the organism, in both cases, gives rise to relatively large spherical bodies, which increase in numerical proportion until they fill the entire cell.
5. Under certain conditions the larger bodies divide into two, and then each divides again, and possibly even further, until they lose their identity and a group of bacilli remain in their place.
6. *Pseudomonas radiculicola* is a polymorphic organism, the bacillus and coccus being different forms of one and the same organism.
7. In *Elaeagnus* the nuclei of the host cells appear to undergo some change under the influence of the zoogloea.
8. In *Elaeagnus* the Bacteria are found mainly in the region immediately behind the growing point, whilst in *Alnus* the bacteroidal tissue traverses the entire length of the nodule.
9. In *Elaeagnus* the food storage cells are found towards the base of the tubercle, in *Alnus* there are zones of tissue concentric with the endodermis, and in both the endodermis performs this function.
10. In *Elaeagnus* isolated groups of bacilli occur in the basal region.
11. The coccus form appears to be correlated with scarcity of available carbohydrate and change of environment. It is much more resistant to the influence of external agencies than the rod-shaped form.
12. The organism is capable of fixing free atmospheric nitrogen when isolated from the tubercles, and its presence is undoubtedly beneficial to the plant.

SPRATT—ROOT-TUBERCLES OF ALNUS AND ELÆAGNUS.

On the Cause of 'Blindness' in Potato Tubers.

BY

ELIZABETH DALE

(Sometime Pfeiffer Student, Girton College, Cambridge).

THE disease known as 'blindness' in potato tubers is so called because it more or less completely destroys the 'eyes', so that tubers thus affected are worthless for use as 'seed'. In addition to the symptom of blindness the surface of the tubers becomes rough and dark brown on account of a large formation of cork. When such a tuber is placed in damp air it becomes covered with a fine white mycelium, belonging to *Verticillium albo-atrum*, which produces the characteristic small conidia. If a blind tuber is cut across, the disease is seen to be confined exclusively to the eyes and to a narrow zone immediately below the cortex, which is thickened by the cork formation mentioned above. In this zone there is the fine mycelium of *Verticillium albo-atrum*. The whole of the interior of the tuber remains sound.

Amongst a number of tubers which had been stored for seed during the winter, by far the greater number were blind. Some of these were planted in pots in a cool greenhouse, and others in the open. A few rotted away, some remained sound but produced no shoots, others formed fresh eyes which developed into shoots. These at first appeared healthy, but later most of them showed signs of leaf-curl and leaf-roll, becoming yellow in colour, and gradually withering and drying from below upwards. In the leaves of the plants grown in the greenhouse a bacterial disease appeared which is considered in a separate paper.¹ No mycelium was in any case found in the subaerial parts of the plant, though one shoot was cut down and every internode and leaf microscopically examined by means of sections. The subterranean stems, especially those nearest to the old tuber, were covered with elongated brown patches due to *Verticillium albo-atrum* and exactly resembling the figures given by Reinke and Berthold.² These brown patches spread from the old tuber up the new shoots and along the underground stems which produce the new tubers, and so into these new

¹ Dale: A Bacterial Disease of Potato Leaves. *Annals of Botany*, vol. xxvi, No. ci, Jan. 1912, p. 134.

² Reinke and Berthold: *Zersetzung der Kartoffel*, 1879.

tubers themselves, through the heel. The track of the fungus may easily be traced with the naked eye by means of the brown coloration. On some of the new tubers were many long, straight, brown hyphae, especially near the eyes. These hyphae apparently attack the tubers by means of the eyes and spread through the superficial tissues of the tubers. Possibly the hyphae may also obtain an entrance through the lenticels.

Microscopic sections show that the mycelium on the underground shoots is partly external and partly in the cortical tissues, but that it never penetrates as far as the vascular tissues. Some of the external hyphae are long, straight, and relatively thick-walled, of a light brown colour, and branching at long intervals almost at right angles to the main hyphae. If kept in damp air these hyphae produce the slender colourless mycelium of *Verticillium albo-atrum*. The old mycelium forms, both on the living plant and also on cultures of sterilized potato tuber, a dark brown resting mycelium with small rounded segments containing numerous drops of oil. This mycelium, when kept damp, also puts out colourless hyphae.

According to Reinke and Berthold¹ the disease known as leaf-curl is also due to *Verticillium albo-atrum*. These observers found a mycelium in the vascular tissues of the subaerial stems, and also in the cortical tissues of the subterranean stems. In both cases the mycelium was that of *Verticillium albo-atrum*. The fungus was not found in the tubers except near the heel. Reinke and Berthold distinguish three types of fungus affecting two generations of potato plants, and state that some races of potato are more liable to infection than others.

The late Professor Marshall Ward² found what seems to be the subaerial mycelium mentioned above, and also noticed some of the other symptoms described by Reinke and Berthold, but apparently not leaf-curl. He succeeded in tracing the fungus down the stem into the heel of the new tuber.

None of these observers seem to have noticed the fungus in tubers stored through the winter, nor to have observed the destruction of the 'eyes'.

Both the disease known as 'blindness' and that causing 'leaf-curl' seem to be due to *Verticillium albo-atrum*,³ and tubers from crops affected with these diseases should not be used for 'seed', though they are quite fit for culinary purposes and generally keep well on account of the corky layer round the cortex.

¹ Reinke and Berthold : l. c.

² Marshall Ward : A Potato Disease. British Association Report, Bristol, 1898.

³ Note. Leaf-curl and leaf-roll almost certainly occur as symptoms in other diseases.

SUMMARY.

The mycelium of *Verticillium albo-atrum* is present in 'blind' potato tubers, where it causes the destruction of most of the 'eyes'. It grows up into the new shoots, when any are formed, and in some cases it may pass into the subaerial shoots. In other cases it never goes beyond the subterranean stems and creeps along them into the newly-formed tubers, *internally* as a colourless mycelium in the cortical tissues, and *externally* as a scanty thin brown mycelium. Thus the tubers may be infected by means of the vegetative mycelium only, without the formation of any kind of spore. The course of the fungus from the old to the new tuber may be traced by means of the brown coloration of the affected tissues. Tubers have been grown in three successive years from the original diseased crop, and in each year some have been blind and have had a warty and corky outer surface.

1. SYMPTOMS AND MODE OF OCCURRENCE.

IN the course of some experiments made in 1909 with potato plants grown from tubers affected with 'blindness', i.e. in which the 'eyes' had been more or less completely destroyed by *Verticillium albo-atrum*, certain pathological phenomena were observed which were at first thought to be due to the disease then under investigation, namely 'blindness'.¹

Further observations, however, showed that two distinct diseases were in question. One of these, 'blindness', affects the tubers and underground stems exclusively, while the other, which is due to Bacteria, is almost as exclusively confined to the leaves.

The plants in which the latter disease was first observed were three, grown from tubers affected with 'blindness', and containing the mycelium of *Verticillium albo-atrum*. Two of these tubers had been kept in damp air for nine days, and had begun to form new and apparently healthy 'eyes'. The plants grown from these tubers were labelled respectively '1 a' and '1 b'. A third tuber, which was dry and resting, had only traces of 'eyes'. It was marked '3'. Each tuber was planted in a flower-pot on

¹ Dale: On the Cause of 'Blindness' in Potato Tubers. *Annals of Botany*, vol. xxvi, No. ci, 1912, p. 129.

May 12, 1909. Besides these tubers, cuttings of shoots from apparently healthy tubers were planted. It is noteworthy that the plants grown from these cuttings were not attacked by the disease, which appeared on the plants grown from the 'blind' tubers.

Each of the three tubers produced shoots which at first were apparently healthy. But by June 10, i. e. in about a month after the tubers had been planted, the shoot of 'plant 3' began to show symptoms of disease. The leaves were somewhat wrinkled, becoming slightly yellow and covered with small brownish spots.

One of the leaves was cut. In the fresh leaf the brown spots were seen to be due to isolated cells, or rows of cells, densely filled with granules showing active movement. These cells are to be distinguished from other cells containing *colourless crystalline* granules.

In the former cells the granules are stained by dyes, while in the latter the granules are not stained and are refractive, so that if the granules are examined in reflected light they appear white, whereas the stainable granules are black, though both usually exhibit active movements in sections of fresh leaves. The stainable 'granules' were found later to be Bacteria.

By June 15 'plant 3' showed clear symptoms of 'leaf-curl'. The leaves were rolling up at the edges and were going yellow in large patches, and *the veins of the leaves were turning brown from the edge towards the centre of the leaves*. The leaves gradually became more yellow and dropped off, from below upwards. Sections of the leaves with brown veins showed that, in addition to the isolated cells with stainable granular contents, referred to above, the vascular tissues were turning a bright brown. At this stage were first observed, in the larger veins, certain *colourless tubes, with highly refractive walls*, of very irregular size and thickness. These tubes were obviously not fungal, and their significance and nature were not at first apparent.

In 'plants 1 a and 1 b' there were similar signs of disease, and sections showed both cells with granules and also large numbers of tubes.

By June 21 'plant 1 a' (which had been covered with a bell-glass for about a week) was almost dead. It had five large shoots (one had been cut off and fixed earlier) and three small shoots. Three out of the five had no green leaves; the stems were yellow and covered with elongated brown patches. The leaves were brown, shrivelled, and very slightly attached to the stem. The other two shoots had green stems with a few yellowish green leaves at the top. The three short shoots had yellowish green or brown leaves.

'Plant 1 b', which had not been covered, had green leaves on all its three shoots, but the veins were going a purple-brown colour on the under sides of the leaves, and the leaves were shrivelling from the tips downwards, while some were dropping off. 'Plant 3' was almost as badly affected as 'plant 1 a'.

A leaf of 'plant 1 a' was cut to see if any change had taken place in the tubes in the veins. They were still quite distinct, only slightly branched, and they nearly all ended in cells filled with stainable granules.

Plants with this disease almost invariably show marked symptoms of 'leaf-curl' and 'leaf-roll', but 'leaf-curl' may occur in plants which have not, as far as could be determined, yet been attacked by the organism causing the disease. A plant showing marked 'leaf-curl', but no traces of browning or wilting, was cut down, and each internode and its adjoining leaf put into separate bottles in absolute alcohol. A microscopic examination of these leaves and stems showed no traces of tubes, granules, Fungi, or any other sign of disease beyond the actual 'curl'. On the other hand, the brown veins and tubes may occur in leaves which are flat and remain so.

In the spring of 1910, and again in 1911, the disease appeared spontaneously in plants grown in pots in a cool greenhouse, some from the original 'blind' stock and some from tubers which were apparently healthy. Attempts were also made to grow seedlings for infection in sterile soil, but, though the seedlings readily germinated, further growth would not take place in sterile soil, so that plants grown in ordinary soil had to be used. The tubes obtained were in all cases similar. As before, some of the plants, but not all, showed symptoms of 'curl'.

2. HISTOLOGICAL CHARACTERS OF THE AFFECTED POTATO PLANTS.

Leaves from the three plants described above were fixed in chrome-acetic acid. Various stains were used, but by far the best method was found to be double staining with diamond fuchsin and light green. The sections were placed for about two minutes in fuchsin, washed in water, then *very rapidly* stained with light green by pouring the stain on the slide and washing it off again *at once* with absolute alcohol, which must not be left on the slide more than a minute before the sections are cleared in oil of cloves. Hand sections, however, require a longer time in absolute alcohol after the light green, in order to differentiate the stains and wash out the excess of fuchsin.

In the sections thus treated the tubes and Bacteria were stained bright red, while all the tissues of the host plant, with the exception of those which were lignified and of the nuclei, became green. It is therefore quite easy to trace the distribution of the parasite in the host plant by means of the coloration.

The tubes also stained well with alkaline methylene blue. In some cases the sections were treated with alcoholic caustic potash, before staining, to swell the tubes.

In stained microtome sections the tubes are to be found in all parts of the leaf, though they are largest and most numerous in the large veins. In

sections of fresh leaves the tubes are easily overlooked in the mesophyll on account of the presence of chlorophyll. They are also inconspicuous in unstained **hardened material** because of their small size compared with those in the veins.

It was at first uncertain whether the tubes were formed inside the leaf and grew outwards, or whether they originated at the periphery. Various considerations led to the conclusion that the latter is the case.

In early stages of the disease, when there are few or no cells containing Bacteria, the tubes are seen to occur at the periphery and to extend inwards for varying distances. They were never observed in the deeper tissues only.

In many cases the tubes are narrow at the surface of the leaf and widen irregularly towards the centre, but not infrequently they show a large swelling at the surface. In the case of branching tubes the branching usually occurs in the neighbourhood of the vascular tissues and not near the surface. It is much more probable that the tubes branch than that they anastomose, though this does seem to occur occasionally.

It may therefore be concluded that the tubes begin at the surface and pass inwards. How is the entrance effected? *In no single case, amongst the hundreds of sections examined, was a tube seen to enter the leaf through a stoma.* This point has been studied carefully both in surface view and in transverse sections. *In every case the tube pierces the epidermis,* almost always where two adjacent cells are in contact. This may be seen by looking at any of the diagrams representing tubes at the surface, either in surface view or in section.

A horizontal section of a vein is shown in Pl. XV, Fig. 1, where the epidermal cells are seen in surface view. Two stomata are represented surrounded by epidermal cells, on the walls of which, in almost every case where two adjacent cells are in contact, are numerous tubes in early stages of formation. The unaltered tissues of the host are stained green, the parts attacked by the disease take up the red colour.

Figs. 2 and 3 show two later stages. In surface views there is usually a deeply staining, approximately circular mass, often with an irregular lumen in the centre. Comparison with a section (Fig. 4) shows that this deep red area is a more or less hemispherical mass at the mouth of the tube (cf. Figs. 2 and 3 with Fig. 4).

In other cases the tube is extremely narrow at the surface (Figs. 5 and 8, &c.). Whether narrow or wide, it frequently shows one or more points projecting above the surface (Figs. 4, 5, 10, &c.).

After piercing the epidermis the tube grows *at right angles to the surface* along the middle lamella of two adjacent cells. Rarely it seems to cross the centre of a cell. At the point where the tube pierces a wall there is often a swelling (Pl. XV, Fig. 6, and Pl. XVI, Fig. 20). On arriving at an intercellular space the tube crosses the space (Fig. 7), often with a very

tortuous course, and passes between two cells on the other side. Occasionally tubes branch (Fig. 9) and, more rarely, anastomose (Fig. 8). Sooner or later the tube enters a mesophyll cell (Figs. 8, 9, and 12), in some cases near the epidermis (Fig. 8), or even into an epidermal cell, but more usually into a cell near the vascular tissue (Figs. 8 and 9). Though frequently occurring in the vascular tissues, tubes are scarcely ever seen in the vessels, though often in the phloem. The cells in which the tubes end are filled with Bacteria which usually stain red.

The tubes themselves are very irregular in outline and vary considerably in thickness. Irregular constrictions are common (Pl. XV, Figs. 5, 7; Pl. XVI, Fig. 11), and these are independent of the cell-walls of the host plant, as they are clearly visible in tubes crossing intercellular spaces (Fig. 7). The walls often present a corrugated appearance (Figs. 5 and 11). On the other hand, some tubes may be very straight and cylindrical (Figs. 6, 10, and 20). There is usually a lumen which is relatively narrow, though it varies in diameter (Figs. 6 and 7). The two sides of a tube are in many cases by no means parallel (Figs. 7, 11, 13).

The growing end of a tube is generally swollen and pointed (Fig. 5). Such swollen ends may be seen in intercellular spaces (Fig. 7) and also in the cells containing Bacteria. In some cases the tubes appear to pass right through the Bacteria-containing cells, or several tubes may end in one cell (Figs. 10, 12).

In the later stages of the disease the tissues of the host become extremely disorganized, especially in the neighbourhood of the veins. In these stages the affected tissues of the host plant, as well as the parasite, take up the fuchsin, so that the tubes cannot be so clearly followed.

It is noteworthy that sections of *stems* show no tubes or Bacteria, or at most very slight traces. The disease is confined, as far as could be determined, to the leaves. The explanation of this fact seems to be that the cuticle of the stem is too thick for the tubes to penetrate. In this connexion it may also be noted that in pure cultures of the organism grown on sterilized potato there was little or no growth on the 'skin' of the tuber, whereas the cut surface was rapidly covered with a thick mass of Bacteria.

3. THE PARASITIC ORGANISM AND ITS CULTURE.

The appearance of the tubes and of the granule-containing cells strikingly recalls, in many respects, those occurring in the nodules of leguminous plants, and shown by Miss Dawson¹ to contain, and to be formed by, organisms resembling Bacteria. Sections of nodules of *Pisum sativum*, fixed and prepared in the same manner as those of the potato leaves, showed similar reactions towards dyes. Morphologically there is also

¹ Dawson: 'Nitragin' and the Nodules of Leguminous Plants. Phil. Trans., Series B., vol. cxcii, 1899, p. 1.

much resemblance, but the tubes in the potato leaf are the bigger, and in many cases the less branched of the two. The mode of entry in each case is similar, as the infection tubes of leguminous plants penetrate the cell-wall of the root-hair, while those of the potato plant pierce the thin cuticle of the leaf. In both cases there is frequently a swelling at the point of entry and a dilatation where the tube pierces the cell-walls of the host. This may be seen by comparing the diagrams of the different tubes (cf. figures in this paper with those in Miss Dawson's).

In both cases the tubes finally pass into cells which are filled with granules that stain like the tubes. It seemed probable, therefore, that in each case a similar organism was concerned. Attempts were accordingly made to isolate an organism from leaves in which tubes and granules had been found by previous microscopical investigation. These attempts were not made until 1910, as in 1909 the nature of the tubes was still undetermined.

Leaves showing marked 'curl' were obtained from plants grown in a greenhouse from small but apparently healthy tubers which were planted on February 3. By March 11—i.e., as in the preceding year, after about a month—tubes and stainable granules were found in the leaves. From pieces of these leaves Bacteria were obtained by means of plate cultures of gelatine containing extract of potato tubers. The leaves were remarkably free from Fungi or Bacteria, other than the one obtained, so that pure cultures were easily and quickly made.

It may here be noted that various kinds of Bacteria were obtained from potato *tubers*, and compared with those from potato *leaves*, but in no case were they the same in their behaviour on culture media.

In the spring of 1911, from a badly diseased plant, in which tubes and Bacteria were abundant, three kinds of organisms were obtained. One of these was identical with that isolated in 1910. Of the other two, one was an organism with a most remarkable habit of growth: on potato tubers it formed large *Tremella*-like gelatinous masses, a centimetre or more above the surface of the tuber.¹ These masses were corrugated at the edges, and resembled a gelatinous fungus far more than Bacteria. The culture was not slimy but exceedingly tenacious, so that strong pressure with a cover-slip did not break it up. Microscopic examination showed that the gelatinous mass consisted of roundish, highly refractive Bacteria, embedded in masses of gelatinous substance, and relatively widely separated from one another.

The third form was somewhat like the second, but so feebly growing that the culture of it was soon abandoned.

The original Bacteria obtained from leaves in 1910 grew well on a number of media, but most successfully on pieces of sterilized potato

¹ This growth was confined to the cut surfaces of the tuber and never spread to the 'skin' of the potato.

tuber, at a temperature of 25° C. Under such conditions the Bacteria form a dirty white film which quickly grows in thickness, but which is almost exclusively confined to the cut surface. The cultures are very slimy and pull out into strings. As they grow, they give off a quantity of gas which raises bubbles on the surface of the cultures. The cultures, when old and becoming dry, sometimes turn a purplish or reddish-brown colour, recalling that of the veins of potato leaves in which this organism is parasitic.

The organism is very dependent on an abundant supply of water, and growth soon ceases, even on potato tuber, when the substratum becomes in the least dry, even though the food supply is by no means exhausted. Pieces of sterile (boiled) potato tuber, with cultures of the organism, were fixed in chrom-acetic acid, cut with a microtome, and stained with diamond fuchsin and light green (Fig. 14). Sections showed that the Bacteria were present in large numbers *between* the cells, filling up the intercellular spaces, whereas only a few, even in a culture a month old, were seen *inside* the cells and attached to their contents. The starch was apparently not attacked at all, as the contents of the cells gave a dark purple colour with iodine. These contents were chiefly the starch grains, boiled to a paste in the process of sterilization. The distribution of the Bacteria in the tuber was very clearly shown, as they took the usual bright red stain, while the walls and contents of the cell became a uniform green, with the exception of the starch grains and nuclei. It is noteworthy that the abundant proteid crystals resisted all the processes of sterilization, fixing, washing, and staining. They still retained their crystalline form, and stained red with fuchsin.

The organism was also grown on *living* potato tuber, which was sterilized as far as possible by cutting pieces from the centre of a sound tuber with a sterilized knife. The pieces of tuber were put in a sterile Petri dish, and sterile distilled water containing the organism was poured over them. A control section was placed in a dish containing sterile distilled water only. In about a week the control piece of tuber was unchanged, and the infected slice was brown and rotten and smelt strongly ammoniacal. Sections of the living material showed Bacteria *between* the cells, and few or no Bacteria *inside* the cells, which contained unchanged starch grains, stained red with fuchsin. One of the pieces of rotting tuber was fixed in chrom-acetic acid, cut with a microtome, and then stained with fuchsin and light green. In the parts where rotting was only beginning and the tissues were still firm (Fig. 15), the Bacteria were seen to be abundant between the cells, which were widely separated so that they easily fell apart. Apparently the middle lamella is first attacked and dissolved, and then the cellulose walls, which stain red as in the leaves. In some sections spores were abundant, as well as ordinary Bacteria, in the intercellular spaces. Some of the spores are shown in Fig. 15, in the angles between the cells. The

spores stain a deep red; many of the Bacteria stain green, perhaps because the red colour was washed out in the course of preparation of the slide.

In comparing sections of sterilized (boiled) tuber with those of living tuber, it is suggestive that in the former the walls of the host do not stain red in the parts attacked by Bacteria, as they do in the latter. The explanation seems to be that in the living tuber the middle lamella is first attacked and dissolved by the organism, and then the cell-wall itself, whereas in the sterile tuber the isolation of the cells is brought about, before infection by the process of steaming. Thus the organism finds a path already opened.

On potato extract in gelatine the organism grows well and liquefies the gelatine slowly. In a streak culture it first liquefies the part below the streak, forming a deep channel down which the culture slips into the liquefied medium at the base of the tube, where it proceeds to liquefy the remaining gelatine. The completion of the process takes days or even weeks in a low room-temperature.

On potato extract in agar, especially in an incubator at about 25° C. (the ordinary temperature of the laboratory in winter being low), the organism grows well. The cultures were slimy, as in gelatine, and pulled out into strings. As this medium dried up rather soon the growth ceased.

On 'Lemco' beef bouillon in gelatine at a somewhat low ordinary temperature (about 13°–15° C.) the organism grew well. The gelatine was slowly liquefied, at first along a groove as in potato gelatine cultures. The liquid part of the culture was turbid and contained flecks of pellicle.

In a *stab* culture a large circular mass of Bacteria was formed, thick in the centre and thin at the edges. Growth also occurred, but not very abundantly along the line of stab, the separate colonies each appearing as isolated round dots.

In the incubator, at 25° C., a good growth was obtained in liquid gelatine, the organism falling to the base of the tube as a whitish precipitate. A thin pellicle was formed on the surface. This film broke up and sank when the tube was shaken.

Wood ashes in agar, at 12°–15° C.

Streak culture. There was a considerable growth in all the cultures made.

Stab culture. A fair growth was formed along the line of stab, but there was no special development on the surface. The organism spread along the line of stab in wavy films or cloudy masses, which are very characteristic, and quite different from the isolated colonies formed in Lemco, and in cane-sugar and peptone gelatine. The difference seems to be due to the medium, isolated colonies being formed in gelatine, and wavy, cloudy growths in agar.

At 25° C. a fair growth developed on a streak, and a stronger development in a stab culture, as in the cultures at lower temperatures.

Urea in agar. At ordinary temperatures and in the incubator good growths were obtained on both streak and stab. The streak culture forms a broad, straight, and rather wide band. The stab culture formed a film over the surface, and also grew down the medium in a filmy manner as in wood ashes in agar.

*On cane-sugar and peptone in gelatine*¹ growth was very abundant. Large bubbles of gas were given off in such numbers as to form a frothy mass on the surface of the solid medium. Bubbles were also given off along the line of stab cultures, in spite of the solidity of the medium. As in other gelatine cultures, the colonies in a stab were clearly distinguishable with a hand lens as isolated round dots. Liquefaction here also was very slow and was not complete for some weeks. There is a distinct formation of acid, during which the neutral litmus becomes first red and then colourless.

On sterile milk. Several tubes, prepared according to the method given by Percival,² were infected with the organism, and one uninfected tube was placed with them as a control. In the incubator, at 25° C., by the next day the infected milk was going yellow at the top. At about 13° C. no change was visible. On the second day the infected milk in the incubator was coagulated and the violet colour had disappeared. There was a yellow liquid at the top and an almost pure white coagulum below. The milk in the control tube remained unchanged. At the lower temperature of the room the infected milk was changing colour but was not yet coagulated. After some time the coagulum disappeared.

On beer-wort gelatine there was very little growth, which is somewhat surprising as this organism grows so freely on so many media, and also because most organisms grow well on this particular medium.

Acrobism. A test-tube containing a stab culture of the organism in cane-sugar, peptone, and gelatine was placed in a larger tube containing a mixture of caustic soda and pyrogallin. Growth occurred abundantly, as was shown by the evolution of gas in the culture tube.

A second experiment was made, using the method given by Pethybridge and Murphy.³ A streak culture of the organism was made in agar (urea was used in this case) and immediately plugged with melted agar to exclude the air. In this tube also growth was vigorous. The organism can therefore live under anaerobic conditions.

¹ This medium was made up as follows: cane-sugar 1.5%; peptone 0.5%; gelatine 10.0%; distilled water 30 c.c.; neutral litmus.

² The milk was prepared as follows: Milk was passed through a separator. If not neutral it was rendered so, and a little neutral litmus added, which gave the milk a purple colour. The separated milk was sterilized in plugged tubes. Percival, *Agricultural Bacteriology*, 1910.

³ Pethybridge and Murphy: *A Bacterial Disease of the Potato Plant in Ireland and the Organism causing it*. Proceedings of the Royal Irish Academy, vol. xxix, section B, no. 1, 1911.

The size and shape of colonies. Plate cultures were made in gelatine and agar. The colonies obtained were round or oval, and in some cases showed pseudopodial-like prolongations, but this may be due to the pressure of the cover-slip on the gelatine. In the colonies the Bacteria are quiescent, but when liberated they are actively motile.

The organism grows well at 25° C. and also at 35° C. There is no growth between 35° and 45° C., and the thermal death point is about 50° C.

The cultures on the various media were examined microscopically at different ages, fresh, stained alive with water methylene blue, and in permanent preparations made on cover-slips and stained with various aniline dyes. The organism differed considerably according to different conditions, so much so that doubt was felt as to whether the cultures were the same. But the point was settled by cross cultures from one medium to another, the results being constant.

The organism is much more motile in liquid than on solid media. It is rod shaped, but the rods vary greatly in size, and especially in length, and sometimes grow into filaments which may be as much as 5 μ long. The average size is $3.7 \mu \times 1.23 \mu$, the minimum $2.4 \mu \times 0.8 \mu$, the maximum $5 \mu \times 1.7 \mu$.

In cultures on potato tuber, which are extraordinarily vigorous, rods of all lengths were found, some very small and scarcely motile in the slimy masses of zoogloea, others longer and wider in the more liquid parts of the culture. In this same culture, after only three days' growth in an incubator at 25° C., there were quantities of ripe spores as well as spores in process of development.

Formation of spores. The spores and spore-bearing individuals are so much larger than the average vegetative bacillus that at first sight they do not seem to belong to the same organism. But similar preparations have been made from different cultures, and in one and the same preparation all stages may be traced from the ordinary small vegetative bacillus to the ripe spore. The development is shown in Fig. 16. The ordinary bacilli are shown at *a*¹ and a long filament at *a*². Larger and somewhat more deeply staining individuals are seen at *b*. Still larger, and in some cases longer, individuals are represented at *c*, where the contents may be seen to be contracting and leaving the wall. In the next stage, *d*, the protoplasm is breaking up into segments, which vary in number according to the length of the spore-bearing rods. At this stage or earlier the rods may break up into smaller pieces. The spore-bearing rods are often seen to be surrounded by a faintly staining halo (*c* and *d*) which shades off gradually, separating the rods more or less widely from one another. This is no doubt the slimy matrix in which the rods are embedded if they are in a zoogloea, as is frequently the case in subaerial cultures. Inside the rods the spores are formed by the rounding off of the protoplasm, which becomes

surrounded by a thick wall. The contents of the ripe spores show marked apical staining (Fig. 16, *e*). Most frequently two spores are formed in a short rod, or segment of a rod. In some cases a long rod breaks up into many spores, some of which do not attain to maturity. In the case of a short rod with two spores, only one may develop fully (*g*).

A portion of zoogloea with the vegetative rods embedded in a gelatinous matrix is seen in Fig. 16, *h*.

4. INFECTION EXPERIMENTS.

Attempts were next made to infect potato leaves, both of seedlings and of mature plants, with the organisms described above. Some of these experiments were made in 1910 and the others in 1911, some in a greenhouse, others in the open. In both years the climatic conditions were unfavourable for experiments in the field. In 1910 the weather was so damp that the plants soon succumbed to *Phytophthora*. In 1911, on the other hand, the heat and drought were so great that, except early in the year, the Bacteria all dried up before they were able to enter the tissues of the host.

1. In 1910, owing to an unavoidable interruption in the work, the infections could not be made until August. Cultures of Bacteria from both leaf and tuber were used. The latter gave negative results, however, and they were consequently abandoned.

Bacteria from the same culture tube were used to infect both the seedlings and the mature plants. In some cases the Bacteria were laid on the leaf and left to find their own way in; in other cases a wound was made with a platinum needle which had been first dipped into the culture.

The infections were made on August 13. The seedlings used had been grown in a greenhouse and were infected *in situ*. By August 29, i. e. in sixteen days, the infected leaves showed symptoms of leaf-curl, and were also turning brown in places. Some of these leaves were fixed in chrom-acetic acid and examined later.

The mature plants, grown from tubers, were some of an unusually late crop which appeared to be healthy, although most of the potatoes in the neighbourhood had been badly attacked by *Phytophthora*. The infections were also made on August 13. As in the case of the seedlings the organism obtained from tubers did not infect the leaf. The Bacteria were either laid on the leaves, which were wet with rain, or were stabbed into the tissues with a platinum needle. At first the infected plants were covered with bell-glasses and shaded with cloths. The glasses were removed after three days, but the cloths were retained as a screen from the sun and also as a possible protection from the attacks of *Phytophthora*. By August 29 several infected shoots showed signs of leaf-curl and of browning. These were fixed in methylated spirit.

In November of the same year (1910) some potato and tomato seedlings were infected with Bacteria obtained by carrying on the original cultures from the potato leaf. In these later experiments the Bacteria were all laid on the surface (either upper or lower or both) of the leaf, which had previously been wetted with boiled distilled water. *No mechanical injury whatever was done to the tissues of the host by stabbing.*

The plants were covered with bell-glasses and placed in a cool greenhouse. The infections were made on November 16. In two days brown spots began to appear on the infected leaves of those plants which had been kept most *damp*. Some which were *drier* were at first unaffected, until sterile distilled water was put upon the leaves. Both the tomato and potato plants excreted large drops of water round the edges of their leaves, and it was observed that some of these became cloudy with Bacteria. This fact suggests the reason why the leaves begin to wither first at the apex and round the edges. Most probably infection takes place where there is the greatest amount of water, though, as stated above, it is quite independent of the stomata. Several leaves were fixed three days after infection. The infected leaves later became brown in patches and along the veins, and some appeared glassy-looking in patches. By no means all the leaves showed signs of 'curl' even when badly infected.

2. In 1911, infection experiments were begun earlier in the open at the University Farm, in a field of potatoes which was kindly put at my disposal by Professor Biffen.

This year the original organism was used, and also those obtained from the diseased plant cut down and examined in February, 1911.

The first experiments were made on June 8, when the weather was already very hot and dry, but there was some rain at the end of the month. With this exception there was hardly any rain at all until the end of the season, and the temperature not infrequently rose to over 90° F. in the shade¹ (35° C.), and was of course much higher in the sun.

The method used was slightly altered, and was as follows: The lower leaves were cut off to prevent their being confused with those which had been infected. The young upper leaves were wetted with distilled water. In the case of very hairy leaves it was found necessary to rub the water gently on the leaf, especially on the under surface, to ensure its being thoroughly moistened. The Bacteria were laid on the wet leaves and no punctures were made until quite late in the summer, when, owing to the drought, the Bacteria could not enter the host.² Each of the infected shoots was covered with a bag made of thin typing paper, waterproofed with paraffin and petrol, and then sewn up. By this means the plant was pro-

¹ It is important in this connexion to remember that the organism will not grow above 35° C.

² The drought would tend to make the epidermal walls of the host thicker and firmer, and therefore more difficult for the Bacteria to pierce.

tected to some extent from dryness and excessive light. Some leaves were infected on the upper surface only, some on the lower surface only, and others on both sides. Several varieties of potato were infected, including 'White City', 'Up-to-Date', 'British Queen', and 'Maresland Queen'.

The results of these experiments will not be given in detail, partly because later in the season so many gave no results, and also because the plants were attacked by a fungus, apparently *Cladosporium*. The symptoms of the disease caused by this fungus are externally so like those due to Bacteria that only a microscopic examination shows which is present. Both diseases may occur in the same leaf.

The positive results, though few in number, are indisputable, as well-developed infection tubes were found in the leaves. These will be described in the next section of the paper.

With regard to *Cladosporium* it may be mentioned in passing that this fungus attacks the potato leaves chiefly after the plants have been earthed up. It is one of the common Fungi of the soil, and, when the soil is brought into contact with the leaves in the process of earthing up, the spores attack the lower leaves and the fungus gradually passes upwards, until the whole plant may be involved. Each spore and the hyphae formed from it kill a small area of the leaf, causing a yellow or brown spot. The veins are also very frequently attacked and become brown. The diseased areas gradually spread over the leaf, which becomes yellow, then dries up, and finally falls off.

Some experiments, both with seedlings and with plants from tubers, were also made during the summer in a greenhouse, but gave no results, without any doubt because it was not possible to prevent the temperature from rising far too high. On one occasion, with open windows and white-washed roof, the temperature was 104° F. Since the maximum growing point is 35° C. (95° F.), the optimum temperature for growth is of course lower. This fact, as well as the excessive drought, accounts for the fewness of the positive results obtained in the summer of 1911 after artificial infection.

5. EXAMINATION OF THE ARTIFICIALLY INFECTED PLANTS.

1. 1910 *Material*. Few sections were cut through the material infected by puncture, because one of the chief objects in the experiments was to determine whether the infection took place through the uninjured epidermis, and this of course could not be seen when the leaf had been pierced artificially.

As in the case of naturally infected plants, no infection was seen to take place through either the water stomata or the ordinary stomata, though diseased leaf edges were specially examined. The fact that the

withering of the leaves often begins at the apex or round the edges, and that the veins are the parts chiefly affected, seems to be explained by the fact (already pointed out, p. 144) that the water excreted at night round the edges of the leaves at the ends of the veins serves as a medium for the Bacteria, which thus obtain the large amount of moisture necessary for their growth. On the lower surface of the leaves the angle between the projecting vein and the lamina is also a common point of infection, doubtless because it affords shelter for the parasite (cf. Fig. 11).

The Seedling Plants. Only one case of really clear and unmistakable tubes was found in cutting sections of seedling potato leaves. This was in a hand section of a comparatively large vein (Fig. 17). But other sections showed Bacteria in the cells of the affected parts of the leaves.

The Mature Potato Plants. These gave better results, though the experiments had to be stopped sooner than was desirable on account of the attack of *Phytophthora*. But definite tubes were obtained, and also early stages of infections were observed with less well defined tubes. In all cases, as in the spontaneously infected plants, the entrance of the Bacteria was through the epidermis and never by means of the stomata. Fig. 18 is an example of a tube which shows clearly the contained Bacteria, whereas in the naturally infected tubes distinct Bacteria were rarely if ever seen, perhaps because the tubes were older and emptied of their contents. This section also shows many Bacteria between the cells and outside the tube from which they may have escaped. It will be noticed that the tube is lying on the surface of the wall, on which are also Bacteria. Inter-cellular spaces are also to be seen with bacterial contents. Apparently the tubes are in an early stage of development, and the Bacteria have not yet penetrated into the interior of the cells, nor far into the tissues.

Fig. 19 represents a case of infection without definite tubes, in which the bacteria make their way between the epidermal cells and the palisade cells and cross the intercellular spaces. As in the last figure the epidermal cells are injured, apparently by the entry of the Bacteria. In both cases Bacteria occur outside the section on the surface of the leaf. The Bacteria, both in spontaneously and in artificially infected leaves, cling so tenaciously to the outer surface of the leaf that they are not washed off by the various processes involved in making permanent microtome sections. It is therefore often possible to determine the exact spot where the infection was made.

In the case of the *tomato seedlings* no trace of tubes was found, but Bacteria were abundant inside the leaves, especially in the intercellular spaces and in the thin-walled cells of the larger veins. In both potato and tomato plants the epidermal cells were attacked very seriously. This is not usually the case in naturally infected plants. Perhaps the contact of the larger mass of material, often including some of the potato tuber underlying the Bacteria, may account for the greater injury.

Several series of sections through the edges of leaves showed Bacteria entering between the cells and not by the stomata.

2. *Material infected in 1911.* The open-air experiments in 1911, in the earlier part of the season, gave more positive results, though on account of the hot, dry weather, these were fewer than had been hoped and expected. Of the plants infected on June 8 some leaves were cut and examined fresh on June 23, i. e. fifteen days after infection. As before stated, it is difficult, except in the larger veins, to see tubes in fresh material on account of the presence of chlorophyll. It is quite possible, therefore, that tubes in the lamina may have been overlooked.

Three leaflets from a plant of 'White City' infected with the original organism were cut. The signs of disease were not far advanced, and the leaflets were only slightly brown. *A very definite tube was seen in the first leaflet cut.* From these leaflets a fresh culture of the organism was made, which resembled the original culture. On June 30, that is, twenty-two days after infection, some more leaves were cut. A leaf of 'Up-to-Date' infected with the original organism contained good tubes in a vein which was cut. One large tube and some smaller ones were also seen in a leaf from a plant of 'White City' infected with the original organism (Fig. 20). A leaf of 'White City' infected with the thick gelatinous form also contained well-marked infection tubes and also many fungal hyphae. There is, however, no danger of confusing the two, as the fungal hyphae are thin-walled, have granular contents, branch, and are septate, whereas the bacterial tubes have thick refractive walls, and a narrow lumen with no contents, and seldom branch. There is, however, a doubt as to whether these tubes were really formed by the gelatinous organism or by the original Bacteria, as the infections were made on the *upper* side only, while the tubes were found only on the *lower* side. It is possible that some of the original Bacteria, known to form tubes, may have been transferred from one plant to another by the hands of the operator. To avoid this danger, subsequently only one kind of organism was used for infection on a given day, as there were no means of sterilizing one's hands properly in the field.

After this time, however, a severe drought set in, and the plants also became attacked by *Cladosporium*. No definite and unmistakable tubes were found in the leaves which were subsequently cut, except on July 8, on another leaf of 'White City' infected on June 8 with the original organism. It is noteworthy that the tubes were confined to the upper side of the leaf, and that the upper side only had been infected. The leaf was so very slightly diseased that to the naked eye it seemed almost healthy.

No tubes were found in plants infected with the organism which was obtained from the plant in 1911, and which seemed identical with that obtained in 1910. Bacteria were, however, found inside infected leaves. Leaves infected with the gelatinous organism, though showing no tubes,

except in the doubtful case recorded above, not infrequently showed masses of Bacteria, in the condition of zoogloea, inside the tissues of the host and between the cells. It therefore seems as if this organism were also pathogenic to the potato.

In the case of plants infected with the original organism, Bacteria were sometimes found inside the host plant when no tubes were seen. This would seem to be a case of infection without definite tubes like those noticed the year before.

6. DISCUSSION OF RESULTS.

The experiments and observations recorded above lead to the conclusion that the disease under consideration is bacterial in nature. Various bacterial diseases of the potato and allied plants have already been described by different authors. A history and comparison of these diseases has lately been published by Pethybridge and Murphy¹ in a paper describing a bacterial disease of potato shoots known as '*Black stalk-rot*' or '*Blackleg*', occurring in Ireland.

The bacterial diseases of the potato which have been most fully described are the one just referred to, and another worked out by Erwin Smith² and called by him '*Potato Bacteriosis*', which attacks not only the potato but other species of *Solanum*, especially the egg-plant (*S. [Melongena] ovigerum*) and tomato (*Lycopersicum esculentum*).

In potato '*Black stalk-rot*', or '*Black-leg*', as described by Massee, the symptoms are as follows: ³The leaves wilt and turn yellow, the lowest first. When the leaves droop the surface of the underground parts of the stem bearing such leaves is more or less covered with brown stains. Discoloration *goes up the stem*, which becomes black and decays. This disease was regarded by Carruthers,⁴ who does not, however, describe it in detail, to be due to *Bacillus phytophthorus*, which was first isolated and named by Appel.⁵ An organism was also isolated by Pethybridge and Murphy from potatoes affected with black stalk-rot, but it was not considered by them to be the same as (though closely allied to) that obtained by Appel. They therefore regard it as a new species, to which they give the name *B. melanogenes*.

The symptoms of '*Black stalk-rot*' differ considerably from those of the disease at present under consideration, especially in the fact that the disease begins from *below* and spreads *upwards*, attacking chiefly the stems

and tubers, whereas in the disease here described the mischief not only *begins* in the leaves but is exclusively confined to them, so that, as far as can be determined at present, the stems and tubers are only indirectly affected by means of the destruction of the foliage. As is to be expected, the organisms isolated in each case also differ from one another. In the potato *bacteriosis*, described by Erwin Smith (l. c.), the parts chiefly attacked are also the stems and tubers, though the organs *first* attacked are the leaves, as in the disease now being described. But the two diseases differ essentially in the fact that, while in *bacteriosis* the *vascular* tissue is first attacked and the vessels blocked with the organism, the parenchyma being only affected subsequently, in the present disease the injury begins in the *parenchyma*, and spreads to the non-vascular tissues of the veins, while not apparently affecting directly the stems and tubers. For convenience in description the latter disease may shortly be called *bacterial leaf disease* to distinguish it from bacterial diseases chiefly affecting other organs, and also to distinguish it from leaf diseases, such as 'blight', due to *Phytophthora* or other Fungi. The *mode of infection* in the two diseases is also different. *B. Solanacearum* enters the vessels by means of the water stomata or through wounds, whereas in bacterial leaf disease the organism pierces the uninjured epidermis and passes first between the cell-walls.

Again, as might be expected, there are marked differences between the *organisms* causing the two diseases. The differences between the three organisms, viz. *B. Solanacearum*, causing bacteriosis, *B. melanogenes*, causing black stalk-rot, and the bacillus causing bacterial leaf disease, may most readily be seen and compared by means of the accompanying table¹ (p. 151).

There seems to be no doubt, as a study of the table shows, that the organism causing bacterial leaf disease differs markedly from those already described, and that it must therefore be regarded as a new species, reluctant though one is to add another to the already long list. Since its most distinguishing characteristic is the power of forming tubes in the tissues of the host, like those already known in the Leguminosae, the most obvious specific name is one indicating this character. I propose, therefore, to call it *B. Tubifex*, n. sp.

The species, though parasitic on potato leaves, is also a saprophyte, as it grows strongly on various culture media as well as on the living leaf and tuber.

With regard to the mode of formation of the tubes a few words may here be said.

The organism evidently pierces the epidermis and passes between the cells by a process of fermentation in which the middle lamella is dissolved. That Bacteria possess this power has already been demonstrated by previous

¹ Reference may also be made to the table given by Erwin Smith, in the paper above referred to, showing the differences between *B. Solanacearum*, *B. tracheiphilus* (the organism causing cucumber rot), and 'Kramer's Bacillus', causing a rot in potato tubers.

workers. That *B. Tubifex* is able to cause fermentation is shown by its behaviour on culture media.

The tube itself is doubtless formed, as in the Leguminosae, by the union of the individual organisms into a zoogloea by means of the gelatinous envelope surrounding them. This envelope is only developed in subaerial cultures and not in liquid media. That the tube is not formed from the dissolved middle lamella of the cells of the host plant seems to be indicated by the fact that the tubes can be formed in, and cross over, large intercellular spaces in the mesophyll of the lamina.

The tube is therefore a kind of zoogloea, which penetrates the host by means of a ferment action which dissolves the middle lamella of the cells of the potato leaf. Apparently the Bacteria pass out of the tube into the cells of the host plant, leaving the matrix as a resistant, deeply staining tube, since all attempts to differentiate Bacteria by means of staining failed in the old tubes, though the same methods were used which were successfully employed by Miss Dawson in the case of the nodules of the Leguminosae.

Whether there is any relation between bacterial leaf-disease and leaf-curl is uncertain. The constant symptoms of the former disease are a yellowing of the leaves accompanied by the formation of brown patches in the lamina and of a brown colour in the veins. These symptoms may or may not be accompanied by leaf-curl or leaf-roll. On the other hand, as stated above, leaf-curl may occur when no organism can be found in the subaerial shoots. Reinke and Berthold¹ observed this fact, and came to the conclusion that curl is due to the presence of *Verticillium albo-atrum*, which may, however, be confined to the subterranean parts of the host and to the lower parts of the subaerial stem, though it may eventually grow upwards along the whole length of the shoot, and kill it by blocking up the vessels.

7. CONCLUSIONS AND SUMMARY.

Bacterial leaf-disease is due to *Bacillus Tubifex*, n. sp., which attacks the leaves of the potato plant by piercing the cuticle where this is thin enough for it to penetrate. The bacilli form a kind of zoogloea and dissolve the middle lamella of the host plant by means of a ferment, and so pass between, or in some cases across, the cells of the host plant by means of infection tubes like those present in the nodules of certain leguminous plants. Infection generally takes place near the edges of the leaves or along the veins either on the upper or under surface. The infection tubes grow at right angles to the surface of the lamina and sooner or later end in cells of the host plant, which become filled with Bacteria.

The disease appears to be more of theoretical than of practical importance, as in a fairly dry, hot summer the cuticle of the potato leaves would

¹ Reinke and Berthold: *Zersetzung der Kartoffel. Die Kräuselkrankheit der Kartoffel*, 1879, p. 67 et seq.

generally be too thick, and the temperature too high, to allow of the penetration of the organism. Any considerable attack would, however, be serious, as the leaves and shoots are completely destroyed and the formation of tubers consequently stopped. The disease has been most marked in plants grown in a *cool greenhouse*. The organism causing the disease is a bacillus differing in so many respects from those previously described as the cause of other potato diseases that it must be considered as a new species. On account of its power of forming infection tubes in the host plant it has been named *Bacillus Tubifex*, n. sp.

In culture it forms slimy masses of zoogloea on steamed potato tuber. These masses string out and stretch in films over large bubbles of gas, which are given off as the organism grows. The Bacteria have the power of causing fermentation. They are aerobic and anaerobic, and can live either as parasites or as saprophytes. Spore formation readily occurs.

My grateful thanks are due to Professor Biffen for allowing me to work in the School of Agriculture and at the University Farm, and for helping me with his advice during the course of my investigations.

TABLE SHOWING THE CHARACTERISTICS OF DIFFERENT BACTERIA
PATHOGENIC TO SOLANUM TUBEROSUM.

	<i>Bacillus Solanacearum</i> (Smith).	<i>Bacillus melanogenes</i> (Pethybridge).	<i>Bacillus Tubifex</i> , n. sp.
1.	Not sticky in the plant or on culture media, except slightly on agar.	Exceedingly sticky and slimy in cultures, especially on potato tuber. It strings out from the needle.	Like <i>B. melanogenes</i> .
2.	Dirty white or yellowish white, then brownish and finally <i>smoke-black</i> . Browns vascular bundles.	White, except on sterile potato.	White, then dirty white.
3.	Strictly aerobic. Will not grow in closed fermentation tubes with any sugar.	Slight growth occurs in stab cultures covered with agar.	Not strictly aerobic. Will grow in presence of caustic soda and pyrogallin, and also in agar stab covered with agar.
4.	No acids with any sugar.	Forms acid in glucose broth and in cane-sugar broth.	Forms acid in cane-sugar and peptone in gelatine.
5.	Intense alkali producer.		
6.	Slowly saponifies milk.	Coagulates milk within 48 hours. Gas bubbles formed. Colour of litmus goes.	Coagulates milk in 1 or 2 days with formation of acid. Gas bubbles formed. Decolorizes neutral litmus.
7.	Decided but not particularly obnoxious smell—likesome, but not all, rotting potatoes.	—	Slight odour. On living potato smells ammoniacal.
8.	Grows readily at 37° C.	—	Grows readily at 35° C.
9.	Thermal death-point 52° C.	Thermal death-point between 45° and 50° C.	Thermal death-point between 45° and 50° C.
10.	Zoogloea in top layers of beef broth or peptone water as innumerable tiny whitish flecks, which are sometimes slightly inclined to unite into pellicle but diffuse through the liquid on shaking.	Zoogloea not recorded.	Like <i>B. Solanacearum</i> , but also forms films on the surface which break up and sink when the fluid is shaken.

	<i>Bacillus Solanacearum</i> (Smith).	<i>Bacillus melanogenes</i> (Pethybridge).	<i>Bacillus Tubifex</i> , n. sp.
11.	Growth on gelatine not leaf-like.	—	Forms circular colonies on gelatine plates.
12.	Does not liquefy gelatine.	Liquefies gelatine fairly rapidly. Begins the second day in gelatine stab.	Liquefies gelatine rather slowly.
13.	No gas in potato or in media with various sugars.	Slight formation of gas with sugar.	Forms large bubbles of gas on potato and in cane-sugar and peptone in gelatine.
14.	No acid formed in potato or glucose solutions containing nitrogenous substances.	Forms acid.	Forms acid in cane-sugar and peptone in gelatine.
15.	Goes through bundles into tuber, where cavities are formed.	In subaerial stems.	Not found in tuber nor in stems, but only in leaves, especially in the veins but not in the vessels.
16.	No spores.	No spores.	Spores formed readily and plentifully in a few days on potato tuber.
17.	Sluggishly motile, active in young cultures.	Actively motile. Peritrichous flagellae.	Actively motile in liquid media.
18.	Bacilli in short rods.	Bacilli often in pairs or in threes or in long chains. Vary little in size. 1.3 to 1.8 \times 0.9 μ . Chains up to 20 or 70 μ . 5 to 10 peritrichous flagella.	Bacilli in short rods and long filaments of all lengths according to conditions of growth, nature of medium, age of culture, &c. Flagellate. Average size 3.7 \times 1.23 μ , minimum 2.4 \times 0.8 μ , maximum 5 \times 1.7 μ .
19.	Bacilli blocking up vessels of host plant. At first only in the vascular tissues, but later in parenchyma.	In vascular tissue of the stem of the potato plant.	Bacilli in and between the cells of the parenchyma and phloem. Seldom in the vessels and only in later stages.
20.	Infection through wounds caused by insects, &c.	Infection chiefly from the tuber, the organism growing up the stem through the vascular tissues.	Infection through uninjured epidermis by means of infection tubes, as in the nodules of certain leguminous plants.
21.	Injury caused chiefly by the blocking up of the vessels. Almost entirely confined to stems and tubers.	Injury chiefly as in <i>B. Solanacearum</i> .	Injury caused by disorganization of tissues due to passage of infection tube, and by lesions in cells filled with Bacteria. Also indirectly by the using up of the products of metabolism. Almost confined to leaves.
22.	Causes wilting and browning of foliage and stems.	Causes blackening of stems, withering of leaves, and rotting of tubers.	Causes withering and drying of leaves from outside inwards. Often accompanied by 'curl', but not always.
23.	—	On gelatine plates forms minute white dots. Liquefaction after the second day.	White dots on second day on gelatine plates and along line of stab. Liquefies gelatine.
24.	—	On agar white dots are formed in 48 hours as in gelatine. Surface covered with greyish white growth, somewhat crenated along the margin.	On agar plates dots as on gelatine. In stab cultures forms wavy films along the line of stab.
25.	—	Not vigorous in beef extract peptone.	Rapid growth in 'Lemco'.
26.	—	In cane-sugar broth gas and acid produced.	In cane-sugar-peptone gelatine gas and acid produced.
27.	—	Active growth in potato juice.	Active growth in liquid extract of potato tuber.

	<i>Bacillus Solanacearum</i> (Smith).	<i>Bacillus melanogenes</i> (Pethybridge).	<i>Bacillus Tubifex</i> , n. sp.
28.	—	Produces enzyme capable of dissolving the middle lamella of cells.	Produces enzyme capable of dissolving the middle lamella of cells.
29.	—	On <i>sterile</i> potato at 25° C. yellow slimy growth is formed in 2 days. After 6 days becomes brown.	On <i>sterile</i> potato at 20° C. a dirty white slimy growth is formed, raised up into bubbles.
30.	—	On <i>living</i> potato. Slight brown colour, later black. Middle lamella dissolved. Moisture needed.	As <i>B. melanogenes</i> . Smells strongly ammoniacal on living potato. Goes brown.

EXPLANATION OF FIGURES IN PLATES XV AND XVI.

Illustrating Miss Dale's paper on a Bacterial Disease of Potato Leaves.

PLATE XV.

Fig. 1. Surface view of the epidermis of a potato leaf, showing the bacterial infection tubes entering the tissues of the host through the cuticle and not through the stomata. The tubes are coloured red in all the figures. 4 oc. 2 mm. obj. (oil immersion).

Fig. 2. Surface view of older stage to show the lumen. Note that the cell-walls on each side of both tubes are stained pink because they have been chemically altered by the parasite. 4 oc. 2 mm. obj.

Fig. 3. Another surface view of older stage with the end of the tube more thickened. 4 oc. 2 mm. obj.

Fig. 4. Transverse section of an epidermal cell and of adjacent cells, showing two tubes which are markedly thickened at the surface of the leaf. Note the prolongations above the surface in the left-hand tube and the lumen, and the dilatation where the right-hand tube pierces the cell-walls of the host. 4 oc. 2 mm. obj.

Fig. 5. A young complete tube with a single narrow projection beyond the epidermis. The tube widens gradually with very irregular contours and shows several constrictions. Towards its inner end it becomes narrower, and there are traces of granular contents in the lumen. 4 oc. 2 mm. obj.

Fig. 6. A short piece of a tube, shown where it crosses three cell-walls. The swellings at the points where the walls of the host cells are pierced is very marked. 4 oc. 2 mm. obj.

Fig. 7. A portion of a tube to show the behaviour in an intercellular space. The surrounding cells are more or less diseased and contain some Bacteria. 4 oc. 2 mm. obj.

Fig. 8. Two tubes in a later stage of the disease. These tubes anastomose and branch, ending in the phloem of a small vein. A few Bacteria are to be seen on the surface of the leaf near the outer ends of the tubes. One of the cells of the host, immediately below the epidermis, is filled with Bacteria and its chloroplasts are degenerating. The intercellular course of the tubes is very clearly shown in this section. 4 oc. D obj.

Fig. 9. One tube is here seen branching and passing between the cells of the host into a small vein where some of the cells and vessels contain Bacteria. 4 oc. D obj.

Fig. 10. This shows an unusually large number of tubes, in close proximity, in the neighbourhood of a large vein. The tubes are seen at the surface, where each ends in several points. They have a more or less nearly straight course and are unbranched. Numerous cells containing Bacteria are also represented. Other examples, showing equally numerous tubes, were met with in examining series of microtome sections. 4 oc. D obj.

PLATE XVI.

Fig. 11. A long tube is here seen from the point of entrance in the angle between the vein and the lamina of a leaf to its ending in the phloem of the vascular bundle. On each side of the tube, along its tortuous course, are diseased cells containing Bacteria, and a few Bacteria may be seen lying outside the leaf round the mouth of the tube. Incidentally this section shows how the tubes, so to speak, avoid the stomata, one of which lies close to the outer end of the tube. 2 oc. D obj.

Fig. 12. The section is of a considerably diseased leaf with several branching and anastomosing tubes passing from the exterior into a small vein. The Bacteria have only attacked the cells and not the vessels. Many cells of the parenchyma are filled with Bacteria. 4 oc. D obj.

Fig. 13. This shows a few cells filled with Bacteria and containing the endings of the tubes. One tube is seen in transverse section in an intercellular space. 4 oc. 3 mm. obj.

Fig. 14. Section of potato tuber, sterilized by steaming, and infected with Bacteria. The Bacteria are very numerous between the cells, which, after being steamed, are only loosely attached to one another. There are only a few Bacteria inside the cells, whose starchy contents are apparently only slightly attacked. 2 oc. $\frac{1}{2}$ inch obj.

Fig. 15. Section of living potato tuber infected with Bacteria. Rotting was only beginning and the tissues were still firm. As in the dead tuber, the Bacteria are most abundant between the cells, whose walls have here been separated by the organism, which has destroyed the middle lamella and chemically changed the cell-walls so that they stain red. The organism has formed spores in the intercellular spaces. The large red spheres are starch grains, which have not been attacked by the Bacteria. 2 oc. $\frac{1}{2}$ inch obj.

Fig. 16. Formation of spores in the bacilli. a 1. Ordinary vegetative bacilli. a 2. Very long rod. b. Rods enlarging to form spores. c. Contents contracting from the wall. A faintly staining halo of zoogloea surrounds these rods. d. The contents breaking up into short lengths. e. Ripe spores showing deep apical staining. f. Two spores in a rod. This is very frequent. g. Rod with two spores, only one of which has matured. h. Portion of a zoogloea. 4 oc. 2 mm.

Fig. 17. Section of a leaf of a seedling potato plant, artificially infected with Bacteria from a pure culture. Two tubes are seen entering at the lower surface and growing towards the vascular tissues. The plant was grown and infected in a cool greenhouse. 2 oc. D obj.

Fig. 18. An artificially infected leaf of a mature plant from a tuber, grown and infected in the open. Many of the Bacteria used for infection are still clinging to the upper epidermis. A single tube is seen passing along a palisade cell. Bacteria are also seen in the intercellular spaces and inside the epidermal cells. 4 oc. 2 mm.

Fig. 19. Represents a case of infection without definite tubes. Numerous Bacteria may be seen passing between the cells and also inside an epidermal cell. 4 oc. 2 mm.

Fig. 20. Several tubes from a leaf of 'White City' variety of potato, artificially infected on the University Farm. The tubes are typical and exactly like those found in naturally infected plants. The swellings where the cell-walls of the host plant are pierced are very marked. 4 oc. 2 mm.

N.B.—It should be noted that in all cases the tubes run across the veins and lamina, and never in any case parallel to the surface of the leaf.

A Contribution to the Life-history of *Viola*.

BY

MARY C. BLISS.

With Plates XVII-XIX.

INTRODUCTION AND METHODS.

THE present study is based upon an investigation of the chasmogamic flowers of *Viola odorata*, *Viola pedata*, *Viola fimbriatula*, *Viola cucullata*, and *Viola pubescens*. Of these *V. cucullata* and *V. pedata* were found to be the most favourable species for study. The ovules are larger than in the other species, and the structures of the embryo-sac are less difficult to determine. The cleistogamous flowers were studied only by way of comparison, and offered no interesting differences as regards the development of the embryo-sac up to the eight-nucleate stage. Beyond this stage, the development of the female gametophyte in these flowers was not observed. Material has been collected for a comparative study of the floral parts of the cleistogamic and chasmogamic flowers, and it is my purpose to determine, if possible, the causes and conditions which operate to produce the cleistogamic flowers or which tend to modify the structure of the chasmogamic flower. It is interesting to note that violet plants transplanted from the open to the greenhouse in early spring produced only a few chasmogamic flowers and many cleistogamous flowers, but often transitional forms were developed, cleistogamous flowers with rudimentary petals and with more than the usual two stamens. The details of these phenomena will be considered in a later paper.

The material for this present work was collected in Wellesley and Needham from March 10 to May 27, 1903, and in Philadelphia from March 25 to May 1, 1908. Long before the first signs of leaves appeared in most of the species, *V. odorata* was in bud. The buds of the other species appeared in the following order: *V. fimbriatula*, *V. cucullata*, *V. pedata*, and *V. pubescens*. Buds of various sizes were collected and classified under the following heads: smallest buds, colourless, embedded in the crown of the root-stock; buds green, medium; buds larger, but still wholly green; buds with corolla visible; buds just opening and buds half

open. From this point, flowers from one to five days open and withered flowers were collected. The buds collected in Philadelphia were measured for greater accuracy.

In order to determine the exact age of a flower at a certain stage of structural development, the buds were tagged in the open field with a tiny square of white paper tied to the stem by a thread. For instance, fifty buds which were to open the next day were tagged with the number 1, and this number with date of tagging was recorded in a notebook. The next day some of the flowers were collected and fixed; others from the same group were collected on the second and third days and so on. In this way about a thousand violets were tagged and collected. The following table shows stages of structural development and relative size of bud or age of open flower.

TABLE SHOWING RELATIVE SIZE OF BUD AND STAGE
OF DEVELOPMENT.

<i>Buds.</i>	<i>Oogenesis.</i>
Buds smallest, colourless. <i>V. cucullata</i> .	Placenta differentiated. Ovular papillae not yet visible.
Buds medium, green. <i>V. pedata</i> .	Ovular papillae developed.
Buds small, green. <i>V. odorata</i> .	Ovule nearly anatropous; integuments visible, archesporial cell differentiated, tapetal cell cut off.
Buds large, corolla not visible. <i>V. cucullata</i> .	Second division of tapetal cell. Megaspore-mother-cell in prophase of division.
Buds large, corolla visible. <i>V. cucullata</i> .	Growth of functional megaspore.
Buds large, corolla not visible. <i>V. pedata</i> .	Two-celled embryo-sac.
Buds just opening. <i>V. cucullata</i> .	Four-celled embryo-sac.
Buds just opening. <i>V. fimbriatula</i> .	Eight-celled embryo-sac.
Buds just opening. <i>V. pubescens</i> .	Fusion of polar nuclei.
Flowers first day open. <i>V. cucullata</i> .	Presence of pollen-tubes. Stages in fertilization. Division of endosperm.

Two fixing fluids were used, Flemming's chrom-osmo-acetic acid and chrom-acetic-acid solutions. Both gave good results. The pistils were removed from the bud and the ovaries only fixed. The wall of the larger ovaries was cut away so that the fixing fluid might penetrate more quickly to the ovules. In some cases, the style was left in position in order that the path of the pollen-tube might be traced. Some of the buds collected were so small that it was impossible to dissect out the ovaries. These buds were fixed whole, and in section offer an interesting comparison of relative microsporangial and macrosporangial development. Two stains, Flemming's triple stain and Heidenhain's iron-alum haematoxylin, were used. Both gave good results.

ORIGIN OF OVULES.

The ovary of the *Violaceae* is unilocular with three parietal placentae. At a very early stage the placental line is recognized by a layer of closely set cells differing from the other cells in their denser and more deeply staining cytoplasm. Very soon the placenta becomes more conspicuous by the rapid growth of the cells directly back of the placental region, so that the line of placentation extends out into the cavity of the ovary. It is interesting to note that before the primordial cells of the ovule are visible, the anther lobes are well developed, the cells of the tapetal and the sporogenous tissue are clearly differentiated, and the spore-mother-cells are in the early prophase of the heterotypic division. The ovules arise as minute papillae on the placenta, and at first grow directly out into the cavity of the ovary. Soon, however, the ovule became anatropous.

DIFFERENTIATION OF ARCHESPORIUM AND TAPETUM.

The primary archesporial cell is hypodermal in origin, and is differentiated before the ovule has become anatropous. This cell differs from the cells of the surrounding tissue by its greater size, denser cytoplasm, and larger nucleus (Pl. XVII, Fig. 1). A transverse division soon cuts off a tapetal cell from the primary archesporial cell (Fig. 2). The tapetal cell may divide first by an anticlinal or by a periclinal wall (Figs. 2, 3). Further divisions of the tapetal cells are variable, but finally a cap of considerable depth is formed, and the definitive archesporial cell comes to occupy a central position in the nucellus (Fig. 4). In *Viola*, the nucellar cap persists up to the time of embryo formation, and at the time of fertilization the pollen-tube makes its way through this tissue in its passage from the micropyle to the egg.

The interesting phenomenon of twin nucelli was noted in several preparations. In one preparation observed, the embryo-sac was developed in each nucellus as far as the eight-nucleate stage, and the egg apparatus had been established. If in such cases fertilization should take place, we would have a case of polyembryony in *Viola*, or according to Ernst (4) a case of pseudo-polyembryony, brought about by the division of the nucellus at an early stage of development.

FORMATION OF THE AXIAL ROW.

During the formation of the tapetal tissue the definitive archesporial cell increases in size, its cytoplasm becomes scanty, and the nucleolus appears as a densely staining granular mass of chromatin (Fig. 3). At this time the cells of the nucellus surrounding the archesporial cell are actively dividing. In the nuclear plate stage of the first division, the macros pore-

mother-cell has increased to several times its original size, and occupies a central position in the nucellus. Its cytoplasm is very scanty, except in the region of the spindle. In some cases the macrospore-mother-cell has elongated to twice its width at the metaphase of the first division, but often the cell is still spherical as in the early prophase of division (Fig. 4).

At the close of the first division a distinct cell-wall is laid down, giving rise to two cells of nearly equal size (Fig. 5). Each of these two cells divides, and the result is an axial row of four cells. The development of the axial row in *Viola* differs from that described for *Trillium* by Coulter and Chamberlain (2), for *Houstonia* by Lloyd (6), for *Larix* by Juel (5), and for the great majority of Angiosperms as described by other writers, in that the upper daughter-cell, the one nearest the micropyle, divides first.

The cells of the axial row in *Viola* are not always arranged in a vertical row as represented in Fig. 6, but the walls may be laid down obliquely (Fig. 8), resulting in a group of cells in which the arrangement of the macrospores more nearly approaches the tetrad arrangement characteristic of typical spore formation. In this respect, the arrangement of the cells in the axial row in *Viola* corresponds to the arrangement figured for *Delphinium* (Mottier, 7), and for *Fatsia japonica* (Ducamp, 3). In *Viola*, generally the lower megaspore, the one furthest removed from the micropyle, is the functional megaspore, and develops into the embryo-sac. This order of development, however, was not invariable. Cases were observed in which the third megaspore became the functional megaspore (Pl. XVIII, Fig. 10), and still others in which, although the second and third cells increased equally in size for some time, the second without doubt was to develop into the embryo-sac. That the other cells of the axial row are disintegrating at this time is evidenced by the densely staining irregular masses of cytoplasm (Fig. 11).

DEVELOPMENT OF THE FEMALE GAMETOPHYTE.

During the rapid growth of the functional megaspore, the dense cytoplasm of its early development becomes vacuolate. Preparatory to its germination the nucleus moves from a central position in the cell to the micropylar end. At this stage, the mother-cell of the embryo-sac extends nearly one-third the length of the nucellus. The changes subsequent to the formation of the axial row take place rapidly, the integuments very soon extend to the top of the nucellus, and in Fig. 12 are just beginning to curve, preparatory to enclosing it. In the two-celled embryo-sac shown in Fig. 12 A, the nucleus has divided and the two daughter nuclei have separated, one nucleus remaining at the micropylar end of the sac, while the other has passed to the extreme opposite pole. The two nuclei are connected by strands of cytoplasm, and there is a slight condensation of cytoplasm at both poles and at the periphery of the embryo-sac. In the central portion

of the sac is an irregular vacuole, two-thirds as long as the entire embryo-sac.

The embryo-sac continues to lengthen and broaden, the nuclei at either pole divide simultaneously, and the four-nucleate stage is established. At this stage, the embryo-sac is twice as long as at the two-nucleate stage, but the comparative length and breadth are the same. The third division soon follows, and gives rise to the typical eight-nucleate embryo-sac of Angiosperms. Immediately after this division, the three cells which are to form the egg apparatus increase rapidly in size, surround themselves with a delicate cytoplasmic membrane, and begin to assume their characteristic shape. The egg extends from the apex of the sac about one-third its length. The protoplasm is condensed in the basal portion of the egg, and in it lies the nucleus, close to the basal line. Just above the dense cytoplasm is a large vacuole, which occupies fully two-thirds of the entire egg. The synergids are not quite as long as the egg-cell. They are pointed at the apex and broadly oval at the base. The upper portion of each is filled with dense cytoplasm, while the lower one-third of the cell is occupied by a large vacuole, characteristic of synergids in the majority of Angiosperms investigated. The nucleus generally lies in the middle of the cell, surrounded by dense cytoplasm, but quite close to the vacuole (Fig. 15).

While the egg apparatus is being formed in the micropylar end, various changes are taking place at the antipodal end of the sac. The antipodal polar may be distinguished from the other antipodal cells at an early stage by its greater size and larger nucleus. The usual number of antipodals in *Viola* is three. Their development and arrangement is varied. In some preparations the antipodals appear as definite cells with distinct limiting membranes, in others the antipodal nuclei lie naked in the general cytoplasm at the base of the sac. The antipodal cells are generally much smaller than those at the micropylar end, but their nuclei are large and, almost without exception, each contains a single nucleolus. These cells may be arranged in a row, side by side, or in a quadrant. As a rule the antipodals are not conspicuous, and in many cases when the embryo-sac is fully mature, the antipodals have already disappeared or are present merely as disintegrated masses at the basal end of the sac. In only one instance observed was there any suggestion of the haustorial development of the antipodals as described for the Rubiaceae (Lloyd, 6), *Aster* (Opperman, 8), and other genera (Fig. 17).

Soon after the egg apparatus has been established, the polar nuclei move towards each other. The antipodal polar moves more rapidly than the micropylar polar, consequently fusion is often completed just beneath the egg. At first nucleus only fuses with nucleus, and for some time the nucleoli remain distinct. Finally, however, the nucleoli fuse, and the result is a large endosperm nucleus twice the size of either polar nucleus. The

network of this nucleus is extremely delicate, and only slight condensations of chromatin are visible at the periphery and in the meshes of the net. The endosperm nucleus is very easily recognized, when present, by the large size of its nucleolus. This nucleolus is always characterized by a conspicuous vacuole which very nearly fills it.

POLLINATION AND DEVELOPMENT OF THE POLLEN-TUBE.

Before the pollen-grain is shed the contents of the microspore divide into a larger and a smaller cell. The smaller or generative cell becomes lenticular and lies free in the cytoplasm of the tube cell (Fig. 18). Chamberlain (1) and Wylie (9) figure similar generative cells for *Salix* and *Elodea*. The pollen-grains lodge on the inner surface of the stigmatic cavity where germination takes place. Often the upper portion of the stylar canal is completely filled with these pollen-tubes, although I could trace comparatively few into the ovary. There is no evidence of branching in the pollen-tube as it passes down the stylar canal, and no penetration of the stylar tissue. The passage of the pollen-tube through the micropyle and between the tapetal cells was clearly observed many times.

The pollen-tubes stain densely at this period, compared with the egg, and in most cases their exact contents could not be determined. From careful observations, I am led to believe that the generative nucleus divides immediately after the entrance of the pollen-tube into the embryo-sac. In cases where the sperm nuclei could be distinguished lying in the densely staining mass emitted from the pollen-tube, they were small, very nearly equal in size, and spherical in outline, giving no suggestion of the spiral form described by so many authors. The nucleus proper stains lightly, but it contains a large, spherical, deeply staining nucleolus.

In *Viola*, the embryo-sac has reached its mature size previous to the entrance of the pollen-tube (Fig. 15). At this time it is broadest at its middle diameter, narrowing somewhat at the micropylar end, but tapering more conspicuously at the antipodal extremity; the egg apparatus occupies nearly three-fourths the width and about one-third the length of the sac, and the endosperm nucleus has moved away from the egg, and occupies a central position in the embryo-sac. Following the entrance of the pollen-tube into the embryo-sac, one or both of the synergids disintegrate, the nucleus of the egg increases in size, and, in some instances, the growth of the antipodal cells is very conspicuous (Fig. 16). In such cases the size and shape of the antipodals recall the antipodal egg described by Chamberlain (12) and by Opperman (11) in *Aster*, but in no case was there any evidence of fertilization of these cells. Never more than two enlarged cells were found at the antipodal end of the embryo-sac, thus there was never found any structure suggesting an egg apparatus.

The sperm nuclei, small at first and spherical in outline, increase rapidly in size. One passes down and fuses with the endosperm nucleus. This fusion is clearly shown in Pl. XIX, Fig. 19, in which the endosperm nucleus is easily recognized by the characteristic vacuole of its nucleolus. The sperm nucleus is very large, nearly spherical in outline, and differs from the endosperm nucleus very conspicuously in appearance, in that masses of chromatin are held in the rather close network of the nucleus, and it contains a small densely staining nucleolus. The second sperm enters the egg at its apex. Fusion may take place in the central or in the basal portion of the egg. In both cases the two nuclei are surrounded by a mass of densely staining cytoplasm. Before fusion of the sperm and the egg nucleus is completed, and in some cases before the two nuclei are in contact, the so-called endosperm nucleus divides from one to several times (Figs. 21, 22). The young endosperm surrounds the egg and outlines a cavity beneath it which extends to the base of the embryo-sac.

This cavity persists in the seed of both the chasmogamic and the cleistogamic flowers when the embryo is fully formed and the seed is nearly mature. The formation of endosperm is very rapid at the last, and in the mature seed we find a solid mass of endosperm surrounding the tiny green embryo at the micropylar end of the seed.

The first division of the egg is transverse, dividing it into two cells nearly equal in size (Fig. 24). There is no suggestion of a suspensor. The oldest embryo figured (Fig. 27) shows a spherical mass of actively dividing cells at the apex of the embryo-sac; the endosperm is limited to a parietal layer lining the embryo-sac, and forming a sheath of cells which completely encloses the embryo, and separates it from the cavity beneath. In mature seeds of the chasmogamic flowers collected and studied in the spring of 1909, the embryo was an eighth of an inch in length, bright green in colour, and clearly differentiated into radicle, caulicle, and cotyledons.

SUMMARY.

The primary archesporial cell arises from a hypodermal cell of the nucellus.

A tapetal cell is cut off, which by vertical and transverse divisions forms a cap three or four cells in depth, directly beneath the micropyle.

The definitive archesporial cell divides into an axial row of four cells. The innermost of the four cells is generally the functional megaspore, but cases were observed where the second or third cell of the axial row was enlarging to form the embryo-sac.

The polar nuclei fuse in contact with the egg, generally before the entrance of the pollen-tube.

The synergids are pear-shaped with a large vacuole in the basal portion, and the nucleus lies just above the vacuole.

The cytoplasm of the egg is condensed at its base, and surrounds the large spherical nucleus.

Fusion of the second sperm with the endosperm nucleus was observed in *Viola cucullata*.

The endosperm nucleus divides several times before the sexual nuclei have fused, and in some cases before they are in contact.

The first division of the fertilized egg results in the formation of two cells nearly equal in size. There is no suggestion of a suspensor.

As the endosperm increases it forms a sheath around the embryo, and outlines a cavity beneath it which nearly equals in length that of the embryo-sac. This cavity persists until the seed is nearly mature.

In the mature seed the embryo is about an eighth of an inch long, and lies at the micropylar end of the seed surrounded by a solid mass of endosperm. It is bright green and is clearly differentiated into caulicle and cotyledons.

In conclusion, I wish to acknowledge to Professor Ferguson my sincere gratitude for her constant inspiration and invaluable aid throughout this work, and to thank Professor Macfarlane for the many courtesies extended to me during the weeks spent at the University of Pennsylvania.

MCBliss del

Reduction and Reversion in the North American Salicales.¹

BY

RUTH HOLDEN,

Wilby Prize Student of Radcliffe College.

With Plates XX and XXI.

IN the accepted classification of the Angiosperms, as presented by Engler and Prantl in 'Die natürlichen Pflanzenfamilien', the Salicales are placed as the third alliance under the Archichlamydeae, the families below them being the Casuarinales and Piperales. A few families above them are the Juglandales and Fagales, with which the Salicales were formerly united to constitute the Amentiferae. The sequence of these orders is based on the development of the perianth and the character of the floral members. On this criterion the Salicales are certainly low in the series, having catkins of flowers which are naked in the axils of bracts. Even on floral structure there is one objection, however, to relegating them to this primitive group, viz. the nectaries of *Salix*. Insect pollination is generally conceded to be characteristic of the higher orders, yet the entomophilous *Salix* is placed below the anemophilous Juglandales and Fagales. Another objection to the existing classification is the fact that the Salicales are porogamous, while the Casuarinales below, the Juglandales and some of the Fagales above, are chalazogamous. Although there is some difference of opinion as to the relative primitiveness of porogamy and chalazogamy, it is a significant fact that chalazogamy is confined to lower families of the Archichlamydeae, while all the higher Dicotyledons and all the Monocotyledons are porogamous. Further, the step from the gymnospermous condition, where the pollen-grains fall on the ovule and burrow through the intervening cells to the archegonia, to chalazogamy is short, but from the gymnospermous condition to porogamy is obviously great.

Granting that insect pollination and porogamy are points against the primitiveness of the Salicales, geological evidence has been cited to prove their antiquity.² From the Potomac of Virginia, however, the lowest of the

² Penhallow, D. P.: A Systematic Study of the Salicaceae. *American Naturalist*, vol. xxix, No. 464, Aug. 1905, p. 525.

Cretaceous, remains have been discovered not only of *Saliciphyllum* and *Populophyllum*, but also of at least twenty other Angiospermous genera.¹ Until more data are secured, then, it is impossible to prove anything regarding the phylogeny of the Angiosperms from palaeobotanical evidence.

In view of these conflicting standpoints, it seems desirable that something should be said regarding the anatomy of the Salicales. Before doing so it will be well to enumerate some of the principles upon which comparative anatomy rests at the present time. The fundamental one is Haeckel's law of recapitulation. According to this we should look for primitive conditions in the seedling and the first annual ring, as applied to plants. Investigation has shown the soundness of this principle and has added other primitive regions, viz. the tissue about outgoing traces in both root and stem, the reproductive axis, the leaf petiole, &c. Further, experimental work has shown that reversion to a primitive condition often takes place after injury. It is from a study of these regions then, that phylogenetic deductions must be drawn.

Turning now to the Salicales, Figs. 1, 2, and 3 (Pl. XX) represent the wood of a typical poplar, *Populus trichocarpa*, in transverse, radial, and tangential planes respectively. From these it is evident that the rays are one cell in width, or uniseriate, and the parenchyma only at the end of the annual ring, or 'terminal'. Another diagnostic feature of the wood of the Salicales is the end-wall of the vessel, which has one large pore constituting the so-called porous perforation, as opposed to the scalariform perforation characteristic of *Betula*, for example. The type of fibres is obviously not primitive, and the type of vessel-end-wall is likewise high.

Populus tremuloides has normally the same wood structure as that of *P. trichocarpa*; Figs. 4 and 5 show, however, transverse and tangential sections through the wood formed after injury. Here the rays are bi- and triseriate, and the parenchyma, instead of being terminal, is present also around the vessels.

Seedlings of *P. tremuloides* were examined and show that, while the rays are always uniseriate, the parenchyma around the vessels, as well as in the terminal position, is common. This is especially true of the transition region between stem and root—in the hypocotylary stem. Above and below, the vasicentric parenchyma tends to die out. In the stem it is always present to a greater or less extent in the first annual ring, while in the root it persists fairly abundantly throughout. Fig. 6 represents a section through the root at some distance from the hypocotylary region and shows most of the vessels with one or two parenchyma cells next their tangential walls. Fig. 7 represents at the same magnification vessels with parenchyma cells, and Fig. 8 represents at a higher magnification another vessel with one cell.

¹ Fontaine : Potomac or Younger Mesozoic Flora. U.S. Geological Survey, vol. xv.

The last section includes the end-wall of the cell, and its simple pits prove conclusively that it is parenchymatous.

The other regions retentive of ancestral characteristics confirm the evidence supplied by the study of wounds. Fig. 9 represents a tangential view of the tissue subtending an outgoing leaf-trace; Fig. 10 an outgoing root-trace. Both show aggregations of bi- and triseriate rays.

Another species, *P. balsamifera*, may now be considered. The normal wood is similar to that of the two species already described, with uniseriate rays and terminal parenchyma. Figs. 11 and 12 are of wounded tissue and show the presence of biseriate rays. As in *P. tremuloides*, the wound also recalls the parenchyma around the vessels. In the former, however, wounds tend to bring back the parenchyma to a much greater extent than in the latter; as regards reversion in the rays, the condition is exactly opposite, i. e. a wound which in *P. tremuloides* would bring multiseriate rays only in the immediate vicinity of the injury, in *P. balsamifera* recalls the rays half-way around the stem. In the root of *P. balsamifera* the parenchyma is mostly terminal, with a slight tendency to the vasicentric condition; a very slight wound, however, suffices to bring it back in abundance around the vessels. Conditions similar to those of *P. tremuloides* were found in the first annual ring of the stem and under the leaf-trace.

P. nigra var. *italica* is another species with terminal parenchyma and uniseriate rays. Wounds in stool shoots bring back the parenchyma and rays in a striking way, an interesting feature being that the vasicentric parenchyma extends completely around the stem after a wound, while the multiseriate rays are confined to the immediate vicinity of the injury.

Among other poplars with terminal parenchyma and uniseriate rays are *P. grandidentata* and *P. laurifolia*. On investigation of the latter it was found that a very slight wound in the second annual ring is sufficient to recall the parenchyma to a moderate extent, while a severe wound further out brings back abundant vasicentric parenchyma and multiseriate rays.

P. deltoides presents a new condition. In this species the parenchyma is normally around the vessels, but the rays are uniseriate like those species already described. In the first two annual rings of a seedling the rays are practically all biseriate, dwindling thereafter to uniseriate, while vasicentric parenchyma in that region is extremely abundant. Slightly higher in the stem, where the leaf-traces go off, there is a comparatively large amount of parenchymatous tissue above and below each trace. A transverse section slightly above a trace shows a ray ten to twelve cells wide, which runs out for a short distance and then is dissected into multiseriate rays three to four cells wide. The other rays throughout the periphery of the stem are bi- and triseriate. Abundant vasicentric parenchyma is present in the first two annual rings, growing less so in the succeeding years of growth, but a transverse section in the plane of an outgoing trace shows that on

each side of the trace the vessels are surrounded by a jacket of parenchyma. Higher up in the stem biseriate rays disappear entirely except in immediate relation to the leaf-trace, while vasicentric parenchyma is scantily present throughout.

Another poplar with the same type of normal wood is *P. rotundifolia*. Here the wound reactions are what might be expected—multiseriate rays and abundant vasicentric parenchyma, while a moderate amount of ray parenchyma subtends the trace.

One species remains to be mentioned, the cottonwood of California, *P. Fremontii*. The wood of this species, represented in Pl. XXI, Fig. 13, has normally biseriate rays, but the parenchyma is exclusively terminal.

To sum up, the normal wood of the majority of poplars has uniseriate rays and terminal parenchyma. Investigation of regions characterized by ancestral conditions shows that vasicentric parenchyma is retained by the root and seedling and recalled in post-traumatic tissue in the stem. Further, multiseriate rays are retained in the seedling, and in connexion with leaf- and root-traces, and are likewise recalled by wounding.

Conditions in *Salix* are to a large extent similar to those in *Populus*. Figs. 14, 15, and 16 show three planes of *Salix Nuttallii* with uniseriate rays and terminal parenchyma. Fig. 17 represents a radial view demonstrating the vertically elongated 'marginal' cells of the rays. These cells are a perfectly constant diagnostic feature, and serve to differentiate between *Salix* and *Populus*.

Seedlings of various species of *Salix* show more or less abundant vasicentric parenchyma near the pith, but no biseriate rays except in immediate relation to a leaf-trace. Roots show vasicentric parenchyma normally and an abundance of biseriate rays after wounding. Both leaf-trace, Fig. 18, and root-trace, Fig. 19, show abundant subtending multiseriate rays.

Wounds in the stem result in the appearance of parenchyma around the vessels and multiseriate rays. Fig. 20 shows the wood of *S. nigricans* var. *primulifolia* after wounding. Almost every vessel in the field has at least one parenchyma cell on its tangential wall and some have two. Fig. 21 shows a portion of the same under a higher degree of magnification, Fig. 22 under a still higher magnification. This species gives an especially good wound reaction, parenchyma about the vessels being formed to a less extent on the side of the stem opposite the wound.

Young twigs a year old show considerable parenchyma around the vessels opposite the protoxylem clusters. At the node a large medium trace goes off to the bud, and two lateral ones to the leaf. The bud-trace leaves an extensive gap, some distance above and below which are clusters of bi- and triseriate rays. The leaf-traces often have subtending them rays four or five cells wide, which, half-way through the annual ring, are dissected into biseriate rays by the intrusion of vessels.

Leaf petioles and the mid-rib of the leaf itself have such a small amount of vascular tissue that no rays are developed, but the vessels are surrounded with parenchyma.

Other species of *Salix* with terminal parenchyma and uniseriate rays are *S. Hookeriana*, *S. japonica*, and *S. daphnoides*.

There are a number of species with uniseriate rays and vasicentric parenchyma—*S. fluviatilis*, *S. sitchensis*, *S. purpurea*, *S. lutescens*, and *S. viminalis*. Fig. 23 represents a transverse section of *S. fluviatilis*, showing vasicentric parenchyma.

S. laevigata, Fig. 24, has biseriate rays and terminal parenchyma normally, while both *S. sessilifolia*, *S. lasiolepis*, and *S. taxifolia* have biseriate rays and vasicentric parenchyma.

To sum up the genus *Salix*—the wood of the majority of species has normally uniseriate rays and terminal parenchyma. Vasicentric parenchyma is recalled after injury and retained in the root, in the seedling, and usually in the first year's growth throughout; multiseriate rays are recalled after injury and retained in connexion with leaf- and root-traces.

Applying then the principles of comparative anatomy as enumerated at the beginning, it is evident that the Salicales were primitively characterized by multiseriate rays and vasicentric parenchyma. A few species retain these features, while others have been reduced and have lost them, except in certain regions especially retentive of ancestral characteristics. In considering the relative position of different species of *Populus* and *Salix*, Penhallow suggests that on the basis of its wide distribution *P. balsamifera* is the most primitive and represents an ancestral type from which many of the localized types have descended. In view, however, of the anatomical considerations, it is evident that such forms as *P. balsamifera*, *P. trichocarpa*, *P. tremuloides*, *Salix Hookeriana*, *S. japonica*, &c., appear to represent reduced types, while such forms as *Populus Fremontii* and *Salix sessilifolia* represent the primitive condition.

Professor Penhallow also regards *Populus* as more primitive than *Salix*, since (p. 808) 'the parenchyma in *Populus* is always terminal' and (p. 813) biseriate rayed forms are more common in *Salix* than in *Populus*. The first statement appears to be a mistake, *P. deltoides* and *P. rotundifolia* having vasicentric parenchyma, but if it were true it would only serve to reinforce the second in showing, not that *Populus* is more primitive, but that it is more reduced and therefore higher than *Salix*. On p. 820 he says that 'the general trend of evidence so far collected, geological, geographical, and anatomical, is all in one direction, and that is to show that the genus *Populus* is essentially the more primitive'. The geographical evidence consists in the fact that the willows are more widely distributed and less localized than the poplars—the latter being supposedly survivors of some ancestral type. This evidence, if unsupported by other more convincing

testimony, is of little weight. The geological evidence consists in the fact that *Populus primaeva* is supposed to be older than any *Salix*, but the finding of both *Saliciphyllum* and *Populiphyllum* in the Potomac discredits any conclusions from fossil evidence. As for the anatomical evidence, there is only one species of *Populus* with biseriata rays, and there are only two with vasicentric parenchyma, as opposed to a dozen or more with terminal parenchyma and uniseriate rays. On the other hand, there are more species of *Salix* with vasicentric than with terminal parenchyma, and almost as many with biseriata as uniseriate rays. Accordingly, since both *Salix* and *Populus*, as shown by comparative anatomical evidence, are descended from forms with multiseriate rays and vasicentric parenchyma, it seems clear that *Populus* is more reduced than *Salix* and consequently higher.

The geographic distribution of the different species is of interest. The three North American species of *Salix* with vasicentric parenchyma and biseriata rays are indigenous west of the Mississippi, and the one species of *Populus* with biseriata rays is a native of California. On the other hand, the more reduced forms with uniseriate rays and terminal parenchyma grow in the eastern as well as the western part of the country. It is not uncommon to find that the western species of the United States are more primitive and less reduced than the eastern. For example, Mr. Bailey has recently investigated the western chestnut, *Castanopsis*, and finds here various structures, present in a greatly reduced form in the eastern *Castanea*.

Having discussed the anatomy of the Salicaceae, it is now desirable to discuss its bearing on their systematic position. Recent investigations in wood structure have shown that the most constant feature for diagnostic purposes is the distribution of the wood parenchyma, and the next best the width of the rays. The evolution of rays in the vascular plant series would be somewhat as follows: most Gymnosperms have uniseriate rays. In the epicotyledonary seedling stem of *Quercus* there are uniseriate rays near the pith which on passing out in certain segments become bi- and triseriate; then by approximation of the rays and elimination of vessels these segments become 'false' rays—the permanent condition in the adult Live Oak. Further on, by the elimination of the intervening tracheides the rays become solidly parenchymatous, as represented in the homogeneous masses of ray parenchyma in the mature wood of North American White and Black Oaks.¹ That rays of this type are made up of compounded multiseriate rays is proved by the wound reaction.² In genera slightly higher than *Quercus*, i. e. *Carya*, *Ostrya*, *Fagus*, &c., these rays, solid at the pith, break up as they pass out, until by the intrusion of fibres and vessels in both

¹ Eames, A. J.: On the Origin of the Broad Ray in Oaks. The Botanical Gazette, xlix, pp. 161-7, No. 3.

² Bailey, I. W.: Reversionary Characters of Traumatic Oak Woods. The Botanical Gazette, l, pp. 374-80, No. 5.

horizontal and vertical planes they become the multiseriate rays characteristic of the mature wood of most Dicotyledons.¹ This process can be observed especially well in certain of the Ericaceae and Casuarinaceae, where the compound ray is present only near the leaf-trace. In fact, it has been shown that the leaf-trace has played the chief part in the formation of compound rays.² As these multiseriate rays go from the pith, they are apt to dwindle, as seen in the seedling of *Populus deltoides*, for example, until uniseriate rays are formed. This is the condition in the Salicaceae, *Aesculus*, and, as Mr. Bailey has ascertained, in *Castanea*, all of which have uniseriate rays normally in the adult, but multiseriate rays in the primitive regions.

Whether the direct ancestors of the Salicales ever attained compound rays like those of the oak, it is impossible to say. All that comparative anatomical evidence shows is that they are descended from ancestors which possess multiseriate rays, and adequate palaeobotanical evidence on their origin is lacking at present. It is evident, however, that the compounding process must have taken place in very remote geological time, since multiseriate rayed forms are common in the Upper Cretaceous of Japan.³

The development of parenchyma is somewhat as follows: In the Abietineae there is no parenchyma in *Pinus*; but in all the other members there is terminal parenchyma. In the Sequoieae and Cupressineae the parenchyma is diffuse, i. e. scattered through the year's growth. Since the Gymnosperms never developed vessels the parenchyma never got beyond the diffuse condition. It is likewise diffuse in the Gnetales and in the lower Angiosperms, as the Casuarinaceae, Betulaceae, Fagaceae, and Juglandaceae; while in the highest Angiosperms it is clustered around the vessels, as in the Oleaceae, Ulmaceae, Leguminosae, &c. Reduction then sets in and the Saliceae and Magnoliaceae have terminal parenchyma in the stem, but vasicentric in primitive regions. It is of interest to note that conditions in the Magnoliaceae are similar to those in the Salicaceae—the Asiatic genus, *Michelia*, has vasicentric parenchyma in the stem, and *Liriodendron tulipifera* has vasicentric parenchyma in traumatic tissue. Another interesting case of reversion is seen in *Osmanthus*, a member of the Oleaceae, where the parenchyma is exclusively terminal.

From this consideration of the evolutionary tendencies in the development of rays and parenchyma, it is evident that the Salicaceae, instead of coming low down among the Dicotyledons, as is assumed by systematic botanists, in reality represent, from the anatomical standpoint at least,

¹ Thompson, W. P.: The Origin of Multiseriate Rays in Dicotyledons. *Annals of Botany*, vol. xxv, 1911, p. 1005.

² Bailey, I. W.: The Relation of the Leaf-trace to Compound Rays in the Lower Dicotyledons. *Annals of Botany*, vol. xxv, No. xcvii.

³ Stopes and Fujii: Studies on the Structure and Affinities of Cretaceous Plants. *Phil. Transactions of Royal Society of London, Series B*, vol. cci.

a condition of reduction from a high type. The evidence for this view may be briefly stated as follows: The primitive distribution of wood parenchyma in the Salicaceae as shown by this investigation is obviously vasicentric or centred around the vessels, a condition uniformly characteristic of such high families as the Compositae, Oleaceae, &c. In ray structure, the Salicaceae are likewise clearly allied with the higher and not the lower Dicotyledons, since their uniseriate rays obviously represent a condition of reduction from the multiseriate type characteristic of the higher woody Angiosperms and not a primitively simple condition as suggested by the late Professor Penhallow.

CONCLUSIONS.

1. Most eastern representatives of the North American Salicales are characterized normally by terminal parenchyma and uniseriate rays.
2. In primitive regions vasicentric parenchyma and multiseriate rays are found.
3. Certain western North American representatives of the Salicales have normally vasicentric parenchyma and multiseriate rays.
4. The primitive condition for the wood of the Salicales is vasicentric parenchyma and multiseriate rays.
5. The low position assigned to the Salicales by systematists appears not to be justified.
6. Since their simple structure is due to reduction from a condition originally more complex, the Salicales have a high position in the dicotyledonous series.

In conclusion, I wish to express my thanks to Professor E. C. Jeffrey for his helpful advice and for aid in securing the photomicrographs accompanying this article; to Professor J. G. Jack of the Arnold Arboretum for seedling material he was kind enough to send me; and to Mr. I. W. Bailey for sections of various western species.

the protoxylem is brought into the exarch position but still remains in the plane of the cotyledons; finally, the two groups of phloem- and of metaxylem-elements of one cotyledonary bundle fuse with the corresponding tissues of the other cotyledon, the resulting strands being situated in the inter-cotyledonary plane. A diarch root-structure is thus formed.

This is Van Tieghem's third type of transition, and it will be referred to in the following pages as type 3.

Calandrinia speciosa shows no important feature of difference from *C. Menziesii*.

Calandrinia amoena, Vis., in all essentials is identical with *C. Menziesii*; the cotyledons, however, are not so rounded and the bifurcation of their central bundles does not take place at so high a level.

Calandrinia grandiflora, Lindl., is chiefly remarkable from the fact that the rearrangements of the cotyledonary strands are more complete at a higher level than in any of the other species of the genus examined, the rotation of the bifurcated bundle being carried so far that the two groups of metaxylem elements are closed up, with the protoxylem in the exarch position, at a level just above the cotylar tube (Diagram 1, Fig. 7). This feature is also shared by *C. umbellata*, although not in so marked a degree.

Claytonia perfoliata, Don. The main features of dissimilarity between the transition phenomena in the very small and slender seedlings of this plant and those of species of *Calandrinia* are that the two lateral bundles of each seed-leaf of *Claytonia* early fuse with the larger central one; the main cotylar bundles are endarch and collateral through the whole length of the seed-leaf; and, finally, the vascular rearrangements which take place in a very short vertical distance leading to the diarch root-structure occur during the passage of the seed-leaf-traces from the cotyledons to the central region of the axis and in the upper part of the hypocotyl.

Portulaca oleracea, L. The seedling is very small and its cotyledons are much flatter than those of any of the preceding plants. The seed-leaves have several bundles in their blades, one large central one with two or three smaller strands on each side. The latter fuse on to the main central bundle, which shows bifurcation and rotation before the last of the laterals have effected a junction with it in the basal region of the blade (Diagram 1, Fig. 8). The transition is of type 3 and closely resembles that of *Calandrinia umbellata*.

CARYOPHYLLACEAE.

SILENOIDEAE.

Cucubalus baccifera, L. The transition resembles that of the foregoing plants in following type 3. Of the differences, relatively unimportant, which obtain between *Cucubalus* and *Calandrinia* for example, the following are

the more striking: in the former plant, as in *Claytonia*, the lateral strands of each cotyledon fuse on to the larger central bundle in the upper region of the petiole before any vascular rearrangement is inaugurated in the median bundle; this strand, in transverse section, appears like a widely opened U with the xylem-elements, situated on the concave side, well dispersed owing to the development of much parenchyma, the presence of which makes it difficult to trace the movements of the protoxylem; finally, no cotyledonary tube is formed. As in the majority of the foregoing plants, the vascular rearrangements begin in the petioles of cotyledons, but in the basal rather than in the upper regions.

Lychnis Viscaria, L. The transition phenomena resemble those of *Cucubalus*; the central bundle of each cotyledon is, however, very small in *Lychnis* and the vascular rearrangements are more ill defined. A cotyledonary tube is formed.

Lychnis Githago. According to Gérard¹ the transition follows the same course as in *Silene inflata*.

Silene inflata follows type 3. From Gérard's account it appears that the transition phenomena commence in the upper regions of the petioles of the seed-leaves, but at a level just above the cotyledonary node the bifurcated bundles again close up. This is in accordance with our observations on *S. pendula*.

Silene pendula, L., shows no features of particular interest; the transition follows type 3, and the bifurcation of the main cotylar strand begins in the petioles of the seed-leaves before all the small laterals have fused with it. On tracing these half-bundles downwards, they are seen gradually to close up so as partly to sandwich the protoxylem-elements between them; thus at the cotyledonary node these bundles are closely apposed with the protoxylem towards the exarch position. There is a well-marked cotylar tube.

Silene Otites, Sm., closely resembles *S. pendula*.

Silene Schafta, Gmel ex Hohen., does not differ in any important feature from *S. pendula*. The bifurcation begins at a relatively high level in the cotyledons, and the lateral strands unite with the adjacent portions of the divided central bundles at about the same level.

Another example showed the unusual feature of a triarch root. The changes which led to this were as follows. One cotyledon was normal in having in the base of its blade one large central bundle and two small lateral ones; the other had two central ones and two laterals. The lateral

¹ Gérard: Recherches sur le passage de la racine à la tige. Ann. Sci. Nat., Bot., sér. 6, t. xi, 1880.

strands fused on to the central ones, which in the petiole bifurcated and rotated in the usual way (Diagram 2, Figs. 1 and 2). In the case of the cotyledon *c. 2* there are thus two pairs of phloem-masses and two groups of protoxylem-elements. Fusion takes place between the phloems which lie side by side, and the resulting strand remains in position, whilst the other two rotate inwards (Diagram 2, Fig. 3). The completion of these rearrangements in the axis results in a triarch root-structure (Diagram 2, Figs. 4 and 5).

Dianthus barbatus, L. The mode of transition is that of type 3. The lateral bundles in the base of the blade of the seed-leaves fuse on to the central bundles so that one strand only occurs in each cotyledonary petiole. Although these bundles commence their division at the top of the cotyledonary tube, the major part of the transition takes place during the inward

DIAGRAM 2. *Silene Schafta*.

passage of these strands to the centre of the axis, and in the upper part of the hypocotyl.

Dianthus chinensis, L., differs from *D. barbatus* in two features: the main bundle of each seed-leaf commences its vascular rearrangements in the base of the blade before the lateral strands have joined on to it; also, the protoxylem of each seed-leaf-trace becomes completely exarch during its passage down the short but well-marked cotyledonary tube.

Dianthus arcnarius, L., resembles *D. barbatus* very closely.

Gypsophila Saxifraga, L. The third type of transition is followed, and the vascular rearrangements begin in the base of the seed-leaves on a level with the top of the cotyledonary tube. The main changes take place in the upper part of the hypocotyl as in *D. barbatus*.

Saponaria cerastoides, Fisch. ex C. A. Mey. (Fig. 1, B), does not differ in any essential feature from *Gypsophila Saxifraga*, with the exception that a cotyledonary tube is not formed.

Saponaria Vaccaria, L. (Fig. 1, A), shows a few points of difference when compared with *S. cerastoides*. *S. Vaccaria* has much larger seed-leaves and a well-marked cotyledonary tube; also the petioles of the cotyledons each have three bundles, a main central one with a lateral on each side, which do not fuse until just above the cotyledonary node. Although the transition takes place as in *Gypsophila* and *Dianthus barbatus*, it is inaugurated at a lower level, namely at the base of the cotyledonary tube.

Saponaria vulgaris is practically identical with *S. Vaccaria* as regards the phenomena under discussion; the vascular changes, however, are initiated at a slightly higher level than in *S. Vaccaria*.

Dangeard¹ has pointed out the similarity in the essentials of the seedling anatomy of *Saponaria*, *Atriplex*, *Chenopodium*, *Kochia*, *Salsola*, *Basella*, and *Rivinia*; and so far as our observations overlap we are in agreement with him.

Tunica prolifera, Scop., does not differ in any important feature from *Gypsophila Saxifraga*. One example recalled *Silene pendula* in the fact that the strand of one cotyledon bifurcated and then closed up at a slightly lower level.

The diarch root-structure is arrived at in a very short vertical distance.

ALSINOIDEAE.

FIG. 1. A. *Saponaria Vaccaria*; B. *S. cerastoides*. Natural size.

Cerastium perfoliatum, L. The transition phenomena are practically identical with those of *Dianthus barbatus*; there is, however, in *C. perfoliatum* no cotyledonary tube, and the separation of the phloem-masses of the bifurcated seed-leaf-traces is more marked.

Stellaria graminea, L., also closely resembles *Dianthus barbatus*. Unlike *Cerastium perfoliatum*, *S. graminea* has a short cotyledonary tube.

Spergularia salina, J. et C. Presl,² does not differ in any essential feature from *Dianthus barbatus*, the chief point of dissimilarity being in the fact that in *S. salina* the vascular rearrangements start at a higher level and the cotyledonary bundles enter the axis in a more advanced state of division and rotation.

Spergula arvensis, L., has a larger seedling than *Spergularia salina*, and its vascular rearrangements recall those of *Calandrinia Menziesii*; thus,

¹ Dangeard : Recherches sur le mode d'union de la tige et de la racine chez les Dicotylédones. Le Botaniste, i, 1889.

² This may possibly be *S. rubra*, J. et C. Presl.

unlike *Spergularia salina*, the central bundle of each cotyledon bifurcates before the lateral strands have effected a junction with it, and this beginning of the transition phenomena takes place high up in the seed-leaf.

Polycarpon tetraphyllum, L., closely resembles *Spergula arvensis*. A cotyledonary tube is formed.

Corrigiola litoralis, L. The seed-leaves do not form a tube at their base. The resemblance to *Spergula arvensis* is very close.

AMARANTACEAE.

AMARANTOIDEAE.

Celosia cristata, L., *C. plumosa*, ?, and *C. spicata*, Spreng. The transition phenomena in these three seedlings are almost identical with those of *Calandrinia grandiflora*. The bifurcation of the central cotyledonary strand takes place at the top of the petiole or even in the base of the foliar part of the seed-leaf, and the so-formed 'double bundle', in its passage towards the cotyledonary node, is accompanied by two lateral strands which fuse on to the divided central bundle at a level a little above the insertion of the seed-leaves which do not form a tube.

One example of *C. spicata* had three cotyledons, of which one was markedly larger than the other two. The central bundle of this large seed-leaf was more massive than that of the others, and the corresponding pole of the root was similarly much stronger. The triarch root-structure was arrived at in exactly the same way as the diarch arrangement in normal dicotyledonous specimens.

Amaranthus caudatus, L. The vascular re-arrangements closely resemble those of *Celosia*. The central cotyledonary strands bifurcate in the blades of the seed-leaves and the protoxylems are fully exarch at the cotyledonary node. Also, as in *Celosia*, the lateral strands join on to the median bundle at a level just above the insertion of the seed-leaves. The only point of dissimilarity from *Celosia* lies in the fact that in *A. caudatus* the four groups of phloem-elements in the upper region of the hypocotyl derived from the two seed-leaf-bundles may postpone their union for some distance downwards; similar observations have been made in some Cactaceae.

Amaranthus abyssinicus, ?, *A. Dussii*, Spreng., *A. hypochondriacus*, L., *A. paniculatus*, L.—which has also been investigated by Gérard,¹ with whose observations we are in agreement—and *A. viridis* all closely resemble *Amaranthus caudatus*.

Amaranthus sylvestris, Desf., is remarkable chiefly from the fact that not only do the central seed-leaf-bundles bifurcate and rotate in the blades

¹ loc. cit.

of their respective cotyledons, but they divide completely into two, leaving protoxylem elements isolated between them, a feature which is characteristic of *Phytolacca*, *Allionia*, *Mirabilis*, and other Nyctaginaceae; also it occurs in some species of *Lupinus* and *Dahlia*. A minor point to be remarked upon in *Amaranthus sylvestris* is that the union of the laterals with the central bundles of the cotyledons is effected at a much higher level than in *A. caudatus*, &c.

Pupalia purpurea, unlike any of the foregoing species of *Amaranthus*, does not show an early inauguration of the transition phenomena; in fact the bundle from each cotyledon enters the axis in an undivided endarch condition, all the changes leading to the formation of a diarch root-structure taking place rapidly in the upper part of the hypocotyl.

GOMPHRENOIDEAE.

Gomphrena haageana, Klotzsch, resembles *Amaranthus sylvestris* in the division of the central cotyledonary bundles and isolation of protoxylem elements in the blade of the cotyledon. A feature of difference is found in the fact that one of the laterals may delay fusion with the adjacent half of the central strand until the upper region of the hypocotyl is reached.

Gomphrena globosa, L., is, in essentials, identical with *G. haageana*; the isolation of the protoxylem, however, is not so well marked as in the latter plant. In both species a cotyledonary tube is formed, a point of difference from *Amaranthus* and *Celosia*.

CHENOPODIACEAE.

The anatomy of the seedlings of this Order has formed the subject of investigations by previous authors. Van Tieghem¹ has remarked upon the occurrence of diarchy in the primary roots of *Beta vulgaris*, *Spinachia oleracea*, and *Atriplex hortensis*.

Gérard² has shown that the transition of *Atriplex hastata* follows that of type 3, and that it is not by any means rapid.

The work of Dangeard³ in this connexion has already been alluded to; it may, however, be further remarked that he considers that the venation of the cotyledons has an important bearing on the primary root-structure and concludes that the seed-leaves with pinnate venation have a diarch root, whilst those with a palmate venation have a tetrarch root-structure.

Fron⁴ has made the, hitherto, most extensive study of the seedling anatomy of this Natural Order, and points out that the structure of *Atriplex hastata* is typical for the genus. He also draws attention to the similarity

¹ Van Tieghem: Recherches sur la symétrie de structure des plantes vasculaires. Ann. Sci. Nat., Bot., sér. 5, t. xiii, 1870.

² loc. cit.

³ loc. cit.

⁴ Fron: Recherches anatomiques sur la racine et la tige des Chenopodiacées. Ann. Sci. Nat., Bot., sér. 8, t. ix, 1899.

between *Salsola Kali*, *S. Soda*, *S. vermiculata*, *Suaeda*, *Chenopodium*, *Blitum*, *Roubiera*, and *Beta*. He concludes that the transition in the Chenopodiaceae takes place at different levels of the hypocotyl: at the lower end in *Atriplex*, *Salsola*, and *Suaeda*; slightly below the level of the insertion of the cotyledons in *Beta* and *Spinachia*; whilst, finally, in *Blitum* and *Chenopodium* it takes place in an intermediate position.

CYCLOLOBEAE.

Beta brasiliensis, ?, *B. chilensis*, Hort., *B. hortensis*, Mill., and *B. vulgaris*, Moq. The details of the transition in these plants are like those of *Amaranthus caudatus*, the only differences being that in *Beta* a short cotyledonary tube is formed and there is no marked delay in the fusion of the phloem-masses in the hypocotyl.

Chenopodium ambrosioides, L., *C. Atriplicis*, L., *C. Bonus-Henricus*, L., *C. Botrys*, L., *C. calulatum*, ?, *C. capitatum*, Aschers, and *C. scoparium*, L., all resemble *Amaranthus* and *Beta*. A short cotyledonary tube occurs in *C. Bonus-Henricus*, *C. capitatum*, and *C. scoparium*. The bifurcation of the central cotyledonary strand takes place well within the blade of the seed-leaf, but in no case is the protoxylem entirely isolated as in *Amaranthus sylvestris*. The V-shaped bundle is accompanied downwards by two laterals, and their union occurs at different levels: in *C. ambrosioides* and *C. Botrys* this coalescence takes place at a level well above the cotyledonary node; in *C. Atriplicis*, *C. Bonus-Henricus*, *C. calulatum*, and *C. capitatum* the junction is at, or just above, the cotyledonary node; finally, *C. scoparium* is remarkable in the fact that the laterals make no junction with the central strand, but come to an end.

It may also be remarked that there is no particular delay in the fusion of the groups of phloem-elements in the axis, as obtains in *Amaranthus*.

Atriplex hastata, L., has its transition-characters in common with many species of *Amaranthus*, *Gomphrena*, &c. The main seed-leaf-bundle bifurcates at a relatively high level, and the separation of the two halves is so complete that the protoxylem appears in an isolated position at a level above the cotyledonary node. There is thus a close resemblance to *Amaranthus sylvestris*, the only difference, of degree rather than kind, in this respect being that in the last-named plant this isolation takes place at a much higher level. A minor feature of difference is that the main bundle may be accompanied in its passage down the petiole by two or three laterals on each side, not two as is the case in all the foregoing plants. These lateral strands join on to the adjacent halves of the divided central bundle at the cotyledonary node, and sometimes even in the top of the hypocotyl, a feature of resemblance to some of the foregoing plants, *Gomphrena haageana* for instance. Again, as in many species of *Amaranthus*, there is a marked delay in the union of the corresponding pairs of phloem-masses within the

hypocotyl; indeed, considering the advanced state of preparation in the cotyledons for the vascular rearrangements, the assumption of a proper root-structure takes place at a surprisingly low level.

A well-marked cotyledonary tube is present.

Atriplex littoralis, L. With regard to the features under discussion this plant is practically identical with *A. hastata*.

Atriplex thamnoides, ?, which has a much smaller seedling, shows some differences. It has no cotyledonary tube, the lateral bundles fuse on to the central one in the base of the blade of the cotyledons, and there is no undue delay in the fusion of the phloem-masses within the axis.

FIG. 2. *Obione portulacoides*.
Natural size.

Obione portulacoides, Moq. (Fig. 2). The seed-leaves are fleshy and the behaviour of their important vascular bundles, both in the cotyledon and in the axis, is precisely like those of *Atriplex hastata*. The laterals, however, vary pretty much; in the lower part of a seed-leaf there are, as is usual, two, one on each side of the divided central strand; of these some may die out, especially if very small, or may branch into two before coming to an end, or they may ultimately fuse with the central strand.

Spinachia oleracea, L. very closely resembles those species of *Beta* examined.

Kochia trichophylla, ?. The main features of the transition strongly recall those of *Calandrinia grandiflora*. Each seed-leaf, in its more basal region, has the usual bifurcated strand with two laterals on each side of it; of these, those situated immediately on either side of the central bundle fuse with it, whilst those placed on the outermost sides die out. As in some species of *Amaranthus*, *Atriplex*, and *Obione* there is a delay in the fusion of the phloem in the axis, but this is not so well marked in *Kochia* as in *Obione portulacoides*.

FIG. 3. *Salicornia europaea*. Two seedlings, one showing the epicotyl in a more advanced stage of development. Natural size.

Corispermum hyssopifolium, L., closely resembles *Kochia trichophylla*.

Salicornia europaea, L. The seedling of this plant (Fig. 3), and also of many other species of the genus, has two small fleshy cotyledons which fuse laterally towards the base to form a short cotyledonary tube or sheath. This tube becomes decurrent down the hypocotyl, forming a succulent 'cortex', a phenomenon exactly paralleled by the leaf-sheaths in the segments of the adult plant.

The distribution of the vascular bundles within the cotyledon is precisely

similar to that in the leaves of the mature plant, and may be understood best by tracing the strands outwards from the cotyledonary node (Diagram 3, Fig. 6). A single trace (*c. 1*) leaves the node and branches into three portions; of these the median strand (*c. 2*) divides up and supplies the free leaf-tip, whilst the two lateral strands (*c. 3* and *c. 4*) curve outwards and pass

DIAGRAM 3. *Salicornia*. Fig. 6 illustrates the vascular skeleton of one side of the upper part of a seedling. The dotted horizontal lines indicate the level of the sections represented in Figs. 1, 2, and 3.

downwards, their branches supplying the cotyledonary sheath and ultimately ending blindly in the aqueous tissue.

Tracing the strands downwards, in order to follow the transition, a section through the united cotyledons (Diagram 3, Fig. 1) shows numerous bundles which are the branches of the central cotyledonary strands. Considering one side only, these bundles unite, as the sections are traced downwards, to form one strand (*c. 2*) which, at the node, is joined by the lateral trunks *c. 3* and *c. 4*. Thus from each seed-leaf one endarch collateral bundle

(c. 1) enters the hypocotyl; these strands soon bifurcate and a well-marked rotation rapidly follows, the adjacent phloems unite, and a diarch root is organized according to type 3.

The bundles seen in the outer regions are, of course, the branches of the lateral strands (c. 3 and c. 4 on the one side) already referred to.

The endodermis of the root is well marked, and immediately surrounding it is an aerating zone.

The primary condition of the root is maintained downwards only for a very short distance, anomalous secondary thickening beginning even in the roots of quite young seedlings.

S. perennis, Mill., and *S. Smithiana*, Moss, are in all essential features similar to *S. europaea*.

SPIROLOBEAE.

Suaeda maritima, Dumort, is very like *Calandrinia Menziesii*, with the exception that the behaviour of the laterals is rather irregular; their number is variable and those adjacent to the central bundle may fuse with it, whilst others end blindly below. No cotyledonary tube is formed. As in *Kochia*, *Obione*, and others of the preceding plants, there is a delay in the fusion in the groups of cotyledonary phloem-elements in the axis.

Suaeda dendroides, Moq., has a much smaller seedling than the previous plant; the transition phenomena are, however, essentially similar. The only point of difference is that the lateral strands are disposed of at a higher level, and there is not much delay in the organization of a proper diarch root-structure.

Salsola Kali, L. Seedlings of this plant in different stages of development are shown in Fig. 4.

FIG. 4. *Salsola Kali*. In the two younger seedlings the cotyledons are still enclosed within the fruit. Natural size.

With regard to the transition phenomena, they are almost precisely similar to those of *Amaranthus caudatus*, the only difference being that in *Salsola* the protoxylems of the main seed-leaf-bundles are not so fully exarch at the cotyledonary node. With regard to other features, there is a well-marked cotyledonary tube in *Salsola*, and the palisade parenchyma, with its associated cells, of the upper part of the seed-leaves, which are centric in structure, is continued downwards in four columns to the cotyledonary node.

PHYTOLACCACEAE.

Phytolacca paraguayensis, ? , in most of its transition characters is very like *Amaranthus sylvestris*. There is the same division of the chief cotyledonary bundle and the isolation of the protoxylem-elements which takes place in the base of the blades of the seed-leaves. The only feature of difference is that in *P. paraguayensis* the union of the two laterals with the central seed-leaf-strand is effected at the extreme base of the petioles.

Phytolacca dioica, L., only differs from *P. paraguayensis* in the fact that the two halves of the main seed-leaf-bundle are more compact and their separation is less well marked.

Phytolacca acinosa, Roxb., which has a somewhat smaller seedling, does not show, so far as has been seen, the separation of the protoxylem of the cotyledons in the seed-leaves themselves; otherwise, its vascular rearrangements are like those of the two preceding species.

Phytolacca decandra. The transition phenomena of this plant, judging from Gérard's account,¹ do not appear to differ in any important feature from those of the foregoing species.

Rivina, which has been investigated by Dangeard,² also follows type 3, and so also does *Basella* (N.O. Basellaceae).

AIZOACEAE.

Mesembryanthemum. All the seedlings of this genus are of a fleshy habit, which is more marked in some than in others, and their cotyledons are more or less adnate. This union may be nothing more than the formation of a cotyledonary tube, as in *M. crystallinum*, L.; in other cases the adnation may be quite extensive, especially in the more fleshy forms, the seed-leaves being joined by their ventral surfaces for most of their length, as in *M. Bolusii*. Fig. 5 illustrates the two extreme forms of young seedlings; of the species examined, *M. linguaeforme*, *M. tigrinum*, Haw., and *M. truncatellum*, Haw., very closely resemble *M. Bolusii*, the chief differences being those of size; thus *M. tigrinum* is about half as large as *M. Bolusii*, and *M. truncatellum* about one-third or a quarter the size of this same plant, also it is more rounded. *M. crystallinum* resembles *M. tricolorum*, Haw., and *M. rhomboideum* is somewhat intermediate in appearance.

The transition phenomena are like those of many of the foregoing plants, *Calandrinia Menziesii* for instance. In *M. tricolorum*, *M. crystalli-*

FIG. 5. A. *Mesembryanthemum crystallinum*; B. *M. Bolusii*. Natural size.

¹ loc. cit.

² loc. cit.

num, and usually in *M. linguaeforme* the protoxylems of the cotyledonary strands are exarch before the bundles enter the hypocotyl. On the other hand, in *M. filamentosa*, *M. rhomboideum*, *M. trigrinum*, and *M. truncatellum* the protoxylems referred to are not fully exarch, sometimes even practically endarch, although the bundles may be opened like a V. This feature, however, is variable; thus in one seedling, e. g. of *M. rhomboideum*, the central seed-leaf-bundle of one cotyledon may be well divided, at a level immediately above the cotyledonary node, with its protoxylem mesarch or partly exarch in position, whilst the other bundle may show no division at all and the protoxylem endarch in position.

Before passing on, attention may be drawn to a peculiarity in some species of this genus which is unique in the plants examined.

In *Mesembryanthemum Bolusii* and *M. linguaeforme*, the two species with the fleshiest and largest cotyledons, the main central bundles of the seed-leaves are, for some distance above the cotyledonary node, surrounded by an irregular endodermis, not necessarily consisting of a single layer of cells, but often of two or three. In the more upper regions, the endodermis may not entirely enclose the bundle, but at lower levels, especially in *M. linguaeforme*, it is complete and singularly convincing. In *M. filamentosa* and *M. rhomboideum* this endodermis is not so extensive, but it forms a more or less complete sheath around the main bundles of the seed-leaves at the cotyledonary node. In these cases an endodermis surrounds the vascular tissues of the axis before the root-structure is organized.

Tetragonia expansa, Murr. The transition phenomena do not differ in any essential feature from those of *Mesembryanthemum*. The main cotyledonary strands bifurcate in the base of the blades of the seed-leaves, or in the top of the petioles, and their protoxylems become exarch before the bundles pass into the axis. The fusion of the laterals with the central strands takes place at a low level, just above the top of the cotyledonary tube.

NYCTAGINACEAE.

Abronia. The seedlings of the species of this genus examined, *A. umbellata* and *A. villosa*, are of interest from the fact that the cotyledons are very unequal in size. Fig. 6 represents a number of seedlings of different ages of *A. villosa*; it will be observed that in the younger plants one of the cotyledons is extremely small, whilst in the older plants it approximates more closely to the larger seed-leaf. In the youngest seedling (A) the rudiment of one seed-leaf is inserted on the axis at about the same level as the well-developed cotyledon, but in older seedlings, owing to the more rapid growth of the large cotyledon, the small one appears to be inserted lower down the hypocotyl. Also it will be ob-

served that the base of the hypocotyl, especially in the younger plants, is distinctly swollen and bears on one side a prominent peg or foot (*p*).

Charles and Francis Darwin¹ have drawn attention to these peculiarities in *A. umbellata* and *A. arenaria*, and have figured them in the former plant; they compare the swollen hypocotyl to a corm, and point out that the peg functions in rupturing the coat of the fruit.

Avebury² also has described the seedlings of *Abronia*, and remarks that in the seed one of the cotyledons is almost aborted and remains quite small for some time after germination. In *A. umbellata* it afterwards becomes the largest and grows like an ordinary leaf. He further remarks that the full-grown cotyledons of *A. arenaria* are very unequal in size.

Abronia umbellata, Lam. In the seedling about to be described there was one large and one small cotyledon. The large seed-leaf (Diagram 4, *c. 1*) has one large central bundle with many smaller ones on either side. Within the blade the central bundle divides into two and shows a certain amount of rotation, so that some, often only one or two, protoxylem elements become isolated between the two half-bundles which move apart (see Diagram 6, Figs. 1-4). This is comparable to what obtains in some of the preceding plants, *Amaranthus sylvestris* and species of *Gomphrena* and *Chenopodium* for instance. But in no case in these plants is the isolation so well marked as in *Abronia*, *Allionia*, and other Nyctaginaceae.

At the base of the blade the condition obtaining is shown in Diagram 4, Fig. 1; the laterals fuse on to the adjacent half-bundles, hence the petiole has two strands, the half-bundles referred to above, partly facing one another and with a small group of protoxylem elements between them (Diagram 4, Fig. 2). At a lower level the two large strands divide, each into two, and clearly are in the first stage of rotation (Diagram 4, Fig. 3). In this condition they enter the axis.

Turning now to the small cotyledon (*c. 2*), which is not nearly so well

FIG. 6. *Abronia villosa*. Natural size.

¹ C. and F. Darwin: The Power of Movement in Plants. London, 1880.

² Lubbock: On Seedlings. London, 1892.

differentiated as the larger, the central strand behaves in exactly the same way as the corresponding bundle of *c. 2* to begin with; that is to say, it divides into halves and isolates some protoxylem in the blade. The lateral bundles are not differentiated, consisting only of desmogen. Lower down (Diagram 4, Fig. 3), these desmogen strands fuse on to the adjacent halves of the central bundle, which do not divide as in the other cotyledon. Thus a transverse section through the top of the hypocotyl has the appearance indicated in Diagram 4, Fig. 4.

The bifurcated bundles derived from the large cotyledon undergo a vascular rearrangement, as a result of which each pair gives origin to a protoxylem pole situated in the intercotyledonary plane; then the two half-bundles derived from the small cotyledon fuse on to the adjacent

DIAGRAM 4. *Abronia umbellata*.

bundles derived from the large seed-leaf, and thus a tetrarch root-structure is arrived at (Diagram 4, Figs. 5–8).

For a relatively long distance downwards the intercotyledonary xylem poles are much the stronger, but eventually a gradual addition of protoxylem elements is made to the poles in the plane of the seed-leaves, so that equality is ultimately arrived at (Diagram 4, Fig. 9). Reduction, however, may take place; in one example, below the level of the peg, the intercotyledonary protoxylem rays diminished in size and disappeared, the corresponding phloem strands united, and a well-marked diarch root-structure resulted (Diagram 4, Fig. 10).

Minor variations in these changes may occur; thus the division of the two half-bundles of the large cotyledon may take place in the upper part of the hypocotyl, and not in the petiole of the seed-leaf, and the union of the

half-bundles derived from *c. 2* may unite with the corresponding strands from the other cotyledon, immediately before, or simultaneously with, the bifurcation of the latter (Diagram 5, which compare with Figs. 4 and 5 of Diagram 4). Finally, the root does not always show a reduction from tetrarchy to diarchy.

Abronia villosa, Wats. The vascular rearrangements resemble those of *A. umbellata* very closely; in fact the only difference found was in one example of *A. villosa*, in which only the two innermost laterals fused on to the neighbouring halves of the divided central bundle of the large seed-leaf. The others, two on each side, united together to form two large strands, so that the result was exactly the same as in *A. umbellata* (Diagram 4, Fig. 3).

In all the examples of these two species examined, the bundles from the larger cotyledon gave origin to three poles of the tetrarch root, whilst the bundles from the smaller seed-leaf gave rise to the smaller pole; this irrespective of the age of the seedling. It may also be remarked that the continuity between the isolated protoxylem elements in the petioles of the seed-leaves and the corresponding poles of the root may be interrupted, so that they are almost if not quite impossible to trace. This is doubtless due to the growth in length either rupturing or pulling together the soft walls of the annular vessels.

DIAGRAM 5. *Abronia umbellata*.

Allionia albida, Walt. The main features of the transition phenomena of this plant resemble those of *Abronia*, the chief differences which obtain being connected with the formation of those poles of the root situated in the intercotyledonary plane. The central bundle of each cotyledon gives rise, in the blade of the seed-leaf, to an isolated strand of protoxylem in the same way as in *Abronia* (Diagram 6, Figs. 1-4). In the upper regions of the petiole of each seed-leaf several strands occur (Diagram 6, Fig. 5): the two large bundles formed by the division of the main cotyledonary strand (*b. 1* and *b. 2*); two or three laterals on the outer sides of each of these (*a*); a few small bundles situated between the first two (*e*), and the group of protoxylem elements (*c. 1*). On tracing these downwards their number becomes less; thus the small medianly placed bundles (*e*) unite with the adjacent large ones, the half-bundles of the main cotyledonary strand, and the lateral strands unite together until there are but one or two on either side. There is also in the centre a group of protoxylem-elements (*c. 1* and *c. 2*) which are never numerous.

Either at, or immediately above, the cotyledonary node, or in the hypocotyl, the laterals *a* fuse on to the neighbouring half-bundles (Diagram 6,

Fig. 6), so that in the upper region of the hypocotyl (Diagram 6, Fig. 7) there occur two groups of protoxylem (*c. 1* and *c. 2*), four large bundles derived from the cotyledons (*b. 1* and *b. 2*, and *b. 3* and *b. 4*), and six plumular strands which soon fuse to form two (*d. 1* and *d. 2*, Diagram 6, Fig. 8). Tracing these bundles downwards, their behaviour is seen to be

DIAGRAM 6. *Allionia albida*.

very complicated; the protoxylems *c. 1* and *c. 2* retain their position, but the bundles *b. 1*, *d. 1*, and *b. 3* anastomose very freely, and so also do the corresponding strands on the other side. Concurrently the bundles *b. 1* and *b. 3*, and *b. 2* and *b. 4*, show certain rotatory movements which tend to bring their protoxylems into the intercotyledonary plane and into the exarch position, but for some space downwards these movements lead to nothing definite owing to the presence of the strands *d. 1* and *d. 2*, which

may give off branches which join on to the adjacent bundles. Eventually the plumular strands *d. 1* and *d. 2* join on to one of the bundles situated on their flanks (Diagram 6, Fig. 9), and a definite rotation of the protoxylems of the bundles *b* takes place (Diagram 6, Fig. 10); thus there is organized a tetrarch root-structure (Diagram 6, Fig. 11), which, however, in a very short vertical distance downwards gives place to a diarch arrangement. The phloem and metaxylem of *b. 1* and *b. 3*, and *b. 2* and *b. 4*, effect a junction and enclose the protoxylems which were derived from these same bundles (Diagram 6, Figs. 11 and 12). These protoxylems die out and thus there supervenes a diarch root-structure, the groups of tracheae *c. 1* and *c. 2*, which have gradually been increasing in number, forming the permanent protoxylems.

Mirabilis longiflora, L. The seedlings of this plant (Fig. 7) are large and have prominent epigeal cotyledons, often unequal in size, with long petioles inserted on a rather massive hypocotyl, at the base of which there is a conspicuous peg (*p.*).

The essential features of the transition phenomena resemble those of *Allionia albida*; but the structure of the hypocotyl is exceedingly complicated and is illustrated in Diagram 7.

The vascular changes in the cotyledons are so like those of *Allionia* that no further description is necessary (see Diagram 6, Figs.

1-6). At the top of the hypocotyl, as in *Allionia*, there obtain two isolated groups of protoxylem-elements—four large vascular bundles (*c. 1*, *c. 2*, *c. 3*, and *c. 4*) derived from the cotyledons, and two masses of plumular vascular tissue (*p*). Tracing these bundles downwards, the plumular vascular tissue passes outwards between the strands *c. 1* and *c. 3*, and *c. 2* and *c. 4*, deploys on either side, and breaks up into isolated vascular strands (*p*), which sometimes consist only of phloem (Diagram 7, Figs. 2, 3, and 4). Concurrently the

FIG. 7. *Mirabilis longiflora*. Natural size.

large bundles (*c.* 1–*c.* 4) give off branches of phloem and xylem which follow the path taken by the plumular tissue and reinforce it as it were. Hence, although these plumular bundles are marked *p* in the Diagram, in order to indicate their nature, it must be understood that at levels below the second figure of Diagram 7 they contain also vascular elements derived from the cotyledonary strands. During these changes the original bundles, *c.* 1, *c.* 2, *c.* 3, and *c.* 4, have each divided up into three; thus *c.* 1 gives origin to *c.* 5 and *c.* 6, *c.* 6 again dividing to form *c.* 15 and *c.* 16; on the other hand, *c.* 4 divides directly into three, namely *c.* 10, *c.* 11, and *c.* 12 (Diagram 7, Figs. 3 and 4). At this level (Diagram 7, Fig. 4) the plumular bundles are clearly defined, and form a zone surrounding the cotyledonary ring of bundles; that is to say, a similar anomaly of scattered bundles obtains in the hypocotyl as in the stem, although arrived at in a different way. Amongst the smaller cotyledonary bundles there is a general movement outwards so that they ultimately come into line with the plumular traces; *c.* 9, *c.* 11, and *c.* 15 are among the first to show this tendency, and in so doing fusion with certain plumular strands may take place. For instance, the two small bundles immediately above *c.* 15 (Diagram 7, Fig. 5) join together and then fuse on to *c.* 15; also *p.* 5 and *c.* 11 effect a junction. Meanwhile the centrally placed cotyledonary bundles show changes, the most interesting of which are the formation of bicollateral structures which result from a strand of xylem passing from the normal wood to a position on the outer side of the phloem. For example, in *c.* 7 such a strand passes between this bundle and *c.* 16 outwards, and rests on the outer side of the phloem (Diagram 7, Figs. 4, 5, 6, and 7). On the opposite side of the axis the corresponding xylem is derived from *c.* 13, and comes to rest on the adjacent bundle, *c.* 12. This appears to be the usual mode of origin of the abnormality, but exceptions occur; thus in another example of *M. longifolia* it was, on one side only of the axis, arrived at in a modified way. In Diagram 7, Figs. 12 and 13, there are represented three cotyledonary strands, *c.* 1, *c.* 2, and *c.* 3, and one plumular strand, *p*. This latter consists almost entirely of phloem, but xylem-elements pass outwards from *c.* 1 and *c.* 2 and divide into two parts, one of which accompanies and completes the bundle *p* (Diagram 7, Fig. 13), and the other for the moment is isolated, then it is joined by a strand of phloem from *c.* 2, so that there is formed, between *c.* 1 and *c.* 2, a collateral bundle showing reversed orientation, which quickly effects a junction with *c.* 1.

Directly after these bicollateral bundles have been organized there is a junction of three bundles to form one situated in the intercotyledonary plane: thus *c.* 16, *c.* 7, and *c.* 8 join to form *c.* 17, and *c.* 13, after its division into two, combines with *c.* 12 to form *c.* 18 (Diagram 7, Figs. 4, 5, and 6). Thus there are formed two large bicollateral bundles with xylem on both sides of the phloem, and in them the extension outwards of the normally

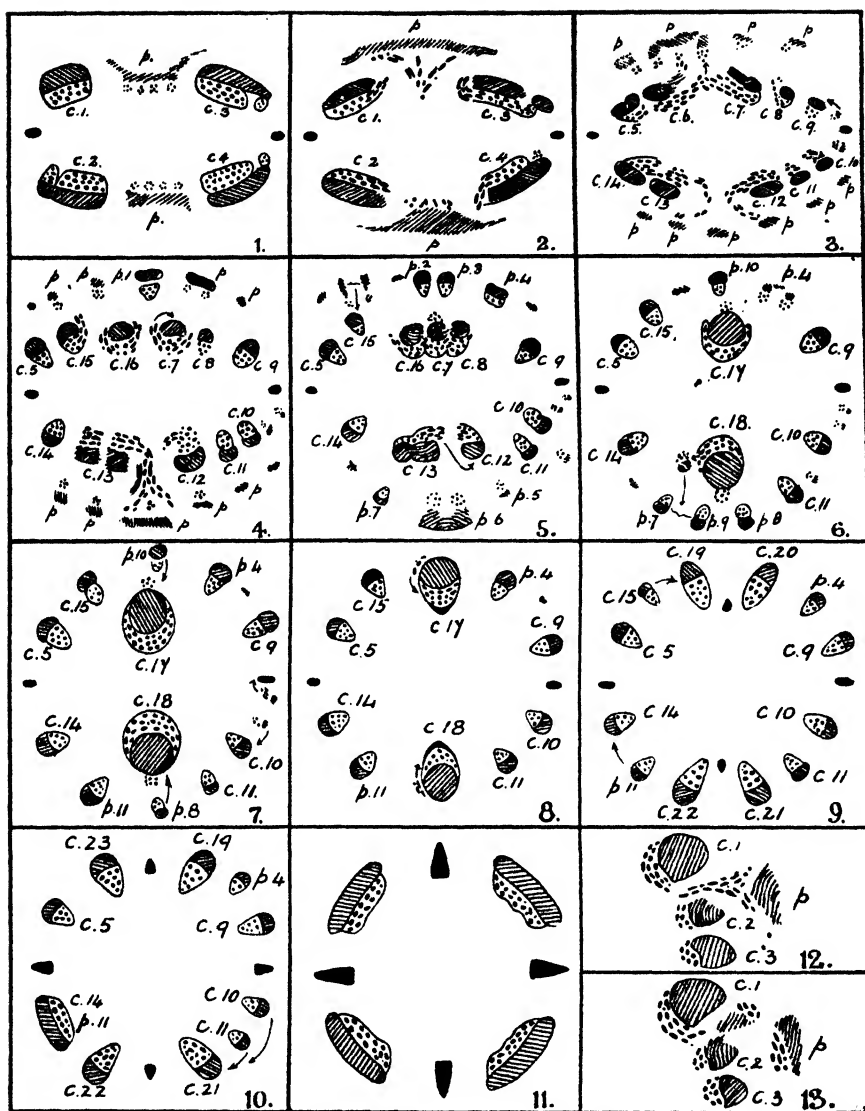

DIAGRAM 7. *Mirabilis longiflora*. Explanation:—c. indicates the bundles derived from the cotyledons; p. represents those of plumular origin. Whenever one important bundle fuses with another, or divides into two, the resulting strands are indicated, when necessary, by the next available higher figures. For instance, c. 1 (Fig. 1) divides into two; the next available numbers are c. 5 and c. 6, so these are used to represent the two branches (Fig. 3). Again, c. 17 (Fig. 8) divides into c. 19 and c. 20, then c. 15 and c. 19 join and so there is formed c. 23 (Fig. 10). Further than this the numbers are meaningless.

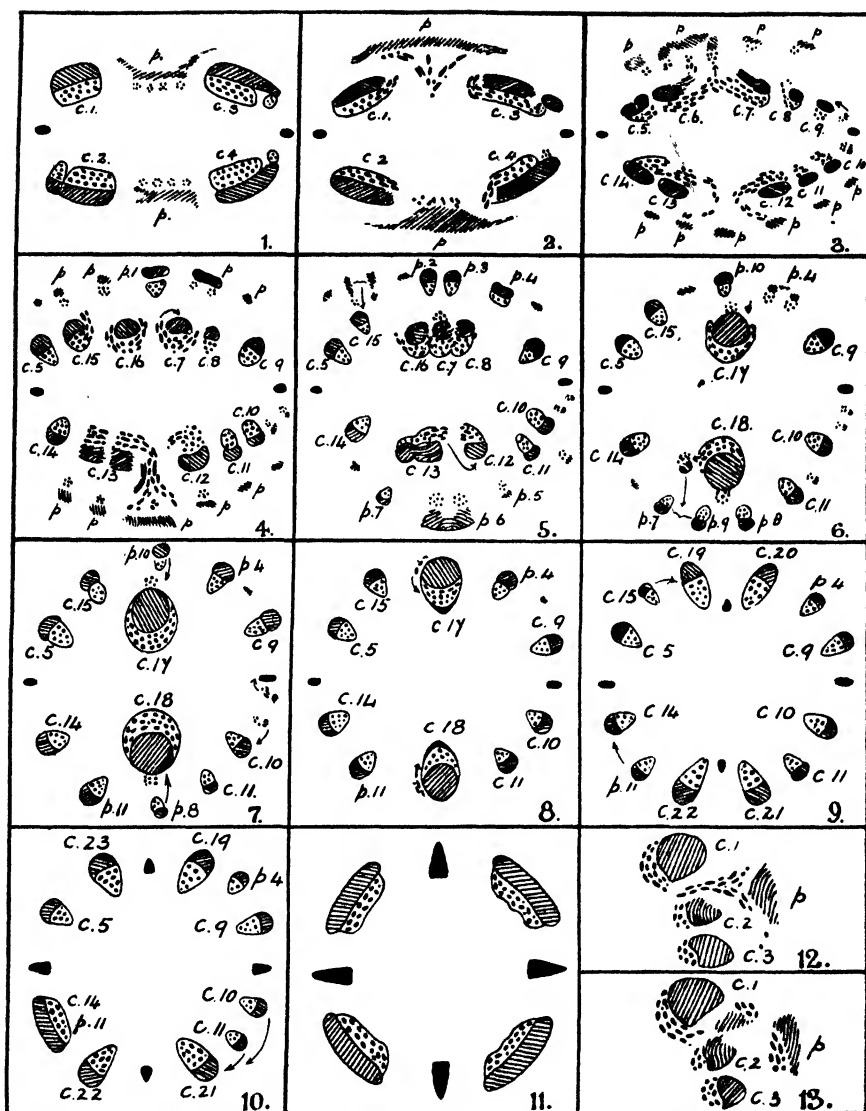

DIAGRAM 7. *Mirabilis longiflora*. Explanation:—*c*. indicates the bundles derived from the cotyledons; *p*. represents those of plumular origin. Whenever one important bundle fuses with another, or divides into two, the resulting strands are indicated, when necessary, by the next available higher figures. For instance, *c*. 1 (Fig. 1) divides into two; the next available numbers are *c*. 5 and *c*. 6, so these are used to represent the two branches (Fig. 3). Again, *c*. 17 (Fig. 8) divides into *c*. 19 and *c*. 20, then *c*. 15 and *c*. 19 join and so there is formed *c*. 23 (Fig. 10). Further than this the numbers are meaningless.

placed xylem may be so extensive as to make them almost concentric (Diagram 7, Figs. 6 and 7), a tendency shown also by the bundles of the stem.¹

While these changes have been taking place the plumular strands have not been idle; *p.* 1 divides into two, *p.* 2 and *p.* 3, but only to rejoin (*p.* 10, Diagram 7, Fig. 6). Also, the strands *p.* 4 and *p.* 6 (Diagram 7, Fig. 5) branch into two; the two branches of the former recombine (Diagram 7, Figs. 6 and 7), but not so the latter (*p.* 8 and *p.* 9). The changes at lower levels are much less complex; the large strand *c.* 18 gives off a slender lateral branch (Diagram 7, Fig. 6) which fuses on to *p.* 7 and *p.* 9, these three forming the larger bundle, *p.* 11 (Diagram 7, Fig. 7). Further, there is a general clearing up of the smaller plumular traces; *p.* 10 joins on to *c.* 17, similarly *p.* 8 unites with *c.* 18, the small strand on the right side of *c.* 10 joins with this bundle, and the xylem of the similar strand just below the right-hand protoxylem joins on to the protoxylem, whilst its phloem comes to an end (Fig. 7). Finally, the abnormally placed xylem elements in *c.* 17 and *c.* 18 creep inwards and join on to the normal wood (Diagram 7, Fig. 8). Thus there is formed a ring of collateral bundles, some of which consist mostly of cotyledonary vascular tissue and two, *p.* 4 and *p.* 11, mostly of plumular vascular tissue, from which the root-structure is organized. Of the root-structure, two xylem poles, those in the plane of the cotyledons, are already in position; the other two are formed in this wise: the two large bundles, *c.* 17 and *c.* 18 (Diagram 7, Fig. 8), divide, each into two; the halves do not show any rotation comparable to what obtains in so many of the foregoing plants, but move apart, leaving the protoxylem isolated (Diagram 7, Fig. 9). There is then a general centripetal displacement, so that the bundles intervening between the four groups of protoxylem-elements fuse to form four large strands, and thus a tetrarch root-structure is organized (Diagram 7, Fig. 11).

Leaving out of consideration the extraordinary series of anastomoses, it will be seen that the type of transition is the same as in *Allionia*. In brief, two protoxylems are isolated in the seed-leaves themselves, the cotyledonary traces enter the axis and form four large bundles (*c.* 1-*c.* 4), the corresponding pairs of which give origin to the two protoxylem poles situated in the intercotyledonary plane.

The main differences between the two plants are these: whereas in *Allionia* the tetrarch arrangement gives place to a diarch root-structure, in *Mirabilis* the tetrarch structure, so far as our observations show, persists; but this is not constant for the genus, for in *M. divaricata* reduction to diarchy takes place, and the same also applies to *M. multiflora*. Further, in *Allionia* the anastomoses between the bundles in the hypocotyl, although

¹ Solereder: Systematic Anatomy. Oxford, vol. ii, 1908, p. 647.

complex, are not nearly so complicated as in *Mirabilis*, nor do the bundles form two distinct zones.

M. divaricata, Lowe, in essential features is like *M. longiflora*, only two points of difference having been observed: in *M. divaricata* the bundles corresponding to *c.* 17 and *c.* 18 in Diagram 7 are never collateral, and the tetrarch root-structure becomes reduced to diarch.

M. multiflora, A. Gray. Out of a large sowing there was obtained but one seedling, which was of interest owing to the small size of one cotyledon (Fig. 8) and to the presence of a prominent peg. Unfortunately an accident happened to the series of microtomed sections, so that we have no observations to make regarding the structure of the upper part of the hypocotyl; sufficient preparations remained, however, to indicate pretty strongly that the fundamental features of the transition are essentially the same as in other species of *Mirabilis*. As has already been remarked, the tetrarch root-structure becomes reduced to diarch.

This also is true of *M. Jalapa*, for Van Tieghem¹ found that out of ten seedlings examined six had diarch roots and four tetrarch.

From Gérard's² account it is clear that the transition phenomena of *M. Jalapa* are of the same nature as those of the species described above, particularly *M. divaricata*, for *M. Jalapa* shows the same reduction of tetrarchy to diarchy.

FIG. 8. *Mirabilis multiflora*.
Natural size.

With regard to the behaviour of the traces within the hypocotyl we are not in agreement. Gérard observed the double series of bundles (Diagram 7, Fig. 5), but he considered that those of the cotyledonary series, not the plumular, moved outwards to form the outer zone (see Diagram 7, Figs. 2 and 3). Apparently also Gérard did not make any observations on the behaviour of the bundles within the cotyledons, and therefore did not realize that the transition really begins—or ends, according to the direction the tracing is done—in the seed-leaves; consequently we do not agree that the protoxylems of the root play no part in the orientation of the bundles.

SUMMARY AND CONCLUSION.

1. The transition phenomena of all the seedlings examined of the Natural Orders Portulacaceae, Caryophyllaceae, Amarantaceae, Chenopodiaceae, Phytolaccaceae, and Aizoaceae follow Van Tieghem's type 3; whilst those of the Nyctaginaceae follow a course which at first sight appears distinctive, but is clearly a modification of this same type.

¹ loc. cit.

² loc. cit.

2. In all the first-named orders the differences which obtain between the various species are chiefly connected with the levels at which the transition phenomena first appear and end, and the level at which the lateral strands of the seed-leaves effect a junction with the divided central cotyledonary bundle.

3. With regard to the first point, the plants may be divided roughly into three classes:

A. The bundle from each cotyledon enters the hypocotyl in an undivided state, with the protoxylem in the endarch position. Examples: *Claytonia perfoliata*, *Pupalia purpurea*, *Salicornia europaea*, *S. perennis*, and *S. Smithiana*.

B. The main seed-leaf-bundle bifurcates at a level just above the cotyledonary node. Examples: *Dianthus barbatus*, *D. arenarius*, *Lychnis Viscaria*, *Gypsophila Saxifraga*, *Saponaria cerastoides*, *S. Vaccaria*, *S. vulgaris*, *Tunica prolifera*, *Cerastium perfoliatum*, *Stellaria graminea*, *Mesembryanthemum* spp., *Cucubalus baccifera*, and *Spergularia salina*. Of these the first one is intermediate between Classes A and B, whilst the last two are intermediate between Classes B and C.

C. The main seed-leaf-bundle bifurcates at a much higher level, sometimes even in the base of the blade of the cotyledon.

All the other species examined, and these comprise the majority, fall into this class; of them, the following show the isolation of the protoxylem-elements either in the petioles, e.g. *Atriplex hastata*, or in the lower regions of the blade of the cotyledon, e.g. *Amaranthus sylvestris*, *Gomphrena Haageana*, *G. globosa*, *Phytolacca paraguayensis*, and *P. dioica*.

This feature is not constant in the genera; thus *A. sylvestris* was the only species of the genus *Amaranthus* which exhibited it; also it was not observed in *Phytolacca acinosa*.

Another character shown by some of the members of this class is the delay in the fusion of the phloem-masses of the otherwise normal diarch root-structure. Examples: All species of *Amaranthus* and *Beta*, *Atriplex hastata*, *A. thamnoides*, *Obione portulacoides*, *Kochia trichophylla*, and *Corispermum hyssopifolium*.

4. With regard to the second point, relating to the lateral bundles, it may be remarked that in very few cases are these strands corresponding in importance to the laterals, say, of *Dahlia Merckii*; also it is rather difficult to make a satisfactory classification, for much depends on whether the seed-leaves have well-marked petioles or not. Roughly, the plants examined fall into two categories:

A. Those in which the lateral bundles of the blade do not extend down to the cotyledonary node but fuse on to the main seed-leaf-strand at the top of the petiole or a relatively high level. This is constant in the Portulacaceae, and in the Caryophyllaceae with the exception of *Saponaria*.

S. cerastoides conforms to type, whilst *S. Vaccaria* and *S. vulgaris* fall into the next category. Of the Aizoaceae, *Mesembryanthemum*, the cotyledons of the species of which show no differentiated petioles, is to be included in the present class, whilst *Tetragonia* is to be placed in the next.

B. Those in which the lateral strands, generally one on either side of the main bundle, extend down as far, or nearly as far as the insertion of the seed-leaves, or in some cases even into the hypocotyl, before fusion with the central strand takes place. Examples: The Amarantaceae, with the exception of *Amaranthus sylvestris* and species of *Gomphrena*, which approach Class A; the Chenopodiaceae, with the exception of *Chenopodium ambrosioides*, *C. Botrys*, *Atriplex thamnoides*, *Kochia*, *Corispermum*, and *Suaeda dendroides*, which belong rather to the previous class; and, lastly, the Phytolaccaceae.

5. A comparative examination of these facts shows that differences sometimes occur in different examples of one species; the dissimilarities between some species of a genus may be greater than the differences between genera; further, *Pupalia*, *Claytonia*, and *Salicornia*, genera widely separated, show very close resemblances.

6. With regard to the Nyctaginaceae, the transition phenomena may be looked upon as a modification of type 3, for after each cotyledonary strand has bifurcated and isolated within the blade of the seed-leaf those protoxylems situated in the cotyledonary plane, corresponding bundles from opposite sides together form the two protoxylem poles situated in the intercotyledonary plane. To this, however, *Abronia* is an exception, three poles of the root-structure being formed from the bundles of the larger cotyledon, and the remaining pole from the vascular tissue derived from the smaller seed-leaf.

7. A connexion between the Nyctaginaceae and the other Natural Orders of the Cohort may be traced. For example, in *Amaranthus sylvestris*, *Gomphrena globosa*, *G. Haageana*, *Phytolacca paraguayensis*, and *P. dioica*, the protoxylem is isolated in the cotyledons; in *Amaranthus*, *Gomphrena*, and other plants there is, in the axis, a delay in the fusion of the four phloems; in other words, for a certain distance downwards the structure is incompletely tetrarch. In this connexion it will be remembered that it is not at all uncommon for the initial tetrarch structure in the Nyctaginaceae to be reduced to diarch.

8. Without entering into any theoretical considerations—they will be published later—it may be pointed out that the Nyctaginaceae have by far the largest seedlings as compared with the other Natural Orders of the Cohort; that the vascular bundles of the large cotyledon of *Abronia* form three of the four poles of the root-structure, the remaining one being from the traces of the small seed-leaf; and that in the much smaller seedlings of the orders other than the Nyctaginaceae a difference is often found in the

structure of two seedlings of a genus which are of different sizes. Thus the seedling of *Saponaria Vaccaria* is much larger than that of *S. cerastoides*; in the former plant the laterals fuse on to the central bundle of the seed-leaf at a much lower level than in the latter plant. *Spergularia salina* and *Spergula arvensis*, *Atriplex littoralis* and *A. thamnoides*, *Suaeda maritima* and *S. dendroides*, and *Phytolacca acinosa* and *P. dioica* are further examples. Also it may be mentioned that amongst the smallest seedlings examined were those placed in Class A (par. 3), and these exhibited the simplest structure. These facts, together with others of similar nature observed in other classes—for instance, the Gymnosperms—suggest that the transition phenomena may depend on the relative abundance and the distribution of the cotyledonary vascular supply, which is in turn influenced by various factors. This will receive more particular attention in our next contribution to the subject.

9. With regard to features of interest not directly connected with transition phenomena, the presence of an endodermis around the cotyledonary bundles of certain species of *Mesembryanthemum* may be referred to.

In conclusion we desire to express our thanks to Mr. Hales, the Curator of the Chelsea Physic Garden, for his never-failing kindness in rearing seedlings for our use.

Cordaites Felicis, sp. nov., a Cordaitean Leaf from the Lower Coal Measures of England.

INTRODUCTION.

IT is not uncommon to meet with Cordaitean leaves in the petrified material from British Coal Measures. As a rule, however, the fragments are badly preserved, and beyond the fact that some of them bore a general resemblance to *Cordaites Wedekindi*, Felix,¹ little has been observed about them.

In two blocks recently presented to me by Mr. Sutcliffe from his mine at Shore, Littleborough, specimens have been met with which are better preserved, and were therefore photographed. A few of these photographs have been reproduced on Pl. XXII, and a camera drawing of a single bundle is reproduced as a text-figure.

Although these new specimens bear a somewhat close resemblance, as above said, to *C. Wedekindi*, other sections more closely resemble the other two forms described by Prof. Felix under the names of *C. loculosus* and *C. robustus*. For this reason, and because a closer comparison revealed constant minor differences from all three forms, it has seemed necessary to refer to the new specimens under a different specific name.

The name *Cordaites Felicis* has been selected because of the much closer affinity they show to Prof. Felix's forms than to any of the French forms.

¹ Felix: Steinkohlen-Pflanzen. Preuss. Geol. Special-Karte (Abhandlungen), Bd. vii, 1885-7

[Annals of Botany, Vol. XXVI. No. CI. January, 1922.]

All the micrographs on Pl. XXII (except Fig. 11) are taken from specimens in a single series from the same boulder. The expense of the work has been in part defrayed by a contribution from the Royal Society Government Grant Committee.

GENERAL ACCOUNT OF THE LEAF.

As may be seen by reference to the micrographs, the specimens exhibit a considerable range of structure, but there seems to be no ground for supposing that more than one species is represented. In the leaves of some recent Conifers, as was shown by Seward and Ford in their monograph on the Araucarieae,¹ the leaf bundles may be diploxylic near the apex, but show no centripetal xylem at the base. Maslen also points out² that the absence of centrifugal primary wood in the specimens described by Dr. M. C. Stopes³ may be due to their having come from distal parts of the leaf, adding: 'Until sections of the lamina of *Mesoxylon Sutcliffii* have been identified, it will be impossible to determine to what extent the centrifugal portion of the bundles persists out into the leaves.'

In the specimens under consideration the thicker parts of the lamina contain bundles with a fair development of centrifugal wood and the bundles are frequently shown in the process of division (Figs. 5 and 6).

In thinner parts of the lamina (i. e. presumably more distal or more peripheral), the centrifugal elements become smaller, are relatively few in number, and in some cases are absent altogether.⁴

The distribution of the sclerenchyma is different in the thicker from that in the thinner parts of the lamina. In the former there is an almost, if not quite, continuous hypodermal layer beneath each surface. In the thinner parts of the leaf the hypodermal layer is interrupted, but both regions of the leaf show supporting plates vertical to the surfaces of the leaf. These plates form complete partitions running the length of the leaf between the bundles and alternating with them (Fig. 3).

They appear in transverse section like columns, and are the more interesting as they do not occur in any of the forms described by Grand'Eury or Renault. They are well represented, on the other hand, in the forms described by Felix, e. g. *C. Wedekindi*, *C. loculosus*, and *C. robustus*. As in most Cordaitean leaves so far described, the vascular bundle is surrounded by a sheath attached to both surfaces by thickening in

¹ Seward and Ford: The Araucarieae, Recent and Extinct. Phil. Trans. Royal Soc., B, vol. cxcviii, 1906, p. 370.

² Maslen: The Structure of *Mesoxylon Sutcliffii* (Scott). Annals of Botany, vol. xxv, 1911, p. 406.

³ Stopes: On the Leaf Structure of *Cordaitea*. New Phytologist, vol. ii, 1903.

⁴ It seems open to question whether this statement is strictly justifiable, as the inner sheath, which appears to represent the centrifugal xylem, is generally present even when the more central elements are undifferentiated (vide Figs. 8 and 10).

the hypoderm. In *C. Felicis* there are also thickened masses of hypoderm between the bundle strand and the partitions (Fig. 10). On the upper surface these masses are surrounded by but slightly differentiated palisade, while on the lower they are surrounded by the lacunar tissue connected with the stomatiferous epidermis.

The horizontal section shown in Fig. 3 is equidistant between the upper and lower surfaces of the leaf and thus escapes the hypodermal masses. The vascular bundles with their well-developed sheaths are approximately circular in section (Fig. 10), and relatively to the thickness of the leaf are larger than those of *C. Wedekindi*, Felix. In the parts of the leaf where division is most frequent, the bundle sheath is scarcely differentiated (Fig. 5). Correlated with the absence of the sheath the partition is more strongly constructed (Figs. 2 and 5), and the specimen approximates to the *C. robustus* type of Felix.

When present the sheath is composed of layers of longitudinally disposed fibres. In some cases pits are shown on their walls, but as a rule the later deposited thickening layers of the wall are dissolved before petrification, and the pits are then no longer distinguishable.

The innermost layer of the sheath is generally composed of cells of narrow calibre, and so the abaxial region of the bundle is partially composed of cells like those of the centrifugal primary xylem, which they slightly exceed in size. This sheath may be present even when no normal centrifugal elements may be differentiated (Fig. 8, *Is*).

To turn to the vascular elements proper, we note that the upper part of the xylem consists of a few large, porose, centripetal tracheides which increase in number as the leaf thickens. A considerable number may be present in the basal part of the leaf, especially when the bundle is dividing (Fig. 6). In the non-dividing bundle the centripetal wood radiates off from a small protoxylem group, which in turn is often separated from the centrifugal elements by a layer of parenchyma. In transverse sections the centrifugal elements, which are small and spiro-reticulate, lie in an irregular crescent which reaches to the periphery of the centripetal wood above and the small-celled inner sheath laterally. Thus, if we regard the tracheides of the inner sheath as primary transfusion tissue derived from xylem, there seems more reason to connect it with the centrifugal xylem than with the centripetal. It will be observed from the text-figure that the tracheides of the inner sheath (*Is*) are of slightly wider calibre than those intervening between them and the protoxylem (*Px*).

It is possibly the increasing development of this inner sheath in later forms that explains the more common absence of centrifugal wood in *C. principalis* as described by Dr. Marie C. Stopes. Below the centrifugal elements is a layer of xylem parenchyma which again is succeeded by the phloem (text-figure, *P*).

The specimens which are here regarded as representing the thicker parts of the leaf of *C. Felicis* correspond in structure much more closely to the forms called *C. robustus* and *C. loculosus* by Felix. That such forms represent the non-assimilating part of the leaf seems obvious from their structure, as there is no apparatus for gaseous exchange with the external atmosphere. Moreover, they occur with sections possessing a stomatiferous surface,¹ and all grades of intermediate structure occur. The treatment of such forms by Felix as different species has rendered it necessary to apply a new specific term to the new type, as it is impossible to identify it with any one by itself of the three forms described by Felix. Otherwise it might

TEXT-FIG. Transverse section of a single bundle surrounded by its sheath. $\times 225$. The centripetal wood (x') is in marked contrast with the centrifugal (x). The protoxylem (Px) is separated by a single layer of parenchyma from the centrifugal wood. The elements of the centrifugal wood which contribute to the inner sheath (Is) are larger than the intervening elements. The inner sheath is limited to the abaxial part of the bundle, but the outer sheath is well developed all round the bundle. Some of the phloem elements are indicated by the letter P . Shore, C. N., 72. 1.

have been best to avoid introducing a new specific term on differences which do not amount to much more than that of size and robustness of development (*vide* next section).

¹ Felix: loc. cit., p. 62. 'Other leaves of this species, i.e. *C. Wedekindii*, occur in the section from the Kgl. geol. Landesanstalt, No. 109.' It was in this section that the specimens called *C. loculosus* occurred (*vide* p. 71).

COMPARISON OF THE NEW SPECIMENS WITH *C. WEDEKINDI*,
C. LOCULOSUS, AND *C. ROBUSTUS*, FELIX.

The dimensions of the various parts have been ascertained by my friend, Miss Lockhart, B.Sc., and comparison made with those cited by Felix for his forms. It is found that the leaf decreased in thickness from the parts where division of the bundles was taking place (Figs. 5 and 6) to the parts where division seems to have ceased (Fig. 10).

The thickness also decreased from the centre to the periphery. The margin of the leaf for about a width of 2 millimetres was not more than 19μ in thickness. From the data available the whole width cannot have been less than 16 mm.—possibly more, but no complete transverse sections are available. The thickness ranges from 19μ to 88μ , but Felix reports for *C. Wedekindi* a range from 82 to 99μ . The space intervening between the partitions ranges from 47μ to 60μ , whereas Felix reports a range from 55 to 66μ . The partitions are seldom less than three fibres in width and often show five even in the upper parts of the leaf (Fig. 10, *Pa*).

In *C. Wedekindi*, on the other hand, even where division of the bundle is still taking place, the partitions are shown to be comparatively thin.¹

The bundle sheath in the new species is also relatively better developed than in *C. Wedekindi*.

In *C. Felicis* the leaf parenchyma is built up of transversely running strands of cells which are slightly elongated in the direction at right angles to the bundles. These strands show very narrow crevices between them which are exaggerated by the shrinkage of the cells in Fig. 3. The lacunae do not show in transverse sections of the leaf, as the sections are thicker than the cells or the lacunae. They can be detected with difficulty in longitudinal sections taken vertically to the surface between the bundles (Fig. 4), but are always clearly seen in horizontal sections (Fig. 3).

No crystals have been observed, though the cells occasionally show blackened contents—a state of preservation which appears to correspond in the bundle sheath with an incomplete differentiation of the fibre.

Thus *C. Felicis* appears to be a leaf of relatively robust build than *C. Wedekindi*. It has a much wider range of structure than was attributed to *C. Wedekindi* by Felix—the term being used to include forms which somewhat resemble *C. loculosus* and *C. robustus*, Felix. The latter, however, like the '*Wedekindi*' form, exceed the basal sections of *C. Felicis* in size, for the section of '*C. robustus*' described reaches a thickness of 115μ as compared with the 75μ reached by a section of *C. Felicis* in what I regard as a corresponding plane (Fig. 5).

¹ Felix: loc. cit., Pl. III, Fig. 4 (the only published figure of this species).

COMPARISON OF *C. FELICIS* WITH RENAULT'S SPECIES,
'*C. PRINCIPALIS*', ETC.

Renault describes and figures six forms under the specific names *C. tenuistriatus*, *C. angulosoistriatus*, *C. rhombinervis*, *C. crassus*, *C. linguatus*, and *C. principalis*. The two last-named species have been further examined by Dr. M. C. Stopes.¹ These forms all differ from *C. Wedekindi*, Felix, and from the new species in having only incomplete partitions between the bundles. The horizontally extended strands of cells of the leaf parenchyma are thus continuous from one bundle to the next in the median horizontal plane of the leaf. Three of the species—*C. rhombinervis*, *C. linguatus*, and *C. tenuistriatus*—show much better differentiated palisade than occurs in *C. Wedekindi* or *C. Felicis*.

The use of the specific term '*Felicis*' for the new species seems therefore doubly appropriate, as it is obviously much more nearly related to the species described by Prof. Felix than to any other described species, and possibly both may have to be placed in a new genus when attribution to their parent plants is possible.

That such an end may be achieved in the near future is rendered more probable by the announcement of a new genus of Cordaitales on stem characters by Messrs. Scott and Maslen in 1910.² It may also be worth while to put on record that at least ten specimens of the supposed Cordaitean seed *Mitrospermum compressum*, Will.,³ occurred in close association with the specimens of the Cordaitean leaf described and figured in this paper.

DIAGNOSIS OF *CORDAITES FELICIS*, SP. NOV.

Leaf of the general Cordaitean type with numerous parallel collateral bundles. Each bundle is surrounded with a well-developed sheath except in the thicker, presumably basal, part of the leaf.

Alternating with the bundles are complete fibrous partitions also disposed longitudinally.

The centripetal elements of the mesarch xylem are better developed than the centrifugal, and consist of two or more tracheides with porose marking. The centrifugal xylem is more abundant in the thicker parts of the leaf and is shown best in the region, presumably basal, where the bundles are dividing. Elements similar to the centrifugal wood partially line the abaxial part of the bundle sheath, and it is suggested they may

Development and Sexuality of some Species of *Olpidiopsis*, (Cornu) Fischer.¹

BY

J. T. BARRETT, Ph.D.

Associate in Botany, University of Illinois.

With Plates **XXIII-XXVI.**

I. INTRODUCTION.

TO students of the lower Fungi, there is an especial interest attached to the genus *Olpidiopsis*, because it is one of the few genera of the Chytridiales that possess a supposed sexual stage. There is also an interesting relation, historically, between the genus and other closely related forms, which emphasizes the danger of hasty conclusions made on imperfect and insufficient observations.

The genus *Olpidiopsis* was founded by Cornu (6), and although he did not diagnose the genus, it seems strongly probable that the main distinctive character was the presence in the life-history of its members of a resting spore to which was attached an empty smaller cell, called by him the 'cellule adjacente'. This term was, of course, indefinite, and although Cornu believed there existed a sexual relation between the two cells, he had no definite evidence.

Since the first recorded observation of a parasitic fungus on a member of the Saprolegniaceae by Nägeli (18), the same or closely related species have occasionally been described by various observers. In certain cases, the resting spores, which are known to be so necessary for the correct determination of the species, were not observed, hence we have no assurance what the forms were. However, the literature concerning these forms previous and subsequent to the founding of the genus *Olpidiopsis* is so related in one way or another, that it seems advisable to give a brief review of it here.

As stated above, the first reference to one of these organisms parasitic on the Saprolegniaceae was made by Nägeli in 1846. He observed in the swollen hyphae of what he called *Achlya prolifera*, now supposed to have been *Saprolegnia ferax*, elongated oval structures which eventually discharged their contents, as small motile bodies, to the exterior through

¹ Contribution from Department of Botany, Cornell University, 142.

[Annals of Botany, Vol. XXVI No. CI. January, 1912.]

a slender tube which perforated the wall of the enclosing hypha. These oval cell-like structures were considered by him as asexual propagative bodies of the *Achlya*. Cienkowski (5), who carefully illustrated and described the development of a similar organism in the swollen hyphae of *Achlya prolifera*, considered the oval bodies as a third form of sporangia of the host. He discovered and figured for the first time what he called 'Stachelkugeln', spiny spheres or resting spores. He did not observe their germination.

About the same time Alexander Braun (2) reported, after a long search, that he had succeeded in finding, in a few hyphae of a characteristic form of *Saprolegnia* on a sick but still living *Limneus minutus*, the oval bodies described by Nägeli. Some of these were empty, while others were still filled with dark granular protoplasm. He did not observe the discharge of the contents of any of these bodies, but from his own observations and from those previously made by Nägeli, he assumed that the structures concerned were not propagative organs, but parasites of the host. Braun placed the species in his new genus *Chytridium* with the name *C. Saprolegniae*, and considered the cell-like structures as zoosporangia and the motile bodies as zoospores.

Pringsheim (20), in his work on the sexual organs of the Saprolegniaceae, figures and describes the same or a similar organism. He, however, opposed the view of Braun in that he was inclined to interpret the oval or elliptical bodies found in the hyphae of *Saprolegnia ferax*, whose oogonia are unaccompanied by male organs, as antheridia, and the zoospores as motile spermatozooids. He also found accompanying the smooth sporangia the 'Stachelkugeln' of Cienkowski. Concerning these he says in part (p. 225): 'Diese Kugeln mit stacheliger Hülle treten entweder isoliert auf oder untermischt mit jenen anderen Körpern, welche eine glatte Hülle besitzen. Man könnte nun geneigt sein, diese Stachelkugeln als die zu den Körpern mit glatter Hülle gehörigen weiblichen Pflanzen zu betrachten, &c.' In his Fig. 15 a, Pl. XXIV, he illustrates a spiny resting spore with what appears to be an attached empty companion cell. He did not observe the germination of the resting spores.

Not until the appearance of Cornu's 'Monographie des Saprolegiées' was the question concerning the nature of these organisms again seriously considered. In the meantime it rested as left by Pringsheim for an interval of some twelve years. Cornu supported the view of A. Braun in considering the bodies in question as parasitic organisms. His careful observations did not include all stages of the life-history of the organisms, nor did he definitely determine experimentally their parasitic nature. He described five species parasitic on members of the Saprolegniaceae, three on species of *Achlya*, one on *Saprolegnia*, and one on *Aphanomyces*. These he included among the Chytridiaceae and in his newly established genus *Olpidiopsis*.

Cornu discovered in three of the species an apparently new and interesting type of resting spore, the large spiny cell being accompanied by a smaller smooth, or slightly echinulate, one which he designated as the 'cellule adjacente', as previously mentioned. In the diagnosis of *O. Saprolegniae*, (A. Br.) Cornu, he specifically states that the presence of an adjacent cell is a distinguishing character of that species. He comments upon the fact that, inasmuch as resting spores were not seen by A. Braun, it is impossible to determine the species described by him, but wishing to preserve Braun's specific name, Cornu used it for his species found on *Saprolegnia*.

Cornu attributed to this new type of resting spore a sexual character. He considered the large cell an oogonium, and the small one an antheridium.

Reinsch (21), some years later, observed a species of *Olpidiopsis* in the ends of swollen hyphae of a species of *Saprolegnia*. He described three types of cells occurring in the same filament. He observed the spiny resting spores with which were associated smaller spherical cells that eventually discharged their contents into the larger. Changes in the protoplasm of the cells were noted, and the actual transfer of the male protoplasm was observed. He states that Pringsheim's assumption as to the sexual nature of the spores is correct, but makes no reference to Cornu's work, which, apparently, he had not seen.

In 1883 Zopf (26) described an interesting species of *Olpidiopsis* parasitic in *Spirogyra*, which he named *O. Schenkiana*. This species is of particular interest in that it shares the peculiarity with one other species of the genus of possessing uniciliate zoospores.

It was observed that the sexual plant arose as a single mass of protoplasm which later put out an evagination to form the companion cell. At the time of fertilization no pore between the two was detected, and Zopf suggested that a diffusion of the male protoplasm through the wall itself took place. At any rate, the antheridium was completely emptied. Zopf had no doubt of the sexual nature of this spore.

The following year, Fisch (10) published an account of a new form, for which he erected the genus *Pleocystidium* and named it *P. parasiticum*. The species resembles very much *O. Schenkiana*, and was likewise found parasitic on *Spirogyra*. One important difference exists in the manner in which the sexual spores are produced. In *P. parasiticum* they arise, according to Fisch, from two or more closely associated masses of protoplasm representing separate individuals. One of these becomes what he terms the central cell, and the others the companion cells, or antheridia. Fisch was not certain whether the cellulose membrane eventually formed about the spheres was developed around each individual separately or around all as a whole. He was inclined to the latter view. The actual passage of the protoplasm from the antheridium into the oogonium was observed.

The investigations of A. Fischer (11) contain a very careful description

of his studies on the development of what he supposed to be *Olpidiopsis Saprolegniae*, (A. Br.) Cornu. Unable, after much searching, to find an adjacent cell associated with the resting spores, he concluded that so far as *O. Saprolegniae* was concerned it was not present, and he strongly suspected that it was absent in Cornu's other species. Believing that Cornu was mistaken concerning this point and the diagnosis of his genus was incorrect, Fischer (12), in a later work, rejected the adjacent cell character and made the genus *Olpidiopsis* to include only those forms with resting spores which are not formed as the result of a sexual act. He accepts three of Cornu's species and considers the other two doubtful.

Schröter (22), in the 'Kryptogamenflora von Schlesien', accepted the change made by Fischer, and established the new genus *Diplophysa* for these parasites possessing an adjacent cell.

In 1892, in Rabenhorst's 'Kryptogamenflora', A. Fischer (13) gives an explanation of the cause of the confusion which his former work created. In the meantime he discovered a species on *Saprolegnia* which possessed a resting spore with an adjacent cell. This fact convinced him of the correctness of Cornu's observations, and he therefore restored the genus *Olpidiopsis* for the form with the adjacent cell.¹

Inasmuch as the life-history of these organisms, especially the supposed sexual stage, is still imperfectly known, through the suggestion of Professor G. F. Atkinson, to whom I am very grateful for his continued advice and kindly criticisms, I am led to take up a study of a few of these forms.

2. STUDY OF LIVING MATERIAL.

A. Methods and Material.

The results of observations presented in this paper are based upon studies made on three species of the genus *Olpidiopsis*, Cornu (emend. A. Fischer), collected in the vicinity of Ithaca. Two are parasitic on *Saprolegnia*, the third on *Aphanomyces*. One of the former, found on *S. ferax*, agrees in every way with the species described and illustrated by A. Fischer in Rabenhorst's 'Kryptogamenflora' as *O. Saprolegniae*, Cornu, but which, for reasons to be stated later, I believe is not Cornu's species, but a new one for which I propose the name *O. vexans*. The other two species, one found on an undetermined *Saprolegnia*, and the other on *Aphanomyces laevis*, are strikingly similar in morphological characters, but because of their biological difference they are believed to

¹ l. c. p. 34. 1. *Pseudolpidium Saprolegniae* mihi. Synon.: *Olpidiopsis Saprolegniae*, A. Fischer, Schröter. *Olpidiopsis Saprolegniae*, Cornu pro parte. 2. *Olpidiopsis Saprolegniae*, (Cornu) mihi. Synon.: *Olpidiopsis Saprolegniae*, Cornu pro parte. *Diplophysa Saprolegniae*, Schröter. *Pleocystidium*, Fisch.

be distinct. The species found on *Aphanomyces* is considered new and is given the name *O. luxurians*, while the other occurring on *Saprolegnia* is believed to be Cornu's species *O. Saprolegniae*.

These organisms appeared in water cultures prepared for the purpose of obtaining terricolons and aquatic Phycomycetes. Water from streams and pools containing Algae, dead twigs, and debris of various kinds, was placed in small glass vessels in fresh water. When soils were used, about one half-inch was placed in the bottom of the vessel and covered with tap-water one-half to one inch above the soil. The vessels used were provided with glass covers, and measured four inches in diameter and two and a half inches in depth. As traps, various vegetable and animal tissues were tried, such as sections of boiled root of *Abutilon*, suggested by Butler (4), sterilized flies, millipedes, Dipterous larvae, the larvae and pupae of ants, aphids, boiled egg albumen, &c. Although all of these, with the exception of the *Abutilon* root and egg albumen, proved to be more or less serviceable, the sterilized flies, aphids, and ant pupae were more extensively used. Ant pupae and larvae served best when cytological studies were made.

Usually in cultures of this nature the most frequent forms secured are species of *Saprolegnia* and *Achlya*. In my cultures, however, *Aphanomyces laevis* proved to be more common than *Achlya* species, and was very commonly associated with some species of *Saprolegnia*. When any Chytridiaceous parasites were present, particularly on *Saprolegnia*, they could be seen with the naked eye within a few days after the culture had been started. Their presence is detected by the bright whitish specks seen among the radiating hyphae of the host (Pl. XXVI, Fig. 75). These specks are the swollen hyphae with the enclosed developing parasite.

When the parasite was once located by means of small scissors, the filaments containing it were cut off under a dissecting lens, washed in sterile water, and transferred to dishes containing pure cultures of the host. By this method reasonably pure cultures were maintained, and infection experiments with the host in various stages of development were carried on.

B. Zoospores.

The zoospores of the three species agree in all important features. They are oval to broadly elliptical, sometimes slightly reniform or anteriorly truncate. In motion they are usually slightly pointed at the anterior end, to one side of which are attached two cilia, rather close together and of approximately the same length. At the point of attachment of the cilia there is a prominent refractive spot frequently referred to as the hilum. With the aid of the high-power objectives, the protoplasm is seen to be slightly granular and not homogeneous as has been described for other

species. This condition is more clearly brought out in zoospores killed with osmic acid.

There seems to be considerable variation among the species of this and other related genera in the position and number of the cilia on the zoospores. Cornu (6) observed in all species studied by him but one cillum. A. Fischer (12) found in the case of *Olpidiopsis* (*Pseudolpidium*), *Rozella*, and *Woronina* that the zoospores possessed two cilia, one placed in front and extending to the fore, the other attached laterally and extending to the rear. This same relation of the cilia was later (18) observed by him for the zoospores of his *O. Saprolegniae*, and was considered to be the normal condition for the genus.

Butler (4) records some interesting observations in reference to this point. He found the arrangement of the cilia as described by Fischer to exist in *Olpidiopsis minor*, A. Fischer; *Pseudolpidium* (? *Olpidiopsis*) *Saprolegniae*, (A. Br.) A. Fischer; *P. gracile*, Butler; and *Pleolpidium inflatum*, Butler. It is interesting to note that in the last-named species, he observed what appeared to be a variation in the position of the cilia. This he attributed to the varying position of the zoospore in swimming. In *Pseudolpidium Aphanomyces*, (Cornu) A. Fischer, and in *Pleolpidium Pythii*, Butler, the cilia are attached laterally and at the same point.

It is difficult, in many cases, to observe the attachment of the cilia on the living zoospore. However, this can be done without difficulty with the proper apparatus. Zoospores were allowed to escape from the sporangium into a small hanging drop of water in a Van Tieghem cell, and there observed with a 2 mm. Zeiss apo. obj. by the aid of strong artificial light. As the zoospores come to rest the attachment of the cilia was clearly seen to be at the same point. As has been frequently observed in other species, one cilium of the zoospore in motion trails behind. My observations revealed that this rear cilium crosses at an angle the upper end of the zoospore, and leaving it usually at the side gives it the appearance of being attached at that point. It was not until a number of observations were made that this peculiar condition was detected. When once seen it was easily verified for all the species of *Olpidiopsis* studied.

The same condition was found on careful examination in stained preparations of zoospores. In cases where the stain was not too deep, the rear cilium could be followed crossing the upper end of the zoospore to its point of attachment near that of the other. Occasionally both cilia extend out free from the body of the zoospore and leave no doubt whatever as to their relative position. In cases which present the appearance of a lateral attachment for one of the cilia, this cilium appears to be shorter than the other, but is actually about the same length (see Pl. XXIII, Figs. 1, 2, and 15). A more careful examination of the zoospores of other species

of these closely related genera may reveal that the above-described relation of the cilia is common, if not the general rule.

As has been described for other species (Butler, 4) there occurs in the life of the zoospores two distinct motile periods. After their escape from the sporangium they swim about actively for a few minutes, two to five, in the vicinity, and then gradually come to rest upon the slide or cover-glass, as the case may be. There is now seen a waving rhythmic movement of the cilia, accompanied by a gentle rocking of the zoospore. These movements become slower and slower, the cilia gradually shorten, and the body of the spore assumes a spherical form. Finally, at the end of seven to ten minutes the zoospore has become quiet, and the cilia, when visible at all, appear as short thickened knobs or projections about the length of the radius of the spore.

The period of rest may last only a few or as many as fifteen or twenty minutes, during which time one, sometimes two, vacuoles are seen to appear and pulsate regularly—in one observed case, at intervals of six to eight seconds—until the second period of motion begins. The reverse condition now takes place. The short cilia begin to move and lengthen, the body of the zoospore resumes the rocking motion, and in a few minutes darts away. There is no change in the position of the cilia, and the fact that, in many cases at least, they do not lose their identity during the resting period makes such an assumption seem improbable. Butler (4) failed to observe cilia on zoospores of *Pseudolpidium Aphanomyces* during the first period of motion when this was followed by a second. The fact that such were seen attached laterally on zoospores killed in the sporangium at the time of discharge led him to state (p. 133): 'From this it would appear probable that there is no alteration in the position of the cilia during the two periods of motion, but it is possible that cases occur in which the first period is suppressed, and the sporangium figured may have been such a case.' He further states: 'As in *P. Saprolegniae*, the occurrence of two periods of motion is not, I think, a constant phenomenon.'

Butler suggests that such a condition may be compared to diplanetism in the Saprolegniaceae and *Pythium*. Inasmuch as diplanetism seems to prepare the zoospore for a more or less continued period of activity, and that in the cases just described the second period may persist for some time, it seems that, so far as it concerns the Saprolegniaceae, such a comparison is, at least, worthy of comparison.

C. Infection of the Host.

Inasmuch as the observations of the writer on the penetration of the host by the zoospores of the parasites differ immaterially from similar studies made by previous investigators, it seems unnecessary to give more than the most important facts as they apply to the species under considera-

tion. No complete observations relative to this point have been recorded, so far as I am aware, for any *Olpidiopsis* species parasitic on the Saprolegniaceae.

Cornu (6) briefly describes this phenomenon for certain species studied by him, while A. Fischer (12), for *Olpidiopsis* (*Pseudolpidium*), *Woronina*, and *Rozella*, records his very careful observations as to both penetration and subsequent development of the parasite.

The zoospores, after a swimming period, the length of which seems to depend considerably on the age and condition of the culture in which it occurs, finally settle down on some favourable part of the host and either produce infection or die. There is at first a slight amoeboid movement, followed by a rounding up of the zoospore body and the formation of a wall (Fig. 3). After resting in this condition for fifteen minutes to one hour, the encysted spore produces from the side in contact with the host a short cylindrical tube which penetrates the wall of the hypha. During this process the zoospores become pushed slightly away from the filament. The penetration tube varies somewhat in length in the different species, being shortest in *O. luxurians*, and longest in *O. vexans* (Figs. 4, 8, and 9). After the formation of the tube, the appearance of a small vacuole in the spore body indicates that the passage of its contents into the host has begun. As observed by A. Fischer (12) and Butler (4) this tube is so small that it is impossible to observe the passage of the protoplasm through it. Occasionally it could be seen extending into the cell cavity beyond the limits of the wall (Fig. 9).

By far the majority of zoospores in all three species fail to infect the host. A greater percentage succeed in *O. luxurians* than in the species on *Saprolegnia*, due, no doubt, to the fact that infection in this species is not so nearly confined to the young hyphae. Those zoospores which fail to enter the host die sooner or later, either by a direct disintegration of the protoplasm, or after germination. In the presence of the host, and usually near or in contact with the hyphae, zoospores frequently put out long slender germ tubes. These have been observed in large numbers on old empty sporangia of *Aphanomyces* and on the old threads of *Saprolegnia*. The germ tubes sometimes entirely surround the hyphae; in other cases they may extend some distance parallel to them (Figs. 5, 6). As has been observed by A. Fischer, the life of the zoospore is much longer in the presence of the host than in pure water.

The germinated zoospores of *Aphanomyces* are frequently infected by *O. luxurians* (Fig. 10). As many as four developing sporangia of the parasite have been found in a very short germ tube. In no case was an infection of gemmae or reproductive organs of *Saprolegnia* observed.

Just how far, if at all, chemotropic stimuli set up by the host influence the behaviour of the parasite zoospores is impossible to state. The writer

has carried on no controllable experiments in reference to this point, but is convinced from careful observations that there is some varying attractive force exerted by the host hyphae on the zoospores of the parasite.

De Bary was inclined to the view that by the secretion of some chemical substance the oogonia of *Saprolegnia* may be capable of inducing the formation of antheridial branches. This assumption is strengthened by the work of Kauffman (16), in which he showed how the development of sexual organs of *Saprolegnia*, especially antheridia, could, to a certain extent, be controlled by the use of chemicals.

A. Fischer (12) theorizes that different organs of *Saprolegnia*, such as young hyphae, gemmae, and oogonia, perhaps give off different metabolic substances, and further that such substances vary in different genera. These diffuse into the surrounding water and within a certain radius exert an attractive or repellent force on the zoospores of the parasite.

D. Development of the Sporangia.

Growth period. After the penetration of the zoospore into the host, it can frequently be observed for a brief time as a small, more or less refringent mass of the protoplasm (Figs. 4, 10). It exhibits slight changes in shape, and in the course of an hour or so is entirely lost to view. The young parasite is now more or less surrounded by the host protoplasm, at the expense of which it begins to grow rapidly, and at the same time it exerts upon the host a stimulus which causes, frequently in a few hours, an abnormal development of the infected hypha (Figs. 7, 11, 76). Usually the parasite undergoes its development at or near the point of entrance. Frequent exceptions to this condition have been observed, however, and are also noted by Fischer for *Olpidiopsis* (*Pseudolpidium*).

The change of position is very probably passive and due to currents of host protoplasm. In cases where a number of sporangia occur in the same intercalary swelling there seems to be no other explanation than that some of the young parasites migrated to that point. Growth of the infected hyphae beyond the position of the parasite usually ceases soon after its infection, especially when such takes place near the end.

In the early stages of development the parasite contains few granules scattered through the homogeneous ground substance, most of them lying about the periphery (Fig. 12). There soon appear a number of larger granules which grow rapidly and present the appearance of being of a fatty or oily nature (Figs. 12, 13, 17). They frequently exhibit a vacuolate character, and show marked changes in form (Figs. 13, 23). Similar granules have been observed by Zopf in *O. Schenkiana* and by Fischer for both species of *Olpidiopsis* (*Pseudolpidium*) studied by him.

The parasite now becomes surrounded by a hyaline wall. The proto-

plasm has become more dense and contains many small granules along with the increased number of oil bodies (Figs. 17, 78). At this time there is a marked radiating condition of the host protoplasm which decreases rapidly in extent as the sporangial development proceeds (Figs. 17, 18, 79, 80). Vacuoles of rather indefinite outline now appear in the parasite (Figs. 18, 81), which soon round up into one or several nearly perfect spheres. The protoplasm is now dense and granular. The large oil or fat-like bodies have disappeared. The sporangium is now said to be ripe and may enter directly into the maturation stages or undergo a limited period of rest before zoospore formation takes place (Fig. 82). I have observed sporangia remain in this condition for several weeks without losing their power of zoospore formation (Fig. 19). The only necessary condition, according to my observations, to start up the internal changes which bring about the discharge of zoospores is that fresh water and oxygen be supplied.

Maturation. Concerning the maturation stages of *Pseudolpidium Aphanomyces*, Butler (4) has given a detailed account. The changes which take place in the ripe sporangium of the *Olpidiopsis* species concerned, just previous to zoospore production, agree in the main with those described for the above species. I find, however, that the minute details in the behaviour of the protoplasm vary somewhat with the different sporangia of the same species.

Soon after the proper conditions are supplied to the ripe resting sporangium, one observes a change in the contour of the prominent spherical vacuoles. Usually the exit tubes begin to develop at this time and the protoplasm has the appearance of already being segmented (Figs. 14, 82). No heapings of the protoplasm such as described by Butler for *P. Aphanomyces* were seen to take place at this time. In a short time the vacuoles suddenly disappear, when the protoplasm presents a rather fine granular, homogeneous, and lighter appearance. It is at this stage, according to Butler, that the first shaping of the spore origins in the sporangium of *P. Aphanomyces* occurs. After a few minutes there may or may not appear a number of smaller spherical vacuoles surrounded by the now denser protoplasm.

After fifteen to thirty minutes the vacuoles disappear and the protoplasm becomes more coarsely granular. The zoospores take on a more definite outline and their movement increases. Suddenly the exit tube opens and their escape takes place.

The number and length of the exit tubes vary with the different species. In *O. luxurians* they usually number one or two, and extend some distance beyond the host wall (Fig. 16). In *O. Saprolegniae* the number of exit tubes is small, one to three, and they are comparatively short. In *O. vexans* they are usually more numerous, often numbering as many as six. Fig. 20 shows a sporangium of *O. vexans* which rested after

a number of exit tubes had been produced. Several of the tubes show a peculiar coiled condition of the end, while one is branched. This latter condition, which seems rare, was also observed once by Fischer in another species. Other sporangia in a similar stage, when given the proper conditions, failed to discharge zoospores.

The exit tube secretes an enzyme which enables it to penetrate the wall of the host. In many cases, at least, mechanical pressure seems to play an important part. I have several times observed that the host wall was stretched out over the end of the protruding tube even when apparently some little distance through it. Very commonly, as has been previously observed, there is an enlargement of the tube just inside the hyphal wall. The escape of the zoospores takes place by the gelatinization and dissolution of the end of the exit tube.

E. Development of Sexual Spores.

The frequency of occurrence of the sexual spores of the organisms under consideration varies with the species and the condition of the cultures under which it develops. It has been assumed, in the case of resting spores belonging to species of a closely related genus, that they were formed only after a somewhat prolonged production of the zoosporangia, and then for the purpose of tiding the parasite over unfavourable conditions such as winter. They have been rarely found in the species of *Olpidiopsis* infecting members of the Saprolegniaceae, which fact, no doubt, partially accounts for our incomplete knowledge concerning their development.

The first of these so-called resting spores found by the writer appeared in a culture of *O. vexans* on *Saprolegnia ferax* growing on ant larvae. Several cultures had previously been made on sterile flies with the result that only smooth sporangia developed, and it was, therefore, impossible to classify the organism. Three days after starting the culture above mentioned, sexual spores were numerous in all stages of development. New cultures were immediately started with a view to securing material for cytological studies. After making several series of cultures, I was somewhat surprised that the desired spores failed to appear. Almost a month of culture experiments finally revealed the requisite condition. Instead of starting new cultures in separate dishes, as I had previously been doing, I kept the old ones, to which at certain periods I added a new supply of ant pupae. These were disturbed as little as possible, and the water remained unchanged. There were always a sufficient number of zoospores of both host and parasite present to start a ready infection of the new substrata.

By this method the otherwise rapid and vigorous growth of the *Saprolegnia* was somewhat retarded, and a large number of sexual spores of the parasite developed. It was detected that some contamination by Bacteria, protozoa, &c., seemed to be an advantage, but when carried too

far would inevitably prevent the desired results. Not all cultures with this species gave results, and the successful ones needed to be carefully watched in order that their productiveness be maintained. After the sexual spores had attained the desired stage of development most of the larvae were transferred to other vessels in order that new ones could be added. It was necessary, at times, to deviate in one way or another from the regular method described, in order to overcome one or more difficulties.

The sexual spores of *O. Saprolegniae* were as difficult to obtain in quantity as those of *O. vexans*. Those of *O. luxurians* were secured in by far the greatest numbers and with the least difficulty. The host, *Aphanomyces laevis*, was grown on green aphids, a supply of which was kept sterile in test-tubes. The value of the aphids as culture media was not discovered until most of the cultures of the other species were brought to a close, but the few trials made showed that the aphids were equally serviceable for them. They furnish a very limited amount of nourishment, in that one can find them of all sizes, which fact seems to bear a direct and favourable influence on sexual spore production of the parasite. Correlated with this factor of a small amount of nourishment is the limited amount of water, which should remain unchanged. One disadvantage in the use of small bits of substrata is the reduced size of the sexual spores of the parasite that results. Another advantage obtains in the use of this method. Having the zoospores of both host and parasite in the culture provides for the immediate infection of the host hyphae as they emerge from the substrata. This enables the parasite to get a good start before the hyphae reach any length, and prevents the formation of a tangled mass of hyphae, so objectionable in the preparation of the material for cytological study. The result is a dense halo of short swollen filaments containing the parasites in all stages of development. In the case of the two species on *Saprolegnia* it is really necessary that infection take place when the hyphae are young.

So far as my observations with the three species of *Olpidiopsis* go, there seems to be no foundation for a view that a production of sexual spores need be preceded by a somewhat continuous production of sporangia, or that the two need alternate with each other. On the other hand, if the proper external conditions are provided, such spores are more or less easily obtained.

It should be stated here that the above-described method also provided good material of the sporangia in the resting stage.

The sexual spores develop in the same position as the sporangia, with which they may or may not be associated. Usually, however, one finds one or more sporangia in the same hyphal swelling containing sexual spores. The greater the degree of infection of the host, the greater the variation in the size of both kinds of reproductive bodies. In general, the manner

of development of the sexual spores of the three species agrees. There are, however, some slight differences, especially between *O. vexans* and the other two whose development resembles each other more closely. For the reason stated the former will be described separately.

The developing sexual cells of *O. vexans* are first detected in the young stage by the darker and more dense appearing condition of the protoplasm of, especially, the larger, or female, cell. It does not require very high magnification to see that closely associated with the female plant are one or more smaller light-coloured protoplasmic bodies. These develop into the antheridia, while the larger become the oogonia. Such an early condition is shown in Pl. XXIV, Fig. 26. No walls have formed about the cells at this stage, and the very close association of the individuals might suggest a division of a single individual rather than the partial fusion of two or more. At this stage, were it not for the presence of the female cell, one could not distinguish the male elements from the young sporangia of the same age.

As growth proceeds, the two cells become more and more distinct and soon surround themselves by cellulose walls, which become fused at the point of contact. Usually one can clearly distinguish what appear to be brace-walls joining the two cells, as seen in Fig. 27. The wall of the oogonium shows early the formation of roughenings on the outer surface, which eventually take on a warty appearance, and resemble an encrustation of some kind. The male cell, or antheridium, remains smooth.

Noticeable changes also take place in the protoplasmic contents of both cells. In the young stages of growth these resemble those that take place in the young sporangia. There is at first in the oogonial cell a very much vacuolated, finely granular protoplasm in which a few larger irregular granules are distributed. Most of the protoplasm lies in a thin layer about the periphery, from which irregular strands extend into the interior. At this time the male cell shows a somewhat similar vacuolate condition, but contains more granular protoplasm.

Following this stage, which, owing to rapid growth at this period, lasts but a short time, is a stage in which the number of large granules have greatly increased in both cells, to such an extent as to make difficult the observation of protoplasmic changes within, especially in the oogonium. Soon the contents of the female cell become more or less clumped, while that of the male shows a fine granular condition with frequently one or more vacuoles. The cells are now ready for fertilization.

This takes place by the passage of all the antheridial contents into the oogonium. The beginning of this phenomenon is indicated by the appearance of a large central vacuole or, as is more usual, a shrinkage of the protoplasm from the wall of the antheridium opposite the oogonium. The whole act may require several hours or may be completed in less than one hour. I have frequently observed long strands of protoplasm still clinging

to the opposite wall of the antheridium after most of the contents had passed over. Very rarely does any protoplasm remain in the male cell after fertilization.

Before the movement of the protoplasm of the antheridium into the oogonium begins, one only rarely detects a communicating pore. In fact, in many cases, it cannot be detected even while the passage of the protoplasm is going on. The pore in the fused wall is small and soon closes by growth of the surrounding wall, apparently after the act of fertilization is completed. Owing to the thick encrustation on the oogonial wall, together with the coarsely granular protoplasm, I have been unable to see the movement of the male protoplasm after it has passed through the communicating pore.

As a result of fertilization the oospore forms about itself a wall in close contact with that of the oogonium. This wall rapidly thickens and serves to protect its contents against unfavourable external conditions (Fig. 21). The now empty antheridial wall may persist for some time in its normal shape, but eventually becomes more or less collapsed.

When more than one antheridial cell is attached to an oogonium there is no apparent difference in their behaviour other than that their contents may or may not simultaneously pass into the female cell. Although one usually finds that the movement has at least started in all male cells before any one is entirely emptied, exceptions to this have been observed.

In the case of the sexual spores of the other two species, *O. Saprolegniae* and *O. luxurians*, what is said of one will apply equally well to the other. Those individuals which are to give rise to sexual cells can be detected early in their course of development by the difference in the appearance of their protoplasm from that of the young sporangial cells, and by the close association of the two or more individuals. This early condition is not so easily detected, however, as in the case of *O. vexans*.

The protoplasm of both the male and female individuals is much vacuolated and somewhat coarsely granular. The limits of the cells are less clearly defined than those of *O. vexans* because of the closer resemblance of the protoplasm to that of the host (Figs. 24, 83). Later their individuality and form is much more marked, as their protoplasm becomes more differentiated than that of the host (Figs. 25, 84, 85). The oogonium contains large vacuoles surrounded by more or less granular protoplasm, while that of the antheridium is finely granular and homogeneous. At this stage walls have formed, and there is observed a pronounced clear zone of protoplasm about the oogonium, which exhibits a strong contrast to the dense granular layer of the host on which it abuts. Dangeard (7) calls attention to this zone in the resting spores of *Olpidiopsis* (*Pseudolpidium*) *Saprolegniae*, Cornu, as interfering with his observations of the nuclei.

The host protoplasm beyond this layer forms a complicated system of

radially arranged strands which communicate with a dense peripheral layer, and along which one can frequently observe a movement of granules towards the parasite. This gradually disappears as growth of the sexual elements proceeds, until at maturity these cells lie in an empty swelling.

The vacuoles of the oogonium now become less apparent and the protoplasm is more or less filled with large and small granules. A similar condition prevails also in the antheridium (Pl. XXIV, Fig. 28). Their development is rapid, as is the disappearance of the host protoplasm which surrounds them.

After fertilization the oospore develops a thick endospore. Fig. 30 shows a mature oospore of *O. luxurians* bearing two empty antheridial cells. The content is differentiated into an outer zone, more or less finely granular, and a central mass of large, more or less regular granules in which is usually one or more large oil globules. The oil globules are not represented in this figure. Occasionally in these species one finds the peculiar condition of one antheridial cell attached to two oogonia, one of which is usually provided with a separate male cell (Pl. XXVI, Fig. 88). Fig. 85 shows a young oogonium with three antheridial cells attached.

The fertilization pore in the sexual spores of these species is, so far as can be determined in the living material, not unlike that described for *O. vexans*. It has frequently been observed, and in some few cases the stream of male protoplasm could be seen passing through it into the female cell. In one interesting case, while observing this act, the weight of the cover-glass, because of evaporation of water under it, suddenly came upon the oogonium as the last of the antheridial contents was passing into it. Immediately a stream of protoplasm was forced through the pore and the male cell was soon refilled.

As yet, no case of germination of the oospores has been observed for any of the species studied. A. Fischer (11) witnessed the germination of the resting spores of *Olpidiopsis* (*Pseudolpidium*) and Zopf the same phenomenon for *O. Schenkiana*. In both cases germ tubes were formed through which zoospores escaped.

Reinsch (21) observed, in a species of *Olpidiopsis* (according to A. Fischer *O. minor*), that at the point of fusion of the two sexual cells a slit formed in the wall which permitted the passage of the male protoplasm into the oogonium. This opening, after fertilization, was closed by growth.

In *O. Schenkiana* Zopf (26) saw no communicating pore or opening between the two sexual cells. To him the contents of the antheridium seemed to diffuse through the wall into the oogonium. I have not had the opportunity to observe the condition in that species, but judging from the ease with which such a pore might be overlooked in the species studied, it seems probable that it occurs in *O. Schenkiana*.

3. STUDY OF SECTIONS.

A. Methods.

The material used for sectioning was secured as described under the heading 'Methods and Material'. The substratum bearing the organisms was washed in several changes of water in order to free it as much as possible from all contamination, then dropped into small phials of killing solution. The latter consisted of weak and strong Flemming's solution, medium and strong chrom-acetic acid, and Gilson's fluid. After killing and fixing, the material was washed either in slow running water or by making frequent changes by means of a pipette. Dehydration was secured both by carrying the specimens through the grades of alcohol, and by evaporating down in 10 per cent. glycerine. After clearing in cedar oil, the material was embedded in paraffin. Sections were cut 2-5 μ thick and stained on the slide.

The stains used were Flemming's triple stain, with the orange G. dissolved in the clove oil, Heidenhain's iron-alum haematoxylin, and Gram's stain followed by eosin in clove oil. For most purposes material fixed in medium chrom-acetic acid and followed by the triple stain gave the best results. The same stain applied to material fixed with Flemming's solutions served best for the maturation stages of the sporangium, and for staining the nuclei of the host. Iron-alum haematoxylin was of little service, while Gram's stain was excellent for bringing out the nuclei during fertilization stages.

Very little histologically and cytologically has been done on the members of the family Olpidiaceae, and nothing, so far as I have been able to learn, on the genus *Olpidopsis* in the sense used in this paper.

Dangeard (7) studied the histology of two species of the genus *Pseudolpidium*, then called by him *Olpidopsis Saprolegniae*, Cornu, and *O. Aphanomycis*, Cornu. Inasmuch as the two genera are very closely related, it seems proper to give briefly the results of Dangeard's observations on the above species. The material studied by him was stained *in toto*, which prevented the clearest definition of the nuclei, especially in the resting spores.

According to Dangeard, the sporangia of *O. Saprolegnia*, Cornu, present two principal phases in their development. In the young condition the protoplasm is very much vacuolated, and is composed superficially of broad meshes at whose nodes are located the nuclei. The nuclei are very small and appear as simple masses of chromatin. From a uninucleate to a multinucleate condition the change is rapid, there being present about twenty at the time the sporangium reaches its final size. Later, the nuclei which have increased in number space themselves, and show

dense, rather large masses of chromatin, which are surrounded by nuclear hyaloplasm.

Successful examination of the histology of the resting spores was impossible. Dangeard observed that the dark zone of colourless protoplasm about the developing spore hindered observation. He states that they are multinucleate.

Concerning the study of the second species, *O. Aphanomycis*, Cornu, nothing of importance was added. Dangeard observed a spiny resting spore without a companion cell, which would place this species in the genus *Pseudolpidium* as *P. Aphanomycis*.

B. Sporangia.

Fig. 31, Pl. XXIV, represents a young parasite soon after its entrance into the host. It is uninucleate, much vacuolated, and not unlike Fig. 35, which is a zoospore from a discharging sporangium. The protoplasm, which is finely granular, exists in the form of a parietal layer. Growth of the individual has not proceeded far until the single nucleus divides.

Fig. 32 shows the binucleate stage. The nuclei are prominent and contain large deeply staining bodies which are presumably nucleoli. As is seen in Fig. 33, the nuclei divide mitotically. Fig. 34 is a section through a slightly older individual, showing three of its four nuclei and the very much vacuolated and granular nature of the protoplasm. It is assumed, from the condition of the protoplasm, that it is about this time in the life of the individual that it becomes lost to view in the host.

Nuclear divisions proceed rapidly, and we soon find the condition shown in Fig. 36. It will be observed that the protoplasm lies principally in the peripheral layer, in which are embedded the many still prominent nuclei. There is also observed a tendency for small granules to collect about the outside of the parasite, indicating, perhaps, the beginning of the formation of a wall, as a very little later one finds that a thin wall has developed. The large irregularly shaped fat bodies observed in the living specimens are in most cases not visible in stained sections.

Following the condition shown in Fig. 36, there is a gradual inward growth of the protoplasm, accompanied by an increase in size of the parasite and a continued rapid nuclear division. A little later the sporangium is almost filled with fine granular protoplasm in which are distributed a few large and numerous small irregularly shaped vacuoles. Fig. 37 represents a section of a small sporangium at that period of development with its nuclei undergoing their last division. The sporangial wall is very distinct and the sporangium has probably reached its maximum size. The large vacuoles have become regular in outline and at the same time the smaller ones show less distinctly.

Fig. 38 illustrates that condition. It shows the appearance of the nuclei after the last division, and around which the individual zoospores are to form. Chromatin masses are arranged about the nuclear membrane in more or less irregular areas. It is in this stage that the sporangium may undergo a period of rest.

I have observed no indication of an amoeboid or otherwise irregular stage of the parasite. A. Fischer (11) describes such a condition as common for *O. (Pseudolpidium) Saprolegniae* even after the parasite had reached some size (see Pl. X, Fig. 5, *a-d*). In the young living specimens it is sometimes very difficult to determine the limits of the host and parasite protoplasts, but in stained sectioned material such a difficulty disappears, for the reason that the protoplasm of the parasite has a different affinity for stain than that of the host. There is no indication whatever of a fusion of two or more parasites to form one, and it seems very evident that each zoospore after entering the host maintains its individuality and gives rise to a single sporangium. In other words, no plasmodium is formed. In abundantly infected material one frequently finds in section a number of very small individuals, sometimes still uninucleate, accompanying the larger ones in swollen hyphae whose protoplasm has been exhausted. In some cases these small parasites have taken on a mature state and may give rise to a small number of zoospores.

Fig. 39 represents a portion of a section of a sporangium in the vacuolate resting condition, and of the same age as that from which Fig. 38 was drawn. The former was killed in weak Flemming's solution, the latter in medium chrom-acetic acid. This section shows very clearly that the uninucleate spore centres are not only definitely formed at this time, but that fragmentation has, at least partially, taken place. The nuclei take a deeper stain than those shown in Fig. 38, in which lines of segmentation of the protoplasm are not visible. There is no apparent indication of vacuoles in the young spores, which indicates, it seems, that during the resting period of the sporangium the water of imbibition of the spore centres is at a low ebb.

From this and many other similar sections I think it is evident that the spore centres are formed before the resting period of the sporangium ensues. The changes which take place subsequently to the resting period, and which have been supposed to give rise to the fashioning of the spore centres, are merely the phenomena accompanying the final stages in the development of the zoospores.

So far as could be determined, fragmentation of the protoplasm is simultaneous throughout the sporangium much as described by Dangeard (7) for the primitive cell of *Synchytrium Taraxaci*. When exit tubes are present at this stage their protoplasm likewise shows segmentation into spore centres.

At the time of discharge of the sporangium the vacuoles disappear, while they are very evident in the zoospores themselves. The zoospores reach the exterior then, not, as Harper (15) described for *Synchytrium decipiens*, in the form of concentrated bits of protoplasm, but as definitely vacuolated structures (Fig. 35). Butler's assumption that an increase in the imbibition water is necessary to the final fashioning of the zoospores seems to be substantiated by my sections.

In sections stained with Gram's stain there are seen in the vacuoles of the sporangia spherical or oval faintly staining bodies the nature of which was not determined (Pl. XXIII, Fig. 22). They were not observed after the use of any other stain. They need further study.

C. Sexual Organs.

Very early in the development of the individual parasite, which is to become the oogonial cell, there is a noticeable difference in its staining reaction. While the protoplasm of all the parasites destined to give rise to sporangia and antheridia has a strong affinity for gentian violet, that of the oogonial cells shows very early a tendency to give up that stain and hold to the orange G. This fact enables one to recognize the young oogonial cell very early.

Most of the material studied in section was that of *O. vexans* because of the larger sexual individuals and their better response to stains. In the youngest oogonial cell of which I could be sure, the nuclei already numbered twenty-five to thirty. Some were distributed more or less irregularly throughout the contents, while the rest were arranged about the periphery embedded in a thin layer of finely granular protoplasm.

Fig. 40, Pl. XXV, represents the earliest stage seen in section in which both male and female cells showed. Enclosing walls have not yet formed and the two gametes are in close contact with each other. The nuclei of both individuals are undergoing mitotic division, and both show a marked vacuolate condition. The male cell possesses, as is the usual condition, proportionately more granular protoplasm. Most of the protoplasm of the oogonium is arranged about the periphery and contains many of the nuclei.

Following this condition there is a rapid increase in the size of the gametes and in the number of nuclei. By the time the cells reach their mature size they are enclosed in cellulose walls. The wall of the antheridium remains smooth, while that of the oogonium soon begins to take on a roughened character.

Fig. 41 shows portions of the two individuals with their walls fused and brace-walls formed. Already gelatinization of the common wall is taking place to form a fertilization pore. This can be detected by the deep stain of the wall at that point. The protoplasm is now more coarsely granular and much vacuolated, especially in the female cell.

Fig. 42 shows an advanced stage of gelatinization of the wall and its diffusion into the contents of the two cells. The nuclei of the oogonium are in the resting condition, while those of the antheridium are undergoing division. Fat globules are scattered throughout the female protoplasm, which is still sparse and exhibits a rather poor affinity for stain in contrast to that of the antheridium.

The next condition that one observes is the beginning of the passage of the protoplasm of the antheridium into the oogonium. Fig. 43 represents a section of the sexual cells of *O. luxurians* stained with Gram's stain, which shows this stage. It is interesting to note that the female nuclei located at the nodes of the protoplasmic meshes are very faint. This is due to the fact that, in order to bring out the male nuclei embedded in the dense, deeply staining protoplasm and gelatinized wall substance, it was necessary to decolorize to such an extent that the female nuclei lost their colour. The nuclei in different stages of division have different affinities for stains. In fact, many sections of antheridia fail to show them, while the nuclei of the accompanying oogonia are perfectly clear and distinct.

There seems to be no relation between the beginning of the passage of the protoplasm and the condition of the nuclei. They have been observed in various stages of division in both cells at the time the transfer of the protoplasm was taking place.

After the completion of the act of fertilization some change takes place in the fused protoplasm which alters its susceptibility to stain. The contents have a much greater affinity for safranin than previously and take up very little of the gentian violet. The nuclei now become distributed irregularly throughout the oospore in variously sized groups (Fig. 44), and are much smaller. The number of oil globules increases rapidly, the oogonial wall begins to thicken, and the communicating pore becomes closed. The nuclei appear under the lower powers as mere rings, but when examined with very high powers can be seen to possess peripherally arranged, deeply staining masses of chromatin (Fig. 46). They are much smaller than formerly.

There is no apparent difference in the male and female nuclei, and this fact, coupled with their extremely small size, makes it impossible to definitely follow their subsequent relation to each other. However, there are indications which strongly suggest a fusion of nuclei. Whether this fusion is always in pairs I am at present unable to say, but in the light of our present knowledge concerning compound fertilization this, it seems, would be assumed. Fig. 47 represents a portion of a section of an oospore of further development. The nuclei, although faint, are much larger than in previous stages and fewer in number. They are more regularly distributed throughout the interior, with a tendency to collect about the periphery. The endospore is now well developed.

In Fig. 48 are shown some nuclei from oospores, highly magnified;

d-g, as they appear soon after the two protoplasts have become fused; *b*, *c*, and *h*, in the fusion stage; *a*, large nuclei from the section represented in Fig. 47.

Unfortunately, no later stages of the oospores of this species were observed in section. In the other species, however, an interesting arrangement of the contents of the mature oospores takes place. Fig. 46 shows a portion of a section of an almost mature oospore of *O. luxurians*. The content is more or less differentiated into zones which show different staining reactions, especially with the triple stain. The outer zone is made up of fine granular protoplasm in which are embedded a large number of faintly staining nuclei. Inside of this is a zone of less definite outline composed of larger granules which stain rather deeply with gentian violet. The outer zone retains more of the safranin. In or near the centre is a large oil globule which stains with orange G.

Fig. 45 shows a section of a mature oospore. The same zonate character of the contents is evident. Fig. 90 is a photomicrograph of the same section. When iron-alum haematoxylin is used on such material the zonate character is less distinct and the nuclei can rarely be seen at all (Fig. 89).

The endospore becomes very much thickened in the mature oospore, while the hyaline spine-bearing exospore remains unchanged. The former stains slightly with orange G and eosin, the latter usually remains hyaline. In sections of *O. vexans* oospores there is only an occasional indication of a roughened or warty condition of the exospore, which would point to the assumption that such markings were due to some encrustation which dissolved in the preparation of the material.

There is no contraction of the oogonial protoplasm to form an oosphere and no apparent changes comparable to those taking place in oogenesis in the higher Oomycetes. After fertilization the oogonium becomes the oospore directly.

D. Nuclear Division.

The nuclei of both sporangia and gametes are small, measuring in the resting stage 4-5 μ in diameter. In the early stages of development of the sporangia, and up to the time of fertilization in the sexual spores, they have a rather strong affinity for stains, especially in division stages. The nucleoli and chromatin masses take on a brilliant red colour with safranin, while the spindle fibres stain very faintly with gentian violet. All material fixed in Flemming's solution proved much less satisfactory than that fixed with medium chrom-acetic acid for nuclear divisions.

The resting nucleus (Figs. 49 and 50) possesses a deeply staining, rather prominent nucleolus and a slightly granular nuclear plasm. A rather indistinct network with frequent deeply stained thickenings, which I take to

be the chromatin material, is present. In cases (Fig. 51) where the nucleolus is absent, the chromatin masses are more prominent. They apparently become elongated and not infrequently assume the condition seen in Fig. 54. The conditions illustrated in Figs. 52 and 53 are frequent. They resemble somewhat the synaptic knot of higher plants, but I do not believe that to be their nature.

Following the condition seen in Fig. 54, the chromosomes become massed together into a large, deeply staining body from which the tips of the spindle appear to emerge. The poles finally extend to the nuclear membrane, which usually persists to the late metaphase or early anaphase.

Figs. 55 and 56 show spindles in the metaphase with large undifferentiated chromatin masses. Figs. 57-62 show indications of individual chromosomes of a rounded or globular form, which, as nearly as I could determine, number six (Fig. 66). In Figs. 57 and 59-61 the chromosomes have evidently divided, while in Figs. 63 and 65 they are passing in mass to their respective poles of the spindle. The nuclear membrane has practically disappeared.

Figs. 67-73 represent succeeding conditions in the anaphase and telophase stages. The conditions represented in Figs. 69-73 are not uncommon, especially in the sexual elements. Similar stages in dividing nuclei have been illustrated for the rusts as well as for a few other Fungi. Fig. 73 represents the still united daughter nuclei with their respective nuclear membranes partially formed. No indication of direct nuclear division was seen.

Very commonly, if not in the majority of cases, the nuclear spindle was more or less bent (Figs. 55-7, 60, 61, and 65). In every case of this kind the poles of the spindle were in contact with the ends of the oval or elliptically shaped nuclear membrane. There was no indication of centrosomes or any structure which would suggest nuclear polarity.

4. DESCRIPTION OF SPECIES.

In 1872 Cornu (5) described a species of *Olpidiopsis* to which he applied the name *O. Saprolegniae*. He was unable to determine whether or not it was the same form observed by A. Braun, but as he wished to preserve Braun's specific name he used it for his species.

In the description of this species Cornu specifically states that the resting sporangia are provided with a large number of very small spines, and are accompanied by an adjacent cell with a smooth wall. He further states: 'It is solely upon that species that the name *O. Saprolegniae* is to be applied. The form of the sporangia, however variable in the species of that group, is not necessarily spherical. The character of the species is not drawn from that, but from the presence of a smooth adjacent cell, coupled with an oospore provided with a large number of spines, isolated and not formed by ridges.'

Cornu's illustration (Pl. III, Fig. 10) of the oospore of this species certainly clearly shows definite spines on the mature oospore rather than warts or tubercles.

A. Fischer (18), in 1892, described what he considered as *O. Saprolegniae* as possessing resting spores with the outer wall thickly covered with hemispherical or blunt colourless warts up to 3μ high. I am unable to reconcile this with Cornu's description. I believe that Fischer was dealing with a distinct and new species for which, as previously stated, I propose the name *O. vexans*.

Olpidiopsis vexans, nov. sp.

Synon. *O. Saprolegniae*, A. Fischer, 1892. Rabenhorst's 'Kryptogamenflora von Deutschland', I, lv, 38.

Sporangia, single or multiple, formed in terminal or intercalary swellings of the host hyphae, elliptical, oval, or spherical, very variable in size, up to 176μ in diam., with smooth, colourless membrane, colourless contents, and one to several unbranched exit tubes; zoospores elongated, slightly inequilateral, with two cilia attached at or near the anterior end. Oospores dark grey, with one, sometimes two, antheridial cells; oospores surrounded by a thick endospore and a thin warty exospore, spherical to oval, sometimes elliptical, up to $116 \times 84\mu$, average 50μ in diam.; antheridia spherical, less commonly oval, average diam. 20μ , with a smooth, colourless wall. Germination of oospores not observed.

Zoosporangiis solitariis v. numerosis, in cellula matricis terminalibus v. intercalaribus viventibus, ellipsoideis, ovalibus, v. sphaericis, magnitudine variis, $50-176\mu$ diam., hyalinis, membrana tenui, levi; zoosporis numerosis, elongatis; ciliis duobus, apici v. proximis apici insertis; oosporis, griseis, sphaericis ad ovalia, interdum ellipsoideis, circ. $116 \times 84\mu$ (saepissime 50μ diam.), endosporio crasso, levi, episporio tenui, verrucoso; cellulis antheridiis hyalinis, sphaericis ad ovalia, membrana tenui, levi cinctis, 20μ diam.

Hab. in *Saprolegnia ferax*, Ithaca, N.Y.

Olpidiopsis luxurians, nov. sp.

Sporangia single or multiple, formed in terminal or intercalary swellings of the host hyphae, oval to spherical, very variable in size, with one to three exit tubes extending considerably beyond the wall of the host; zoospores rather small, elongated, with two cilia attached at or near the anterior end. Oospores spherical, with one or two, rarely three, antheridia, with a thick endospore and a thin exospore provided with numerous conical spines up to 2.5μ in length; oospores $25-50\mu$ in diam., contain one or more large oil globules; antheridia spherical, frequently oval to elliptical, $10-25\mu$ in diam., with a smooth colourless wall. Germination of oospores not observed.

Parasitic in *Aphanomyces laevis*, de Bary, Ithaca.

Zoosporangiis solitariis v. numerosis, in cellula matricis plerumque intercalaribus viventibus, ovalibus ad sphaerica, magnitudine variis, collo 1-3

extra cellulam matricis valde prominente ornatis; zoosporis minutioribus, elongatis; ciliis duobus, apici v. proximis apici insertis; oosporis sphaericis, 25–50 μ diam., endosporio crasso, episporio tenui, spinis numerosis, conicis, basi dilatatis, apice acutissimis; antheridiis sphaericis, saepe ovalibus ad elliptica, 10–25 μ diam., membrana levi hyalina inclusis.

Hab. in *Aphanomyces laevis*, de Bary, Ithaca, N.Y.

This species is made not unmindful of the fact that the form resembles rather closely in some respects *O. minor*, A. Fischer, especially as described and illustrated by Petersen (19, p. 405). The fact that the spines are much more slender than those illustrated by Cornu (6, Pl. IV, Figs. 3 and 4) and that this form could not be transferred to the hosts on which *O. minor*, Fischer, was found, seems to the writer to warrant the establishment of a new species.

Olpidiopsis Saprolegniae, Cornu.

Sporangia single or multiple, formed in terminal or intercalary swellings of the host hyphae, elliptical, oval to spherical, very variable in size, up to 150 μ in diam., with one, less commonly two, exit tubes; zoospores oval to elongated, with two cilia attached at or near the anterior end. Oospores spherical, with one or two, less commonly three, antheridia, with a thick endospore and a thin exospore bearing numerous slender spines up to 10 μ long in large specimens; oospores very variable in size, up to 107 μ in diam., provided with oil globules; antheridia spherical to oval, with a smooth colourless wall. Germination of the oospores not observed.

Parasitic in *Saprolegnia* species. Ithaca.

This species is in some respects similar morphologically to *O. luxurians*. Cross-inoculation experiments with the two species and their hosts revealed that neither could be transferred to the host of the other. This would indicate that they were at least biological, if not morphological, species. The spines of the latter are slightly more slender than those of the former.

The description as given above for *O. Saprolegniae* differs in some minor points from that prepared by Cornu, but on the whole seems too close to it to warrant the formation of a new species.

5. GENERAL CONSIDERATIONS.

The presence of true sexuality in the Chytridiaceae is, indeed, rare. *Urophlyctis* and *Olpidiopsis* have been supposed to possess such a stage, but no cytological evidence has been brought forth. Fisch (10) described the copulation of small motile gametes in *Reessia*, while Sorokin (22), according to Butler (4), reports a similar phenomenon for *Tetrachytrium*. A. Fischer (18) accepts neither of these results, but in view of the fact that Griggs (14) has recently reported a similar condition as existing in his new genus *Monochytrium*, their correctness seems more probable. An interesting

sexual relation is found in the new genus and species *Zygorhizidium Willei* described by Loewenthal (17).

The one species, aside from that of *Monochytrium*, that is well known from a cytological point of view, is *Polyphagus Euglenae*, Now. Nowakowski described the external phenomenon of the union of the two individuals, but the internal behaviour relating to fertilization has until recent years remained unknown. The cytology of the form was first worked out by Wager (25). According to him the unicellular elements are uninucleate. After the fusion of the two protoplasts there ensues a period of rest, and it is not until the time of germination of the zygote that the sex nuclei fuse.

Dangeard (9) took up the study of the same organism and published a long memoir on it. He confirmed in general the results of Wager. He believes that copulation can take place with the male element before it has attained its complete development. This would appear to be another proof of his general theory of sexuality. According to this theory, living forms primitively asexual have become sexual on account of their resistance to unfavourable conditions where they live. In particular, the exhaustion of nutritive material brought about a sort of starvation which induced the appearance of sexual attraction.

The similarity of the mode of development and nuclear behaviour of the sexual elements of *Olpidiopsis* species, together with the relation of internal conditions to the development of the gametes, point strongly to the belief that they are morphologically equivalent to the sporangia. Many of the sporangial characters are retained by the male cells or antheridia up to the time of fertilization, while more marked differential changes in the oogonial forming individuals take place much earlier.

There appears to be no definite or proper time for the transference of the male protoplasm into the oogonium, at least so far as the behaviour of the nuclei is concerned. In other words, fusion of the sex protoplasm may take place before the maturity of one or both cells.

These characters, it seems, point to a primitive condition of the sexual stage. This view would, according to some students, be strengthened by the coenogametic nature of the sex individuals and the multinucleate character of the resulting oospore. This condition, however, is not confined to the lower forms. A similar condition was described by Stevens (24) for *Cystopus Bliti* in a genus showing what appears to be a sequence of species ranging, so far as numbers of fusion nuclei present in the oospore are concerned, from *Cystopus Bliti* to *Cystopus candidus* where only a single nucleus is present. Such a sequence occurring among closely allied species seems to indicate the gradual change from a primitive form to the more usual condition when only one nucleus is present. But when one considers that the sex cells of *Polyphagus Euglenae* are uninucleate, and the sex cells and resulting oospores of *Olpidiopsis* and *Ancylistes Closterii*, Pfit. (Dangeard, 7), are multinucleate,

the importance of such conditions seems lessened. These facts concerning the nuclei of these forms indicate a relationship between *Polyphagus* and *Ancylistes* as close as between *Polyphagus* and *Olpidiopsis*, both belonging to the Chytridiales. The former probably represents an early type of the Zygomycetes, while the latter represents a primitive Oomycete. Similar types are found among the Ancylistales, as *Ancylistes* for the Oomycetes and *Zygochytrium* for the Zygomycetes, although the cytology of the latter form is not known. *Lagenidium* also shows a relation to the Zygomycetes, but here again nothing is known about its cytology.

The entire absence of an antheridial tube and the passage of the entire contents of the antheridium into the oogonium suggest, according to Atkinson (1), 'a primitive and generalized condition of sexuality rather than a condition of degeneration from forms in which it is more highly specialized.'

It would be interesting to know the cytology of the closely related genus *Pseudolpidium*, in which resting spores very similar to those of *Olpidiopsis*, but without a companion or antheridial cell, are produced. In view of the conditions found by Fisch (10) in *Reessia* and Griggs (14) in *Monochytrium*, it seems not altogether impossible that in that genus there may be a similar fusion of elements that has been overlooked.

6. SUMMARY.

1. The zoospores of all three species of *Olpidiopsis* studied possess two cilia of equal length attached at or near the anterior end of the elongated body. They have two motile stages separated by a brief period of rest, which suggests a primitive type of diplanetism.
2. The individuality of the zoospore after entrance into the host is maintained throughout its development, there being no plasmodium formed. Aside from a slight amoeboid movement immediately after entrance, the parasite does not undergo any noticeable changes in form.
3. Segmentation of the sporangial contents has, at least partially, taken place before the entrance of the sporangium into a period of rest, when such occurs, and is apparently simultaneous throughout. The zoospores on escaping contain vacuoles.
4. True sexuality probably exists, and takes place by the fusion of two sexually differentiated individuals and the subsequent passage of the protoplasm of the smaller, male, into the larger, female, cell. This is followed by a supposed fusion of nuclei.
5. Both sexual and asexual reproductive bodies develop rather rapidly from a uninucleate to a multinucleate condition. The oospore is likewise multinucleate.
6. External conditions play a great part in the determination of sex in these organisms. This fact adds evidence to the doctrine that sex in many plants is determinable by external or nutritive conditions.

7. Nuclear division is mitotic with the spindle intranuclear. The number of chromosomes is approximately six. No centrosomes nor any other indication of nuclear polarity was observed.

8. These forms seem to be primitive sexual organisms of the Oomycete type. The influence of external conditions on the development of the sexual stage, the mode of fertilization, the unequal size of the two gametes, and the apparent morphological equivalence of these gametes with the sporangia, seem to the writer to point to that assumption.

EXPLANATION OF PLATES XXIII-XXVI.

Illustrating Mr. Barrett's paper on *Olpidiopsis*.

All figures were drawn with the aid of a camera lucida. The following combinations of objectives and oculars were used: Zeiss. apo. obj. 1.5 mm. N.A. 1.30, compen. oc. 18, Figs. 31-5 and 48-73; same obj., compen. oc. 12, Figs. 23 and 37-9; same obj., compen. oc. 8, Figs. 12-14, 22, 41, and 47; Zeiss apo. obj. 2 mm. N.A. 1.40, compen. oc. 12, Figs. 1-4, 8-10, 15, and 40; Zeiss. apo. obj. 2 mm. N.A. 1.40, compen. oc. 8, Figs. 28-30, 36, and 42-6; Zeiss apo. obj. 3 mm. dry, compen. oc. 12, Figs. 11, 17, 18, 24, and 25; 2/3 in. obj. and 1/2 in. oc., Fig. 26; 1/8 in. obj. and 1 in. oc., Fig. 27.

PLATE XXIII.

Fig. 1. Zoospores of *Olpidiopsis luxurians*. a, Drawn from a living zoospore. All others from stained preparations.

Fig. 2. Zoospores of *Olpidiopsis Saprolegniae*. a, From a living zoospore. All others from a stained preparation.

Fig. 3. Zoospore resting on an *Aphanomyces* hypha preparatory to entrance.

Fig. 4. Contents of the zoospore in the hypha, the empty spore wall outside.

Fig. 5. Germinated zoospore of *O. luxurians* on an empty sporangium of *Aphanomyces laevis*.

Fig. 6. Germinated zoospore of *O. luxurians* on an old, but still living, hypha of *Aphanomyces laevis*.

Fig. 7. A young developing sporangium of *O. luxurians* five hours after infection.

Fig. 8. Zoospore of *O. Saprolegniae* beginning to discharge its contents into the hypha of *Saprolegnia ferax*.

Fig. 9. Same zoospore as in Fig. 8, process nearly completed.

Fig. 10. Germinated zoospore of *Aphanomyces laevis* infected by *O. luxurians*.

Fig. 11. Young developing sporangium of *O. luxurians*.

Fig. 12. A sporangium of *O. luxurians*, showing the homogeneous ground substance containing small granules and a few fat globules.

Fig. 13. Same sporangium as in Fig. 12, three hours later.

Fig. 14. Same as Fig. 12, twenty-four hours later. Zoospores formed and exit tube beginning to develop.

Fig. 15. Zoospores of *O. vexans* from a stained preparation.

Fig. 16. Intercalarly formed sporangium of *O. luxurians* showing two characteristic exit tubes.

Fig. 17. Sporangium of *O. luxurians*, showing the recently developed membrane, vacuolate nature of the protoplasm, and the radiate character of the host protoplasm.

Fig. 18. Stage of developing sporangium showing the organization of regular vacuoles with diminished condition of the host protoplasm.

Fig. 19. Swollen hypha of *Saprolegnia* containing discharged and undischarged sporangia of *O. vexans*. The latter are in the resting condition.

Fig. 20. A sporangium of *O. vexans* in an old culture, showing a peculiar coiling of the long exit tubes.

Fig. 21. A slightly swollen hypha of *Saprolegnia* containing three empty sporangia and two mature oospores of *O. vexans*.

Fig. 21 A. An oospore of *O. Saprolegniae* drawn to the same scale as Fig. 21.

Fig. 21 B. An oospore of *O. luxurians* drawn to the same scale as Figs. 21 and 21 A.

Fig. 22. Portion of a sporangium of *O. luxurians* stained with Gram's stain. Shows the presence of faintly stainable bodies in the vacuoles.

Fig. 23. Large fat granule from a young sporangium. Much vacuolated.

PLATE XXIV.

Fig. 24. Young oogonium and attached antheridium of *O. luxurians*.

Fig. 25. An older stage of the sexual organs of *O. luxurians*. Two young sporangia are present in the same hyphal swelling.

Fig. 26. Young developing oogonium and two antheridia of *O. vexans*.

Fig. 27. Nearly mature oospore of *O. vexans* showing large oil globules and slightly roughened wall.

Fig. 28. Young oogonium and antheridium of *O. luxurians* slightly older than Fig. 25, which shows the developing spines and the large number of oil globules, also the granular protoplasm.

Fig. 29. Same specimen as in Fig. 28, two hours later. Spines are mature and the antheridial contents is passing into the oogonium.

Fig. 30. Mature oospore of *O. luxurians* bearing two empty antheridial cells.

Fig. 31. Young uninucleated sporangium of *O. vexans* soon after the entrance of the zoospore into the host.

Fig. 32. Binucleated sporangium of *O. vexans*.

Fig. 33. Binucleated sporangium of *O. vexans*, showing the nuclei in the act of division.

Fig. 34. Slightly older sporangium of *O. vexans*, showing its vacuolate character and the nuclei in division.

Fig. 35. Mature zoospores at the time of discharge from the sporangium, showing well-marked vacuoles.

The Morphology of *Trichodiscus elegans*, Gen. et Sp. Nov.¹

BY

E. J. WELSFORD, F.L.S.

Research Assistant, Department of Botany, University of Leeds.

OCCURRENCE. In March, 1910, whilst examining some *Azolla carolina* growing in a glass jar of rain-water in the greenhouse of the Royal Holloway College, I found a small green Alga which I was unable to identify. The plants were growing in small circular patches on the glass and also in a few cases on the *Azolla*, but in this situation they were exceedingly difficult to see.

The *Azolla* was bought in the previous November from Messrs. Ware and Sons, Limited, of Feltham, who had imported it from North Carolina, probably from Salem, and it is possible that the Alga was introduced from that district.

METHODS. Glass cover-slips were suspended in water against the side of a jar, and in a few weeks were covered with young Algae. Some of the slips were examined daily, and the development of the plant was studied in this way in the living condition. Material was also fixed in different stages of development in Flemming's weak solution and in 4 % formaldehyde. In the former case it was generally stained with haematoxylin or with brazilin, and mounted in Venice turpentine.

MORPHOLOGY. The Alga forms small circular green patches about 1 mm. in diameter, and is firmly fixed to the substratum. It consists of a flat disc bearing numerous erect branches and long septate hairs. The disc is one cell thick and is formed of branched creeping filaments which cohere to form a pseudo-parenchymatous thallus, the peripheral branches of which are more or less free, and sometimes curve upwards. All the cells of the disc, with the exception of the rapidly growing free apices of the filaments, are capable of giving rise to one or two short erect branches; these branches are more freely developed on old than on young plants. Hairs are not very numerous, and are usually found towards the periphery of the thallus. They are often 300 μ long, and

¹ A short account of this work was read before Section K of the British Association, at the meeting held at Winnipeg in September, 1909, and was published in the report.

germinate in the mother-cell. In *Trichodiscus elegans* the various phases of reproduction occur simultaneously, and sometimes very close together on the same plant. For instance, one of the figures represents a group of cells in which there is a mature sporangium containing gametes, and close beside it a younger sporangium, which after one division of its contents has ruptured and set free an asexual daughter-cell. Growing close to these is the group shown in another figure, in which there are three young sporangia before division, and one in which the contents, while still within the cell-wall, have developed into a thallus. In no case was it found possible to distinguish in any way between those cells which would eventually contain either gametes, asexual daughter-cells, or young plants; the close agreement of their initial cells suggests the possibility that they are homologous structures.

The changes of environment which account for Klebs's results, and which Lang (4) suggests determines whether the sexual or asexual character of a cell is latent or patent, are in this case absent. Here we have both gametes and asexual cells arising under precisely similar conditions. In this case it appears, therefore, that we must look for some stimulus other than the ordinary environmental conditions suggested by Klebs. Such a stimulus is probably closely connected with the nutrition of individual cells, and may be due to some subtle osmotic change acting from within instead of from without, as Livingston (5) has suggested is the case in a species of *Stigeoclonium*.

SUMMARY.

1. The alga *Trichodiscus elegans*, a member of the Chaetophoraceae, is described.
2. In *Trichodiscus elegans* both sexual and asexual cells were found to be developed from similar initials under the same environmental conditions.

NOTE.

NOTE ON A CASE OF DOUBLING OF EMBRYO-SAC, POLLEN-TUBE, AND EMBRYO.—While examining material of a *Lychnis* hybrid with a view to discovering the processes which occur in the formation of gametophytes and embryo, a curious example of duplicity was observed in an ovule, and is perhaps worth recording. The plant examined was a member of the second generation from the cross *Lychnis alba*, Mill. \times *Lychnis flos-cuculi*, Linn., and was a female with white flowers, showing a close resemblance to *L. alba*. Several flowers were pollinated by *L. flos-cuculi*, and an ovary was fixed forty-two hours later, one of whose ovules showed the structure to be described.

The ovule in question was about the normal size, and in the appearance of the nucellus, integuments, and sporophytic tissues generally showed no exceptional features when examined in a series of microtome sections. Within the nucellus, however, were present two embryo-sacs, roughly equal in size, lying in contact side by side in the usual position; each sac was of about the normal length, but of little more than half the normal diameter.

Into the apex of each embryo-sac had penetrated a pollen-tube whose nuclei had been expelled, and whose residual contents had degenerated in the usual fashion. An attempt was made to trace these pollen-tubes backwards, but this was found impossible, owing to crushing, except in the short gap between the micropyle and the apex of the nucellus; here there appeared to be two distinct tubes, but this was very difficult to determine and cannot be considered proven. The probability is strongly that two separate tubes entered the ovule, and it seems very unlikely that two functional apices should have been produced by the branching of a single tube. Moreover, in another ovule (with a single embryo-sac) two pollen-tubes were clearly present, though only one was functional, the other stopping short half-way through the peculiar specialized channel which leads from the apex of the nucellus towards the embryo-sac. The occurrence of two pollen-tubes in the ovule with two embryo-sacs may therefore be considered as almost certain.

Within each embryo-sac was found a single synergid, closely pressed against the apex of the pollen-tube; the second synergid had degenerated, as is usual. The antipodal cells had also disappeared.

Each embryo-sac contained a two-celled embryo of the type observed in other ovules of the same age. The cell towards the micropyle was already being differentiated as the basal cell of the suspensor. The other cell was, as usual, slightly elongated, the nucleus surrounded by dense cytoplasm being at its distal end, a large vacuole at the proximal.

Inside one of the embryo-sacs were found four endosperm nuclei—about the usual number at this stage of embryogeny. The other embryo-sac, however, still

contained the large definitive nucleus with its enormous nucleolus, no formation of endosperm having taken place.

It is possible that if this ovule had been allowed to develop it would have produced two seedlings on germination. It may be recalled that Gaertner¹ grew two exactly similar individuals from a single seed of *Dianthus barbatus* × *D. superbus*, another hybrid in a genus closely related to *Lychnis*.

No similar case to the present appears to be recorded in the literature. The nearest example is described by Schacht² in *Cheiranthus Cheiri*. There the formation of more than one embryo-sac seems to be a frequent occurrence; and in one case Schacht mentions the entrance of two pollen-tubes into a single ovule. He remarks, however, that it appears that never more than one egg-cell is fertilized.

The fact that two pollen-tubes should enter and fertilize an ovule which had developed two embryo-sacs can hardly be a mere coincidence; rather it would seem to indicate a quantitative relation between embryo-sac and pollen-tube in the matter of chemotaxis, two embryo-sacs excreting sufficient of the chemotropic substance to attract two pollen-tubes.

Fig. 14. Part of thallus, showing a young plant developed in a sporangium *in situ*; four young sporangia before division has taken place are also shown. $\times 750$.

Fig. 15. A seven-celled filamentous plant lying within the wall of the sporangium, which has become separated from the plant. $\times 1,000$.

Fig. 16. A five-celled filamentous plant which has begun to increase in size but is still surrounded by the sporangium wall, which has become gelatinous. $\times 1,000$.

Fig. 17. A group of small sporangia, showing empty sporangia and also one which still contains four zoospores. $\times 1,000$.

Fig. 18. A group of aplanospores. $\times 1,000$.

The Structure and Affinities of *Peranema* and *Diacalpe*.

BY

R. C. DAVIE, M.A., B.Sc.

Robert Donaldson Research Scholar of Glasgow University, Assistant in Botany in the University of Edinburgh.

With Plates XXVIII and XXIX.

PERANEMA CYATHEOIDES, D. Don, was first collected in the mountains of Nepal, Sheopore, and Chandagiri by Wallich. It was included in his 'Plantae Asiaticae Rarae', and was sent in 1823 to the Honourable East India Company's Museum at the India House. Duplicates were most liberally distributed in May of the following year. One of these is in the Herbarium of the Royal Botanic Gardens at Kew. On this specimen, however, there is only a written label, bearing the name *Sphaeropteris barbata*, Wall. There is no description of the plant, not even a note of its marked characteristics. Wallich's description was not published until 1830, when his 'Plantae Asiaticae Rarae' was issued. Meanwhile, David Don, in 1825, had published the 'Prodromus Florae Nepalensis' and had described *Sphaeropteris*, though in no great detail, under the name of *Peranema cyathoides*. Thus on the basis of priority of publication, as the label on Wallich's specimen is not printed but written, the name of the Fern must be kept as *Peranema*. Hooker and Baker in the 'Synopsis Filicum' give the specific name as *Peranema cyatheoides*, D. Don. This is also done by Christ in 'Die Farnkräuter der Erde', and by Christensen in the 'Index Filicum'. It is, however, more accurate to retain this specific name than to revert to Don's own 'cyathoides'.

It is included by Presl in his 'Tentamen Pteridographiae' (1836), where it is placed with *Physematium*, Kaulf., *Thyrsopteris*, Kze., and *Cibotium*, Kaulf., in the *Peranemeae*, the first tribe of the *Hymenophoreae*, Cohort I of the sub-order *Cathetogyratae*, Bernhardi. This tribe immediately follows the *Cyatheaceae* and precedes the *Aspidiaceae*. In 1842 it was included in J. Smith's 'Genera of Ferns' in Hooker's 'Journal of Botany', vol. iv, p. 190. There it is placed in Section II of the *Aspidieae*,—the *Orthophlebieae*—a section characterized by their free venation, none of the

venules anastomosing. It is separated from the Cyathea (p. 181), 'because the pedicellate sori of *Sphaeropteris* cannot in my opinion be viewed as an elevated receptacle'. Smith adds, 'On viewing their¹ habit and characters in every other respect I do not hesitate in placing them in this tribe' (Aspidieae). In Hooker's 'Species Filicum' (1846) *Peranema* is again described under the name of *Sphaeropteris*, Wall., and is placed in the Woodsieae, the second sub-tribe of the Dicksonieae, Gaud. In 1856 it was described by Mettenius in his 'Filices Horti Botanici Lipsiensis' and by him put, with *Woodsia* and *Diacalpe*, in the Aspidieae, Group IV of the Polypodiaceae. R. H. Beddome in the 'Ferns of Southern India' (1863) places it in the Polypodiaceae, in the group Peranemeae. It there follows the Davallieae, with *Davallia* and *Microlepia*, and immediately precedes the Cyathea, with *Cyathea* and *Alsophila*. Robert Brown in 1867 gave a full description of *Peranema*, placing it in his family Polypodiaceae. He remarks that it is clearly to be distinguished from several Cyathea, but is closely related to *Woodsia mexicana*, R.Br. 'Hoc ultimo caractere et reticulatione involucri a Cyatheis nonnullis (involucro e medio venae orto) praesertim distinguenda; arctiori tamen affinitate nixa cum Woodsia, mediante specie mexicana (*W. mexicana*, Nob.).' Hooker and Baker in the 'Synopsis Filicum' (1874) place it in their Dicksonieae. H. Christ in 'Die Farnkräuter der Erde' (1897) places it in the Aspidieae. And Diels in Engler and Prantl's 'Natürliche Pflanzenfamilien' includes it in the Woodsieae-Woodsiinae group of Polypodiaceae—the group which immediately succeeds the group Cyatheaaceae.

From the differing positions in which the Fern has been placed it is evident that its systematic position is one of difficulty and debate. The prevailing tendency has been to relate it to the *Woodsia* group, a group included in the Polypodiaceae by most systematists, in the Dicksonieae by Hooker and Baker. In Wallich's account of the Fern ('Plantae Asiaticae Rarae', p. 42) he says of his own specimen sent to the East India Company's Museum: 'In the Museum just mentioned the Fern was labelled "*Cyathea* ? *barbata*, Wall. vix non genus novum, *Sphaeropteris*, Nob. non *Bernhardi*".' This confusion of *Peranema* with *Cyathea* by the Museum authorities is also suggested in David Don's description in the 'Prodromus Florae Nepalensis', where the following concluding observation is made: 'Obs. Genus a *Cyathea*, cui affine, omnino distinctum: indusiis sphaericis indivisis pedicellatis.' Robert Brown's remark, already quoted, confirms this suggestion of an affinity with the Cyatheaaceae. On the other hand, Mettenius and Christ place it in the Aspidieae, while C. B. Clarke in the 'Review of the Ferns of Northern India' ('Trans. Linn. Soc.', 2nd series, i, p. 435, 1880) describes *Peranema* as difficult to separate, when without fruit, from *Aspidium spectabile*, Wall. The intermediate position between

¹ i.e. *Diacalpe*, *Sphaeropteris*, *Woodsia*, *Hypoderris*.

the Cyatheaceae and the Aspidiaceae, adopted for it by Presl, Robert Brown, and Diels, will be confirmed in this account of its anatomy.

The observations here to be detailed, and those later to be detailed for *Diacalpe aspidioides*, Bl., have been made partly on Herbarium specimens, but especially upon material preserved in spirit and upon living specimens, which were supplied from India, through the kindness of the Director of the Calcutta Garden. Strong plants of *Peranema* and *Diacalpe* from this source are under cultivation in the Glasgow Botanic Garden. The investigation was carried on partly in the Jodrell Laboratory, Royal Botanic Gardens, Kew. For facilities afforded there, I am much indebted to Lieut.-Col. Prain, F.R.S. To Mr. L. A. Boodle, F.L.S., and to Professor F. O. Bower, F.R.S., under whose direction the work has been carried on, I am indebted for much help and criticism.

EXTERNAL CHARACTERS.

The stock is distinctly upright, some four to six inches in length. The roots spring from every side of it and are branched and fibrous. The leaves are from one to three feet in length and of a bright green colour. Their stalks are long, sometimes a foot in length, convex at first and then furrowed on the adaxial side. Both stock and rachis are covered with paleae, which are lanceolate, with acuminate tips; they have reticulate marking, almost entire or quite entire margins, and are of a light dusky red colour. These are persistent from the first on the young stalks. The leaves are tripinnate, broadly ovate, with acuminate apices. They have wide alternate pinnac, on the pinnules of which the leaf-segments are sessile. The leaf-segments are linear-oblong with rounded apices; the lower ones are pinnatifid, the upper are broadly crenate. On the main rachis and on that of the branches are short, subulate, hyaline, incurved hairs, on which small glands are borne. Similar glands are also found on the rachis among the hairs, but arising directly from the epidermal cells of the rachis. The venation is open and simple; no anastomosing veins are found in any part of the leaf (Pl. XXVIII, Fig. 1). On the under side the veins are provided with little stalked glands, the stalks of which are sometimes unicellular, sometimes multicellular. The sori are produced superficially on the lower side of the leaf. Each sorus is borne on a short stalk and arises upon the surface of a vein, but always some distance from the tip of the vein. The indusium is entire except for a small pit which is present on the under side and quite close to the junction of the stalk with the indusium. At maturity a vertical split occurs across the sorus, and the two sides of the indusium become reflexed and finally flattened out. The sporangia are very crowded on the elongated receptacle and are long-stalked. Each has a pale dusky red annulus. The spores are sub-globose and covered with warty markings.

INTERNAL STRUCTURE.

The stock is distinctly an upright one, widening gradually from the base upwards. It is covered by paleae of delicate texture and dark brown colour. Some of these are provided with numerous glands on the surface directed towards the stock. The whole stock is enveloped in a thick mass of sclerenchyma, several cell-layers in width. The ground parenchyma is compact, with few air spaces and those of small size, while the cells are filled with starchy and proteid contents. Throughout this parenchyma are scattered little masses of sclerenchyma, dispersed in irregular fashion, but of very firm texture. The leaves are inserted spirally on the stock, the divergence in the mature stock being one-seventh. A transverse section of the stock shows a series of meristeles, usually five or six in number, surrounded at their edges by a varying number of smaller strands (Fig. 2). One or two of the meristeles are elongated, and in transverse section show tracheides cut in an oblique or in a longitudinal direction. Other meristeles are rounded and have quite transversely-cut tracheides. If one of the elongated meristeles is followed up or down in the stock it is found to divide into two parts which assume a structure exactly like that of the remaining meristeles. Sometimes two elongated meristeles may be found opposite to each other. Generally, however, only one oval meristele appears in each section. This shows at once that the vascular system is dictyostelic. On dissection of the stock this dictyostele is found to consist of a series of strands united into a meshwork, in which the gaps have an oval form. It is indeed exactly like the advanced dictyostele generally exemplified in the vascular system of *Nephrodium filix-mas*, Rich. The gaps are found only opposite the entrance-points of leaf-traces into the dictyostele; there are no perforations.

The leaf-trace is itself made up of three main strands and four or five subsidiary ones. Two of the main strands occupy the adaxial corners of the petiole, while the third occupies a median position on the abaxial curved side. Two smaller strands are found between each adaxial main strand and the median one, while often still smaller strands, of the nature of commissures, may be found between these subsidiary strands or between them and the main strands (Fig. 3). Sometimes a commissural strand may be nipped off from one of the adaxial strands, pass up to the next subsidiary strand, fuse with it on one side, then pass off on the other side, to unite with the next subsidiary strand a little further up the petiole. This process is continued up the petiole, the commissural strand passing from one strand to the next until it arrives at the second adaxial strand of the petiole.

When the leaf-trace strands are followed from the petiole into the dictyostele they are found to insert themselves along the sides of the oval

gap. The strands from any one leaf-trace are inserted on the lower half of the two limbs of vascular tissue enclosing the gap opposite the leaf, while the median main strand is inserted at the lower junction of these limbs (Fig. 4, I, II). All the bundles from any one leaf-trace are inserted on the lower half of any leaf-gap. Evidently the upper half receives half the bundles from one leaf-trace which enters from a higher leaf and half the bundles from another. These two leaves are inserted on the axis obliquely above that of which the bundles enter on the lower half of the leaf-gap (Fig. 4; III).

This arrangement corresponds in the main with what occurs in the insertion of the leaf-trace on the dictyostele in *Nephrodium filix-mas*. But in the last-named Fern the adaxial bundles of the leaf-trace enter at the level of the bases of the gaps corresponding to the two leaves obliquely next above that to which the bundles belong. The median main strand enters at the fork on the lower half of the gap, just as in the case of *Peranema cyatheoides* (de Bary, 'Comp. Anat.', Fig. 132, and description, p. 285).

Histologically the meristeles of the stock are uninteresting. The xylem is made up of regular tracheides, interspersed with few parenchymatous cells and with no definitely differentiated protoxylem.

This is a characteristic of the meristeles of the stock among the Cyatheaceae, and except in that respect calls for no comment. The first lignification of the undifferentiated parenchyma in the young stock is on the inner side, as is represented in Fig. 5, which is made from a transverse section just below the apex of the young shoot. The stele is thus technically endarch as regards sequence of development, though no specifically marked tracheides of protoxylem appear to be found. Each meristele is enclosed in an almost complete sheath of phloem, which extends round the xylem on the inner and outer sides of the bundle, but is interrupted at the corners, so that two lenticles of phloem are found, one on each side of the mass of tracheides. The phloem is in turn surrounded by a parenchymatous pericycle of several layers and an endodermis with thickened cell-walls, often enclosing brownish contents. At the corners of the bundle the xylem comes directly into contact with the pericycle.

In the petiole the strands differ in structure from those of the stock. The leaf-trace strands leave the meristeles of the stock in quite simple fashion. In the case of the median leaf-trace strand, which departs first from the dictyostele at the fork below the gap, the oval strand shows a little hump or swelling on its outer surface. This gradually increases in size and rounds itself off from the parent stele as a plate of xylem surrounded by a sheath of phloem. The adaxial leaf-trace bundles leave the corners of two of the meristeles. They are at first simple in structure with a xylem-plate surrounded by a phloem sheath. In no case does a strand of the leaf-trace leave any gap in the xylem of the meristele from which

it springs. Soon after the adaxial strands have passed into the base of the petiole their inner edges become extended, so that ultimately each of these strands is curved in form, with a dilated abaxial portion and a delicate strip of xylem projecting sometimes almost parallel to the lower surface of this, and forming a hook, with its back towards the periphery of the petiole (Fig. 6, *a*). Two or three protoxylem groups are found in the positions *prx.*¹, *prx.*², &c. The whole of the hooked mass of xylem is surrounded by phloem, which, however, thins out or altogether disappears on the side of the mass facing the centre of the petiole. A several-layered pericycle and a single brown-coloured layer of endodermis enclose each strand, while often a mass of sclerenchyma, one or two layers deep, encloses the whole bundle.

The median main bundle has a narrow plate of xylem with its long axis parallel to the adaxial side of the petiole, and with one or two protoxylem masses on the side facing the centre of the petiole. Phloem is present generally only on the side facing the periphery of the petiole. Sometimes a very small amount of phloem is developed also on the side facing the centre of the petiole.

The smaller subsidiary strands have the same structure.

Small groups of sclerenchymatous cells are here and there seen in the tissue of the petiole, generally between the subsidiary strands, but often also between them and the main strands. Other groups of sclerenchyma are found scattered in the ground tissue of the petiole.

When the supply to the pinnae is about to be given off, one of the adaxial strands of the petiole extends towards the adaxial corner of the petiole, lengthening the narrow strip of xylem on its adaxial side and pushing a tongue of xylem towards the pinna (Fig. 6, *b*). Some distance from the back of the hook two swellings occur in the xylem, one in the narrow portion, the other in the wide portion. These soon form a bridge, cutting off an island of parenchyma, the ring of xylem surrounding which has the shape of a signet ring in section, until at last the strand of the pinna-trace goes off as a ring of xylem with a larger amount of tracheides on one side than on the other (Fig. 6, *c*). Then the wider side of the ring pushes up a tongue of xylem, a gap appears, filled with parenchyma, the two halves of the strand draw apart to right and left, leaving a channel of parenchyma between them (Fig. 7, III). These take on the shape of the adaxial strands of the petiole. From one of them is nipped off a median strand of the shape of the early pinna-trace. And from it and from the other pro-rachial¹ strand come two subsidiary strands. The final

¹ As the faces of the rachis of the pinna are not orientated with regard to the stock but with regard to the rachis of the frond, the terms 'adaxial' and 'abaxial' cannot be used in connexion with the pinna-trace strands. It is therefore necessary to use new terms whereby these strands may be distinguished from one another. 'Pro-rachial' means directed towards the rachis; 'aporachial', directed away from the rachis.

condition of the pinna-trace is that of a miniature petiole-trace, except that only two, instead of four or more, subsidiary strands are present. From the prostrachial strands the pinnules are supplied, as were the pinnae from the adaxial strands of the petiole (Fig. 7, IX, X). Through the rachis of the frond from the departure of the first pair of pinnae to the departure of the second pair there run five vascular strands and a commissural strand. To the second pair of pinnae the supply is given off from the prostrachial bundles in the same fashion as to the first pair of pinnae. The same process is repeated for the third pair of pinnae. Between pair 3 and pair 4 the number of strands is reduced to three, with a commissural strand. And pair 4 (pinnae VII and VIII) are given off again in the normal manner. Beyond pair 4 the vascular strands are only three in number with occasional fusions of the median aporachial strand and one or other of the prostrachial strands. Towards the tip of the leaf the strands are reduced in number to two, the pinna-supply going off in the normal fashion. Ultimately only a single strand remains in the rachis. This strand has a narrow plate of xylem, with no incurved ends, and from its edges the simple strands to the ultimate segments are quite simply nipped off. Here the plate extends in the direction towards the pinna to be supplied, and the marginal group of tracheides surrounds itself with phloem, pericycle, and endodermis, while the parent strand re-forms its simple plate. As this type of pinna-supply differs from that given to the basal pinnae, it is proposed to term it the 'marginal' type, while that found in connexion with the lower pinnae and already described may be termed the 'extramarginal' type. To these two types of pinna-supply and their significance reference will be made later on in the paper.

The root is diarch, with a single plate of xylem, composed of a set of four or six tracheides and two protoxylem groups, one at either end. The protoxylem elements abut directly on the pericycle, which is of two layers of cells at these points. Between the secondary xylem and the phloem is a series of parenchymatous cells, one or two layers thick. These have prominent nuclei and dense protoplasmic contents. Phloem surrounds this zone on the outer side. The endodermis has brownish cells, while the cortex is made up of thickened cells with deep brown coloured walls. The greater part of the piliferous layer breaks away, leaving the cortex as the outermost layer of the root. The stele comes off obliquely from the back of one of the meristeles of the stock, the root passing out into the soil in a slightly decurrent direction.

On the petiole and rachis of the mature leaf are innumerable paleae and hairs. The paleae are very similar to those on the stock, but their edges are quite entire. Each runs out into an acuminate apex (Fig. 8). Along the margins of a palea a few unicellular glands are inserted (cf. the paleae of *Blechnum occidentale*, Gardiner and Ito, '87), and these project

directly out from the edges of the palea. Occasionally a gland may be found on the adaxial face of the palea, usually about its centre. Curious curved hairs are liberally distributed upon the surface of the petiole and rachis among the paleae. These hairs are inserted on distended boss-like cells of the epidermis. Each hair is made up of eight or ten cells of rectangular form. Two of these rise directly up from the boss-like cell, while the rest form a tapering series which bends over at its tip almost to touch the epidermis. At the top of the curved part two or three glands are inserted. These are of the unicellular type found on the paleae. Sometimes a gland may be inserted near the tip of the hair, but more usually a group is found on the curved portion of the hair (Fig. 9).

Here and there on rachis, petiole, and on the back of the veinlets of the pinnae and pinnules unicellular glands are also found simply inserted on the epidermal cells. In the young parts of the plant and on the petiole these glands have a hyaline margin, which appears to be filled with a clear fluid secreted by the gland (Fig. 10). Right over the top of this secretion passes a limiting membrane, which does not, however, appear to be cutinized, though it is continuous with the outer layer of the stalk of the gland. In the older parts of the plant and on the lower portion of the petiole the glands have no hyaline covering, but are limited externally by a thin cell-wall, and contain a distinct nucleus and dense cytoplasm (Fig. 11). Apparently the secreted fluid disappears from the glands as they grow older. The glands closely resemble those found in the tissue of the petiole and stock of *Nephrodium filix-mas* (de Bary, pp. 89 and 220, and Schacht, '63). They give to the plant a very distinct odour, somewhat recalling that of *Heracleum Sphondylium*, and also bearing some resemblance to that of *Lastrea Oreopteris*. In the case of *Peranema*, however, the glands do not show the golden appearance of those in *L. Oreopteris*, but rather a pearly white appearance by reflected light, while they are quite translucent by transmitted light.

On the lower surface of the veinlets in the pinnules are found short recurved hairs bearing no glands. They project from the epidermis and give the suggestion of little bent pegs hanging down from the pinnules. They are multicellular, but their cells are in a single series or row, and are some six or seven in number.

The segmentation of stem and leaf goes on in the usual fashion for Leptosporangiate Ferns. The wings of the leaf show the customary marginal series of cells (Fig. 12).

SORUS AND SPORANGIA.

The mature sorus and sporangium have been described by Mettenius ('Filices Horti Bot. Lips.', 1856, No. 40), and by Wallich ('Plantae Asiat. Rar.', p. 42). Drawings of sorus and sporangium after F. Bauer appear in

Engler and Prantl's 'Natürliche Pflanzenfamilien', where habit drawings of the sorus by Diels are also produced. In 'Phil. Trans.', vol. cxcii, 1899, p. 57, Professor Bower has given a description of the sporangium from Herbarium material. F. Bauer's drawings in the 'Genera Filicum' and Professor Bower's drawing (loc. cit., Fig. 92) give representations of the sporangia. The sorus has never been adequately figured. Bauer's figures give no real idea of the nature of the receptacle, and, as Professor Bower remarks, 'suggest a regularity of orientation, which is not, however, to be recognized as constant in Herbarium specimens.'

The sorus is superficial in insertion and stalked. The stalk springs from one of the lateral veinlets on the under side of the pinna, and generally grows out for one millimetre or longer, vertically from the leaf. The sorus is spherical and, as Wallich remarks, 'about the size of a Coriander seed'. The youngest stages have, unfortunately, not been available. The material sent from Calcutta had upon it only mature or almost mature sori. And the living plant which accompanied this material, and which is now growing in the Botanic Gardens in Glasgow, has, during the two years it has been there, produced no sori. From the youngest sori available for examination it appears as though the indusium completely encloses the sorus. But at one point, close to the junction of the stalk with the indusium, a minute pore can be seen on the outside of the sorus. This forms a very narrow slit leading into the interior. Except at this pore, the indusium is quite entire, giving the outward impression of an unbroken covering for the sorus. It is essentially a cup, developed unequally on its two sides and contracted at its rim, which is turned inwards (cf. Fig. 15). When the sorus is mature a series of cells across the top breaks down, and an irregular crack is formed from one side of the sorus to the other. The two flaps of indusium thus formed bend back, exposing the sporangia within to the outer air. In this opened condition the resemblance to the sorus of *Cyathea* is remarkably close and convincing. It is this opened sorus which has been drawn by Bauer.

The indusium is made up of a single layer of cells, except just at the point of insertion on the receptacle, where it may be two layers in thickness. The cells are triangular or quadrangular in outline with triangular thickenings at their corners, giving the whole indusium a lace-like appearance. The receptacle is distinctly elongated, and occupies about one-half of the cavity covered in by the indusium. A series of tracheides runs into the receptacle from the stalk, and they then spread out in fan fashion just above the point of junction of receptacle and indusium (Fig. 13). This vascular supply passes right through the stalk of the sorus in a median direction, and merges into the vascular supply of the vein of the pinna.

On this elongated receptacle, which is distinctly of the Gradate type

and strongly recalls the receptacle of the Cyatheaceae, are inserted some four hundred sporangia. Young and old sporangia are inserted promiscuously round the receptacle, a predominance of younger ones occurring towards the lower edges (Figs. 14 and 15). Young ones also occur at the apex of the receptacle among the stalks of quite mature sporangia (Fig. 14). The sorus is thus one distinctly of the mixed type, upon a receptacle characteristic of the Gradatae. The presence of younger sporangia towards the lower edges of the receptacle confirms the suggestion of the derivation of this sorus from one of a Gradate type.

There is no regularity of orientation among the sporangia in the sorus. Their annuli are arranged pointing in all directions when looked upon from above.

The sporangium itself is long-stalked, the stalk often taking a slightly curved form, the convex side of the curve being on the same side as the annulus (Fig. 16). Two or even three series of elongated cells are found contributing to the length of this stalk. In section the stalk consists of three cells symmetrically arranged about the centre, one rather larger than the other two (Fig. 17) as in *Nephrodium*. The capsule is rather elongated, much like the capsule of a typical Polypodiaceous Fern. The annulus consists of twelve to fourteen cells, indurated on the four sides, though, as usual, least strongly on the outer walls (Fig. 16). It passes right over the top of the capsule, and is continued always right back to the stalk as an unbroken and symmetrical series of typically indurated cells (Fig. 16). Frequently indurated walls are found in the cells past the stalk, though more commonly the induration stops in the one just at its centre. The series of cells of the annulus is, however, always continued past the stalk. As this stalk consists of three cells, they are arranged in a group of two on one side of the capsule, with the single one on the other side. The annulus is continued to one side of the single one, passing right across the tops of the cells in the other two (Fig. 18). It is thus slightly oblique in its insertion (Fig. 19).

The stomium consists of a series of wide cells, often seven in number, which continue and complete the hoop of the annulus round the sporangial head. Two of these cells are always strongly indurated, and are wider than the rest (Fig. 20). It is between these that the first break occurs, which allows the mechanism of the annulus to work and to secure the dispersal of the spores. The dehiscence of the sporangium takes place by a series of irregular cracks stretching across the sides of the capsule from the stomium.

The spores within each sporangium appear to number sixty-four. This number is characteristic rather of the Gradatae than of the Mixtae, though it is a feature to be anticipated in view of the elongated receptacle and the slight obliquity of the annulus. These three features of sorus and

sporangium must be weighed against the long stalk of the sporangium and the mixed condition of the sorus in estimating the systematic position of *Peranema*. For the present it may be noticed that they all indicate that *Peranema* occupies an interesting position intermediate between *Gradatae* and *Mixtae*, and combines in its mechanism for spore production and dispersal the main characteristics of both groups.

The spores are very characteristic. They are of somewhat large size, and have on their surfaces very peculiar markings (Fig. 21). Each spore is surrounded by a membrane which encloses it rather loosely. At certain points, perhaps four or six or more, on its surface, the membrane is attached to the spore itself. These points take the form of little circular discs, each with a minute papilla in its centre, a portion of the membrane detached from the spore wall and filled with air. As a result of the presence of these circular pits and their included papillae, the surface of the membrane appears to be crossed by a series of folds of irregular shape. These are of course the portions of the membrane surrounding the circular pits, portions which are quite free from the spore. Such markings are found with some slight variation among many genera of Polypodiaceae, particularly in the genus *Aspidium*. They have lately been described by Hannig ('11). He finds that in the *Cyatheaceae* (loc. cit., p. 342), and in the genus *Polypodium* (p. 344), there is no loose membrane ('perispore') around the spores. From the characteristic appearance of the perispore in the genus *Aspidium* he has been led to distinguish spores surrounded by a similar perispore as 'aspidioid'. He remarks (p. 340) that the genera *Peranema*, *Diacalpe*, and *Woodsia* possess aspidioid spores.

Unfortunately the first set of germinated spores in the Glasgow Botanic Gardens damped off before the antheridia had developed upon the prothalli, and the second set have not yet produced antheridia. The first stages of development are quite normal. The later stages have not been available, and no conclusions can therefore be made from the characters of the gametophyte generation.

DIALALPE ASPIDIOIDES, Bl., was first described by C. L. Blume in his 'Enumeratio Plantarum Javae et Insularum adjacentium', published in 1828. From the genus *Woodsia*, R. Br., to which he says it bears close affinity, Blume separates it because the indusium is not 'dish-shaped and ciliated'. He places it in the third section of Kaulfuss's family Polypodiaceae, a section characterized by the sporangia being borne on receptacles, and by the indusium springing from below the sorus or being altogether absent. In the same section are included also *Cyathea*, *Alsophila*, and *Hemitelia*. *Diacalpe* grows, he remarks, 'in sylvis Javae altissimis'.

It is included in the Appendix to Presl's 'Tentamen Pteridographiae' (1836), with the query: 'An *Cyatheacca*, an *Cathetogyrate* stirps?'

J. Smith, in Hooker's 'Journal of Botany', iv, 1842, p. 191, assigns it, with *Peranema* and *Woodsia*, to the Aspidieae.

By Sir W. J. Hooker ('Genera Filicum', t. 99, and 'Species Filicum'), it is placed beside *Peranema* in the Dicksonieae, sub-tribe Woodsieae.

In the 'Synopsis Filicum' (Hooker and Baker, '74), it appears next to *Alsophila* and between it and *Matonia*, accompanied by the comments (p. 45): 'This genus seems more appropriately placed with the Cyatheae than with the Dicksonieae. The fronds much resemble those of *Davallia nodosa*' (which is the original *Acrophorus* of Presl). The close resemblance between *Diacalpe aspidioides* and *Davallia nodosa* is mentioned also by C. B. Clarke in the 'Review of the Ferns of Northern India' ('Trans. Linn. Soc.', 2nd ser., vol. i, pp. 434 and 445).

Captain R. H. Beddome in 'The Ferns of Southern India' (1863) separates *Peranema* and *Diacalpe* as the group Peranemaeae of the Polypodiaceae. This group comes between the Davallieae (including *Microlepia* and *Davallia*) and the Cyatheae (with *Cyathea* and *Alsophila*).

Raciborski ('98) in the 'Pteridophyten der Flora von Buitenzorg' places *Diacalpe* between *Asplenium* and *Dicksonia* in the B. II group of Polypodiaceae.

Diels (Engler and Prantl's 'Natürl. Pflanzenfam.') associates *Diacalpe* with *Peranema*, and these two with *Woodsia*, *Hypoderris*, and *Acrophorus* in the Woodsieae group of Polypodiaceae.

By Wallich, *Diacalpe aspidioides* was named *Aspidium foliolosum* (Cat. no. 359) and *Sphaeropteris Hookeriana* (Cat. no. 775). Following on this Presl, though he puts '*Diacalpe aspidioides*, Bl.', among the insufficiently described genera, calls *Aspidium foliolosum* by the name *Cystopteris gigantea*, and places *Cystopteris* next to *Acrophorus*.

By Kunze ('Anal. Pterid.', p. 43) *Diacalpe* was named *Physematium aspidioides*. Another species of *Physematium* (*P. molle*, Kaulf.) is called *Woodsia mexicana* by Robert Brown ('Miscellaneous Works', ii, p. 547), who remarks that it is closely related to *Peranema cyatheoides*. These confusions of nomenclature all converge on a grouping together of *Peranema*, *Diacalpe*, *Woodsia*, and *Acrophorus*.

The hint of a relationship between *Diacalpe* and the Aspidieae given directly by J. Smith, and by Wallich in the name *Aspidium foliolosum*, is confirmed by Christ in a review of Christensen's 'Index Filicum' (Hedwigia, 1908, xlvii, p. 145): '*Peranema*, *Diacalpe*, *Acrophorus* einerseits, *Woodsia* und *Cystopteris* andererseits, werden wohl schliesslich auch zu den Aspidieae (bei *Lastrea*) gezogen werden müssen.'

EXTERNAL CHARACTERS.

The stock is upright, or at first creeping and becoming upright before more than twelve leaves have been produced. It is narrower than that of *Peranema*, and is not covered by a dense felt of paleae. The leaf-insertion depends on the size of the stock; in one case the divergence has been found to be a fifth, in other cases it is irregular.

The leaves are large, from two to four feet long, with a long petiole, and are decomposed and herbaceous. The lower part of the petiole is covered with broad, brown membranaceous scales. Similar but smaller scales appear together with hairs as little tufts at the axils of the primary pinnae on the younger branches. The frond is tripinnate, the primary pinnae often being nearly opposite. The rachis of the frond and that of the pinnae bear short scales and hairs of a single long series of cells. Long hair-like scales also appear on the upper surface of the leaf above the veins. Unicellular glands are found on the petiole and rachis among the scales and hairs, but no glands are present elsewhere on the leaves. On older leaves the scales and hairs disappear from the rachis, which are then quite smooth.

The primary pinnae are lanceolate, the secondary pinnae being obtuse and oblong-cuncate; the lower pinnules are deeply pinnatifid and somewhat decurrent, so that the rachis of the ultimate pinna is generally winged. The venation is open; the veins are simply pinnate, and the veinlets are undivided, not reaching quite to the margins of the leaflets.

The sori are produced superficially on the under surface of the leaf, usually on the lower anterior veinlet of each segment, at a point below its termination. Usually there is only one sorus on each veinlet. The sorus is apparently sessile, but it is not strictly so, being seated on a slightly elevated point, from which the entire sorus can be freely removed without rupturing the base of the indusium or receptacle. The indusium is at first quite entire, completely enclosing the sorus. Its texture is very coriaceous. It ultimately breaks irregularly at the apex, and opens by two or more valves. The receptacle is short and is covered by a large number of sporangia, irregularly arranged within the sorus.

The sporangium is long-stalked, with a somewhat bulky capsule, and an annulus vertical in insertion but slightly twisting to one side as it crosses the capsule. The spores have warty superficial markings.

INTERNAL STRUCTURE.

The transverse section of the stock very closely resembles that of the stock of *Peranema cyatheoides*. The meristeles are inserted in the same fashion, and the leaf-traces bear the same relation to the main vascular system as do those of *Peranema*. The vascular system is in *Diacalpe* also

an advanced dictyostele, but all the gaps are here, too, leaf-trace gaps. Schlumberger ('Flora', cii, N. F. 2, 1911, p. 409) states that there are perforations in the dictyostele in *Diacalpe aspidioides*: 'Ausser den Blattlücken tritt wie bei den Cyatheaceen eine ganze Reihe von "Perforationen" auf.' In the stocks I have dissected I have been unable to discover the presence of any such perforations. In all respects the dictyostele of *Diacalpe* has been found to agree with those of *Peranema cyatheoides* and *Nephrodium filix-mas*. The leaf-trace is made up of three main bundles and a varying number of subsidiary bundles, with occasional commissural bundles uniting one main bundle with the subsidiary ones or with one of the other main bundles. The strands of the leaf-trace are inserted on the lower half of each gap opposite the entrance of the petiole to which the trace belongs, and the median main bundle of the trace enters the dictyostele at the lower fork of the gap. With regard to the histology of the supply of the leaf-trace from the dictyostele, the facts are the same for *Diacalpe aspidioides* as for *Peranema*. The adaxial main bundles of the leaf-trace have deeply incurved hooks on their adaxial faces. From the backs of these hooks the pinna-traces go off in the extramarginal fashion. The pinna-trace is at first a simple strand, but it soon breaks up, as in *Peranema*, into three strands. The pinnules are supplied from these on the extramarginal type. The ultimate pinna is supplied in marginal fashion from a dorsiventrally-constricted simple xylem-plate. The same process occurs in the supply of the ultimate pinnules from the pinna-traces.

Scales of three rows of parenchymatous cells, some six or eight in each row, occur on the leaves, usually above a vein or veinlet. Simple unicellular glands, but no multicellular hairs bearing glands, occur sporadically on rachis and leaves. Paleae of the type found in *Peranema*, but without glands on the edges, are present at the bases of the primary pinnae and on the rachis and petiole in younger leaves; few or none are found on fully-matured leaves.

The sorus is at first entirely covered by the indusium. There is in this indusium no such pit or pore at one side as is found in that of *Peranema*. Here the indusium forms an unbroken symmetrical covering for the sporangia, coriaceous in texture, with cells of polygonal outline possessing triangular thickenings at the corners. In section these cells are rectangular, often square, with thickened walls.

The receptacle is short but not flattened, and is supplied by a short fan of tracheides from the vascular bundle of the veinlet on which the sorus is seated. The sporangia are numerous. They are of all ages in the same sorus and are inserted on the receptacle in distinctly mixed fashion. There is no trace of a basipetal sequence of development. The full developmental stages have unfortunately been unavailable, but even in moderately young sori no traces of very young sporangia were found at the basal edges of the

receptacle. The youngest sporangia, showing merely two or three segmentation-walls, were found at the apex of the receptacle close to fully developed sporangia. There are apparently 95 sporangia in each sorus. Three countings gave 93, 95, 97 for different sori.

The sporangium has a long stalk, scarcely so long as that of the sporangium of *Peranema*, with three rows of cells in the stalk. The annulus stops short of the stalk in its insertion (Fig. 22), but in passing across the head of the sporangium it twists slightly to one side and then back again into the vertical position before reaching the region of the stomium. This very slight obliquity of the annulus makes it possible to discriminate between the two sides of the sporangium, a fact referred to by Professor Bower ('Phil. Trans.', vol. cxcii, p. 104): 'In *Diacalpe* the two sides are so far dissimilar that it is possible still to distinguish the "central" from the "peripheral" face.'

Hairs are sometimes present on the stalks of the sporangia in *Diacalpe* (Fig. 23) as they are in *Nephrodium filix-mas*.

The spores in a single sporangium number about forty-eight. Each has an exospore and a perispore, attached at certain ring-shaped areas to the exospore and forming irregular folds and papillae on the surface of the spore. Here the circular pits with papillae in their centres are few in number; the main portion of the perispore is thrown into irregular folds, causing its projection into a series of warty protuberances (Fig. 22). The spores of *Diacalpe* are characteristic 'aspidioid' spores (Hannig, '11) and quite closely resemble those of *Nephrodium filix-mas*, where there are only warty protuberances on the surface of the spore. In *Peranema* the flanges of perispore are more prominent and numerous than the papillae; in *Diacalpe* these flanges are almost entirely absent.

The prothallus has been described by Schlumberger ('Flora', cii, N. F. 2, pp. 384 sqq.). On the under surface of the developed prothallus multicellular stalked glandular hairs are present. The stalk is composed of two or three cells, the middle one often showing a longitudinal division. The presence of multicellular hairs is a characteristic of the prothalli of the Cyatheaceae (Heim, 'Flora', lxxxii, 1896, pp. 360 sqq.). Schlumberger remarks for *Diacalpe* (p. 385) that 'in many cases, where the terminal cells are not developed as glands, these structures cannot be distinguished from the multicellular hairs of the Cyatheaceae'.

The antheridium of *Diacalpe* has a segmented lid-cell, another characteristic feature of the Cyatheaceae (Bauke, 'Jahrb. für wiss. Bot.', x, p. 72). It is therefore unmistakable that the closest relationship exists between the prothallus of *Diacalpe* and that characteristic of the Cyatheaceae.

An attempt may now be made to compare the features of *Peranema* and *Diacalpe* with those of other Ferns, with a view to locating these genera

in a systematic position among the Filicales. They have so many characters in common that it will be quite possible to consider their position first together, and then to see how far the characters in which they differ may indicate special affinities for each of them with other Ferns which they resemble.

The ascending or upright stock which they show is shared by representatives of various groups of Ferns and cannot in itself be held as a strong diagnostic feature. It may none the less be noted that in *Athyrium filix-femina* and in *Nephrodium filix-mas* the stocks are upright and of a similar type to that described for *Peranema* and *Diacalpe*. But in the latter pair there is a great development of sclerenchyma, which recalls the condition in the Cyatheaceae rather than that usual among the Polypodiaceae. In *Athyrium* and *Nephrodium filix-mas* definite sclerenchymatous sheaths are absent from the stocks.

The presence of both hairs and scales removes the two from such forms as those included in the (1) *Eudryopteris* section of *Dryopteris* (Christensen, '11) and relates them to (4) *Lastrea*.

In both cases the form of the leaf strongly suggests affinity with the Aspidieae. The tripinnate form is characteristic of the leaf in *Nephrodium* (*Lastrea*). The open, simply forked venation is a primitive feature, but it is shared by the members of the *Eudryopteris* section of *Nephrodium* and by numerous other members of the Polypodiaceae.

The hairiness of the leaves suggests a relatively primitive state, while the glands in the case of *Peranema* show resemblances both to those in *Eudryopteris* and in *Lastrea*.

When we look at the anatomical features we find that the general plan of the vascular system, with its advanced dictyostele, which shows no perforations but only leaf-gaps, and its subdivided leaf-trace, at once suggests affinity with *Nephrodium filix-mas*. The latter Fern appears, however, in the method of insertion of the leaf-trace strands on the gaps of the dictyostele to show an advance on the condition found in *Peranema* and *Diacalpe*. In these Ferns the leaf-trace bundles are inserted altogether on the lower half of the leaf-gap; in *Nephrodium filix-mas* the bundles are more spread over the sides of the gap. As in both cases the median main bundle of the leaf-trace is inserted at the lower fork of the limbs surrounding the gap, it would seem that this condition has been derived from that seen in solenostelic and in the simpler dictyostelic types by a breaking-up of the continuous horseshoe-shaped leaf-trace into a series of separate strands. The histology of the bundles would seem to confirm this. For the adaxial face of the leaf-trace in various Ferns, as illustrated in such types as *Loxsonia* (Gwynne-Vaughan, '01, Figs. 5, 6, 7) and *Davallia Speluncae* (Gwynne-Vaughan, '03, Fig. 26), shows incurved edges. And the adaxial leaf-trace bundles in *Peranema*, *Diacalpe*, and *Nephrodium filix-mas* also show such incurved edges. Protoxylem groups appear in these

curved edges of the leaf-trace in *Loxsonia* and *Davallia*. The adaxial strands of the leaf-trace in *Peranema* and *Diacalpe* each possess two protoxylem groups in the hooked portion of the strand (Fig. 6). The facts in *Onoclea* have an interesting bearing on this point. Thus in *Onoclea orientalis* the leaf-trace bundles at their insertion on the leaf-gap are two separate strands with hooks at each end. They are inserted just at the base of the gap and symmetrically on its limbs (Fig. 4, v). At a point higher up in the petiole, however, and before the departure of the pinna-traces, this pair of bundles becomes joined together and forms a single curved trace with hooked ends, from which the supply to the pinnae is given off in extramarginal fashion. The same condition is found in *Onoclea sensibilis*.¹

I find in my specimens of *Lomaria Spicant* (Fig. 4, IV) that three bundles enter the dictyostele at the base of the leaf-gap, one in a median position, the other two in adaxial positions.² The two adaxial bundles have hooked ends. The median one has a slightly curved plate of xylem, rather constricted in the centre and suggesting that it has been derived from the back of a triangular bundle of the type of *Gleichenia dicarpa* (Bower, 'Land Flora', p. 563, Fig. 314) through a suppression on either side of the central part of the limbs of the horseshoe.

Lastrea Oreopteris (Duval-Jouve, Pl. I, Fig. 2), another dictyostelic type, has a couple of strap-shaped leaf-trace bundles, which are inserted on either side of the leaf-gap, almost midway up the gap. In this case also the two widen and ultimately fuse to form a single curved strand in the petiole below the first pair of pinnae.

In *Athyrium filix-foemina* (Fig. 4, VI), on the other hand, the leaf-trace supply goes off from the base of the gap as a single triangular strand which almost at once breaks up into two strap-shaped bundles, and these below the first pair of pinnae fuse again into a single curved strand (Duval-Jouve, Pl. I, Fig. 1), a case recalling that of *Plagiogyria semicordata* (Bower, '10, p. 431), in which a single curved strand breaks up into three parts, to reunite below the first pair of pinnae into a single strand.

These facts would seem to indicate that the broken leaf-trace has originated from a single horseshoe-shaped or curved strand by a suppres-

¹ In *Annals of Botany*, 1911, p. 177, Sinnott considers the *Onoclean* double leaf-trace as an advance on the 'ancestral triangular mesarch bundle'—e.g. of *Gleichenia Speluncae*—and the approximation of the two bundles as a movement towards the ancestral type. But the two bundles do come together in the petiole before the pinnae go off, and so make his 'ancestral character'. Still (p. 167) the base of the leaf-trace is 'the seat of ancestral characters'; 'here we should expect to find indications of what was the primitive foliar bundle in the ferns'; 'in this portion the effect of changing external conditions . . . must be felt last and least.' And yet the base of the leaf-trace in *Onoclea sensibilis* really shows an advanced condition (according to Sinnott's own hypothesis) on what appears higher up!

² This corresponds in substance, though not in exact detail, with the statement of Luerssen in *Rab., Krypt.-Flora*, vol. iii, p. 114.

sion of part of its xylem, or by its breaking up into a series of isolated strands, just as the leaf-trace of *Dicksonia Barometz* breaks up into a series of strands arranged in horseshoe fashion in the petiole (Gwynne-Vaughan, '03, Fig. 17). In some cases (e. g. *Onoclea* and *Lastrea*) the abaxial face has been suppressed, but later on resumes its position. In other cases short portions of the sides have been dropped out, causing a trace of several strands to result. These would seem at first, as in the type of *Lomaria Spicant*, to have been inserted right at the base of the gap. Later they became extended up its sides but kept to its lower half, as in the *Peranema* and *Diacalpe* type; while ultimately they became distributed well over the sides of the gap, extending into the upper half as well as occupying the lower, as in *Nephrodium filix-mas*. It is curious that no case has been found in which the several leaf-trace bundles, such as occur in *Nephrodium filix-mas*, fuse together in the petiole to form the single strand, while in cases with the Onoclean leaf-trace the single strand is regularly found in the petiole below the first pair of pinnae. But it would seem probable, at least, that development has gone along a line of breaking-up of the single horseshoe-shaped strand into several parts (Tansley, '08, p. 120), of the retention of these at first towards the base of the leaf-gap, and later of their extension up the arms of the gap. It would appear on this view that *Peranema* and *Diacalpe* come structurally very close to *Nephrodium filix-mas*, but that they show scarcely so advanced a condition of the arrangement of the leaf-trace bundles on the dictyostele as does that Fern.

The discussion of the relationship of the pinna-traces to one another in different groups of Ferns must be left for a future paper.¹ It will suffice to say at present that, while *Peranema*, *Diacalpe*, and *Nephrodium filix-mas* show exactly the same type of pinna-supply, the criterion of marginal or extramarginal departure of the supply cannot be held as valuable among the different groups. That there is some constancy in the type of pinna-supply in Ferns of the same group has been shown by P. Bertrand ('09) and Gordon ('11) for *Clepsydropsis*, *Diplolabis Römeri*, and *Metaclepsydropsis duplex*. The vascular details in the leaves in *Peranema*, *Diacalpe*, and *Nephrodium filix-mas* are, however, identical. Such a fact may have some weight in confirming an affinity of *Peranema* and *Diacalpe* with *Nephrodium*.

The presence of glands and of stalked hairs bearing glands would seem to indicate a relationship for *Peranema* with *Lastrea*. Glands are present internally in the rhizome and at the base of the petiole in *Nephrodium filix-mas* (Sachs, p. 439; de Bary, pp. 89 and 220), internally at the base of the petiole in *Aspidium spinulosum* (de Bary, p. 220), externally on petiole

¹ The question has already been discussed for the Osmundaceae by Sinnott ('10) and Gwynne-Vaughan ('11).

and rachis in *Dryopteris pulvinulifera*, (Bedd.) O. Ktze.,¹ on the leaf of *N. molle* (de Bary, p. 89), and in *N. Sieboldii* (Goebeler, '86).

The fertile leaf and sorus in both *Peranema* and *Diacalpe* at once suggest relationships with Cyatheaceae and Polypodiaceae. In both the insertion of the sorus is superficial. The sorus is restricted to the veinlet and is inserted at a point short of its termination. This also holds for *Cystopteris*, for the Aspidieae, and for *Woodsia obtusa*.

The indusium is characteristically basal in the Cyatheaceae and in the Woodsiinae (Diels) group of Polypodiaceae. The indusium of *Diacalpe* corresponds in insertion exactly with that of *Woodsia*. In the case of *Peranema* the indusium appears to be unequally developed on the two sides, giving a suggestion of a Cyatheaceous sorus twisted to one side and with its rim tucked in beside the point of insertion (cf. *Allantodia*, which is to *Asplenium* as *Peranema* is to *Cyathea*).

But in the Cyatheaceae the sorus is distinctly of the Gradate type (Bower, 'Studies', IV, p. 54). In *Peranema* and *Diacalpe* the sorus is clearly a mixed one, though suggestions of a basipetal tendency in development have been found in *Peranema*, a fact confirmed by the presence of a distinctly elongated receptacle and a spore-output per sporangium of sixty-four. In *Diacalpe*, where the relationship on the ground of insertion of the indusium appears clearly to be with the Cyatheaceae, the sorus is a characteristically mixed one, with no signs of any basipetal tendency. It must be regretted, however, that developmental stages have been unavailable. In the absence of these, final conclusions cannot be drawn with regard to the sorus of these two Ferns.

The texture of the indusium and its insertion suggests unmistakable affinities with *Woodsia* and *Hypoderris*, in which (e. g. *Woodsia obtusa*) the sorus at maturity bears an exceedingly close resemblance to that of *Diacalpe*.

The stalked sorus of *Peranema* is almost unique, though it does find a parallel in the stalked sorus of *Marattia Kaulfussii*. But in the latter the details are quite distinct, while in its stalk there is no vascular bundle developed. A mixed sorus is found throughout the genus *Nephrodium*. Sections through the sorus of *N. molle* and *N. Sieboldii* show very close resemblances to the sorus of *Diacalpe*. The receptacle in *Dryopteris pulvinulifera*, which in habit closely resembles *Peranema*, is a little larger than that of *Diacalpe*. It is shortly stalked and is supplied by tracheides from the vascular bundle of the vein on which it is inserted. The sporangium is long-stalked, with three series of cells in the stalk. The annulus stops short of the insertion of the stalk. It generally passes vertically across the capsule, but occasionally it may take a slightly oblique course, twisting

¹ For the identification of this Fern (sent from India through the kindness of the Director of the Calcutta Botanic Garden) I am indebted to Dr. Carl Christensen.

a little to one side at its point of maximum curvature and then twisting back into the vertical position. This recalls the condition of *Diacalpe*, in which, though the annulus stops short of the stalk, it is so far twisted in its course that the two faces of the sporangium can be readily distinguished.

Peranema has an oblique annulus, which always passes the insertion of the stalk, though it is not always indurated throughout its whole length. The presence of an oblique annulus in a Fern with a mixed sorus is only paralleled by the cases of *Dipteris conjugata* (Miss Armour, '07) and *Plagiogyria* (Bower, '10). In *Peranema*, however, the obliquity is very slight and is accompanied by unmistakable vestiges of a Gradate condition. In the absence of developmental evidence it would seem that *Peranema* occupies sorally an intermediate position between the Gradatae and the Mixtae, combining the receptacle, the annulus, and the spore-output of the one with the sporangial succession of the other. *Diacalpe* is more distinctly related to the Mixtae, in receptacle, sporangial succession, and spore-output. The annulus, while vertical in insertion, still possesses a tendency to obliquity, which is seen, less highly developed, in the annulus of *Dryopteris pulvinulifera*. This affinity with *Nephrodium* is strengthened by the presence of hairs on the sporangial stalks in *Diacalpe* and in *Nephrodium filix-mas*.

The spores in *Peranema* and *Diacalpe* are distinctly 'aspidioid'. But those of *Diacalpe* are more closely related to those of *Nephrodium filix-mas* than are those of *Peranema*. In *Diacalpe* warty protuberances are much more numerous than perispore flanges and papillate pitted areas. The spores of *Dryopteris pulvinulifera* occupy an intermediate position between those of *Diacalpe* and those of *Peranema*. They possess both warty protuberances and perispore flanges, but the warts are rather more numerous than the flanges.

The characters of the gametophyte generation are only known for *Diacalpe*, but they make its affinity with the Cyatheaceae quite undoubted.

On the whole, then, *Peranema* and *Diacalpe* occupy an intermediate position between the Cyatheaceae and certain phyla of Polypodiaceous character. With the former they are joined on the characters of the prothallus of *Diacalpe* and of the receptacle and annulus of *Peranema*; with the latter they show affinity in the vascular anatomy, the sporangial succession in the sorus, the length of the sporangial stalks, and the characters of the spores.

The affinity with the Aspidieae, and more particularly with the genus *Nephrodium*, which is suggested by their habit, has been confirmed in their dictyostelic vascular system, in the scales on petioles and rachis, in the glands on leaves and leaf-stalks, in the mixed sequence of sporangia, in the hairs on the sporangial stalks in *Diacalpe*, and in the spore-markings in both Ferns.

The natural position for *Peranema* and *Diacalpe* seems to be with

Woodsia and *Hypoderris*. The texture and insertion of the indusium are similar in all the four genera, while they all occupy an undoubtedly intermediate position between the Cyatheaceae and certain phyla of the Polypodiaceae.

It would seem that the very different habit of *Woodsia* on the one hand, and of *Peranema* and *Diacalpe* on the other, can be readily accounted for on the ground of environment, while the same remark applies to *Hypoderris*. *Hypoderris* has probably developed its hardly divided leaf in relation to conditions of shade. *Peranema* and *Diacalpe*, both inhabitants of mountainous tropical forest, have grown luxuriantly, while *Woodsia*, an essentially Alpine Fern, has reduced its vegetative system and elaborated the protective coverings of its indusium in a series of highly efficient scales.

Peranema and *Diacalpe* are undoubtedly very closely related to each other. It is hardly possible to say which is the more primitive, which the more advanced. The receptacle, sporangial succession, and annulus of *Peranema* are more nearly related to those of the Cyatheaceae than are those of *Diacalpe*. On the other hand, *Diacalpe* shows an undoubtedly Cyatheaceous prothallus. The spore-markings in *Diacalpe* most closely resemble those of *Nephrodium filix-mas*; those of *Peranema* are most nearly related to those of *Dryopteris pulvinulifera*. The presence of hairs on the stalks of the sporangia is common to both *Diacalpe* and *Nephrodium filix-mas*.

It would therefore seem probable that *Peranema* and *Diacalpe* fall naturally into the Woodsieae-Woodsiinae group of Polypodiaceae, and that this group occupies an intermediate position between the Cyatheaceae and certain other families of Polypodiaceae. There is very little doubt that both genera are closely related to the genus *Nephrodium*. It seems probable, then, that the Aspidieae sprang from a Gradate drift, of which the Cyatheaceae are near living representatives, and that *Peranema* and *Diacalpe* are related to that drift as relatively early examples. These indications make it seem probable that the mixed condition of the sorus of *Nephrodium* has arisen from a Gradate condition. This position traces one of the polyphyletic lines of the Polypodiaceae to the Cyatheaceae, and establishes a probably parallel series to that shown from *Dennstaedtia* to *Davallia* and its derivatives.

SUMMARY.

1. *Peranema cyatheoides*, D. Don., has an advanced dictyostele without any perforations; its leaf-trace is inserted on the lower half of the leaf-gap; the pinna-supply is 'extramarginal' to all but the ultimate pinnae, to which it is 'marginal'; the sorus, which is borne on a short stalk, is a mixed one; it has a Gradate receptacle, with traces remaining of a basipetal sequence of sporangia; the annulus is slightly oblique; the spores are 'aspidioid'.

2. *Diacalpe aspidioides*, Bl., coincides with *Peranema* in the details

of its vascular anatomy; the sorus is a mixed one, with no traces of an earlier basipetal sequence; the annulus is vertical in insertion, but slightly twisted in its course across the sporangial head; the spores are markedly 'aspidioid'; the prothallus is Cyatheaceous.

3. Both Ferns show relationships with the members of the genus *Nephrodium*, particularly with *Nephrodium filix-mas*, Rich., in vascular anatomy, the character of glands on the leaves, the sporangial stalks, and the spore-markings.

4. *Peranema* and *Diacalpe* are most nearly related to *Woodsia* and *Hypoderris*, and fall naturally into the Woodsiae-Woodsiinae group of Polypodiaceae, which is intermediate between the Cyatheaceae and the Aspidiaceae.

5. It seems probable that the Aspidiaceae sprang from a Gradate ancestry, and that *Peranema* and *Diacalpe* are relatively early members of a phyletic drift to the Polypodiaceae, of which the Cyatheaceae are near living representatives.

DESCRIPTION OF PLATES XXVIII AND XXIX.

Illustrating Mr. Davie's paper on *Peranema* and *Diacalpe*.

Figs. 1-3, 5-21, are of *Peranema cyatheoides*.

Figs. 22 and 23 are of *Diacalpe aspidioides*.

Figs. 1, 2, 3, and 7 are freehand drawings. Fig. 4 is a diagrammatic representation of leaf-gaps and the subtending leaf-traces in various dictyosteles. Figs. 5, 6, 8-23 have been drawn with the aid of a camera lucida.

Fig. 1. Pinna of *Peranema*, showing open, simply forked venation. The veinlets terminate at points short of the margin. $\times 3$.

Fig. 2. Transverse section of stock, showing the dictyostelic arrangement of the meristeles (*st.*), the leaf-trace bundles (*lt.*), and the very numerous sclerotic patches (*sp.*). $\times 4$.

Fig. 3. Successive sections through the petiole, showing the departure of the vascular supply to the basal pinnae. *ad.*, adaxial strands; *m.*, median main strand; *ss.*, subsidiary strands; *cc.*, commissural strands; *pp.*, pinna-trace strands. $\times 8$.

Fig. 4. Series of diagrams illustrating the insertion of the leaf-trace bundles on the dictyostele in various Ferns. I. *Peranema cyatheoides*. Portion of dictyostele seen from within, showing leaf-gap and the bundles from the leaf subtending this gap. II. The same leaf-gap viewed from without. *m.*, median main leaf-trace strand; *ad.*, adaxial main strands. III. Another leaf-gap with the bundles from the leaf opposite to it (*ll.*), and with parts of the traces from the two leaves obliquely next above (*aa*) and (*bb*). IV. *Lomaria Spicant*. Dictyostele at leaf-gap, with the three leaf-trace bundles. V. *Onoclea orientalis*. Dictyostele at leaf-gap, with the two leaf-trace bundles. VI. *Athyrium filix-femina*. Dictyostele at leaf-gap, showing the insertion of the leaf-trace. It leaves the dictyostele as an undivided trace and in the base of the petiole becomes divided into two strap-shaped strands. All considerably magnified.

Fig. 5. Transverse section through the young shoot of *Peranema*, just below the apex, showing the first lignification in the stele. $\times 450$.

Fig. 6. Transverse sections through the adaxial main strands of the leaf-trace, showing the 'extramarginal' type of supply to the basal pinna. All $\times 76$. (*a*) Strand below the level of the pinna, showing the hooked end, from which the supply goes off to the pinna. (*b*) Pinna-supply in process of being given off. (*c*) Reconstituted adaxial strand (*ad*) with pinna-trace (*p*) passing out to the pinna.

Fig. 7. Successive transverse sections through the rachis of a basal pinna to show the development of the pinna-trace, from the point of departure from the petiolar adaxial strand (1) up to the fully constituted condition (x1). All about $\times 8$.

Fig. 8. Palea from young leaf-stalk. $\times 3$.

Fig. 9. Hair from the rachis of the frond, showing glands on the curved portion. $\times 76$.

Fig. 10. Gland from the palea of a young frond. $\times 450$.

Fig. 11. Glands from the surface of the mature petiole. $\times 450$.

Fig. 12. Transverse section through a young pinna, showing marginal segmentation of the usual Leptosporangiate type. $\times 450$.

Fig. 13. Longitudinal section through the stalked sorus, showing the elongated receptacle with its vascular supply and the mixed arrangement of the sporangia. $\times 76$.

Fig. 14. Longitudinal section through the sorus, showing the elongated receptacle and the mixed succession of sporangia. The indusium is two-layered at its base. $\times 76$.

Fig. 15. Longitudinal section through the sorus, showing the way in which the rim of the indusium is tucked in on the lower side, close to the point of insertion of the stalk. $\times 76$.

Fig. 16. Section through a mature sporangium, showing the slight obliquity of the annulus. $\times 150$.

Fig. 17. Section through the stalk of a mature sporangium. $\times 150$.

Fig. 18. Almost mature sporangium, showing the continuation of the cells of the annulus past the stalk. $\times 225$.

Fig. 19. Mature sporangium, showing the slightly oblique insertion of the annulus. $\times 150$.

Fig. 20. Sporangium, showing the indurated cells of the stomium. $\times 150$.

Fig. 21. Spores of *Peranema*, showing the papillate pits formed by the perispore. $\times 450$.

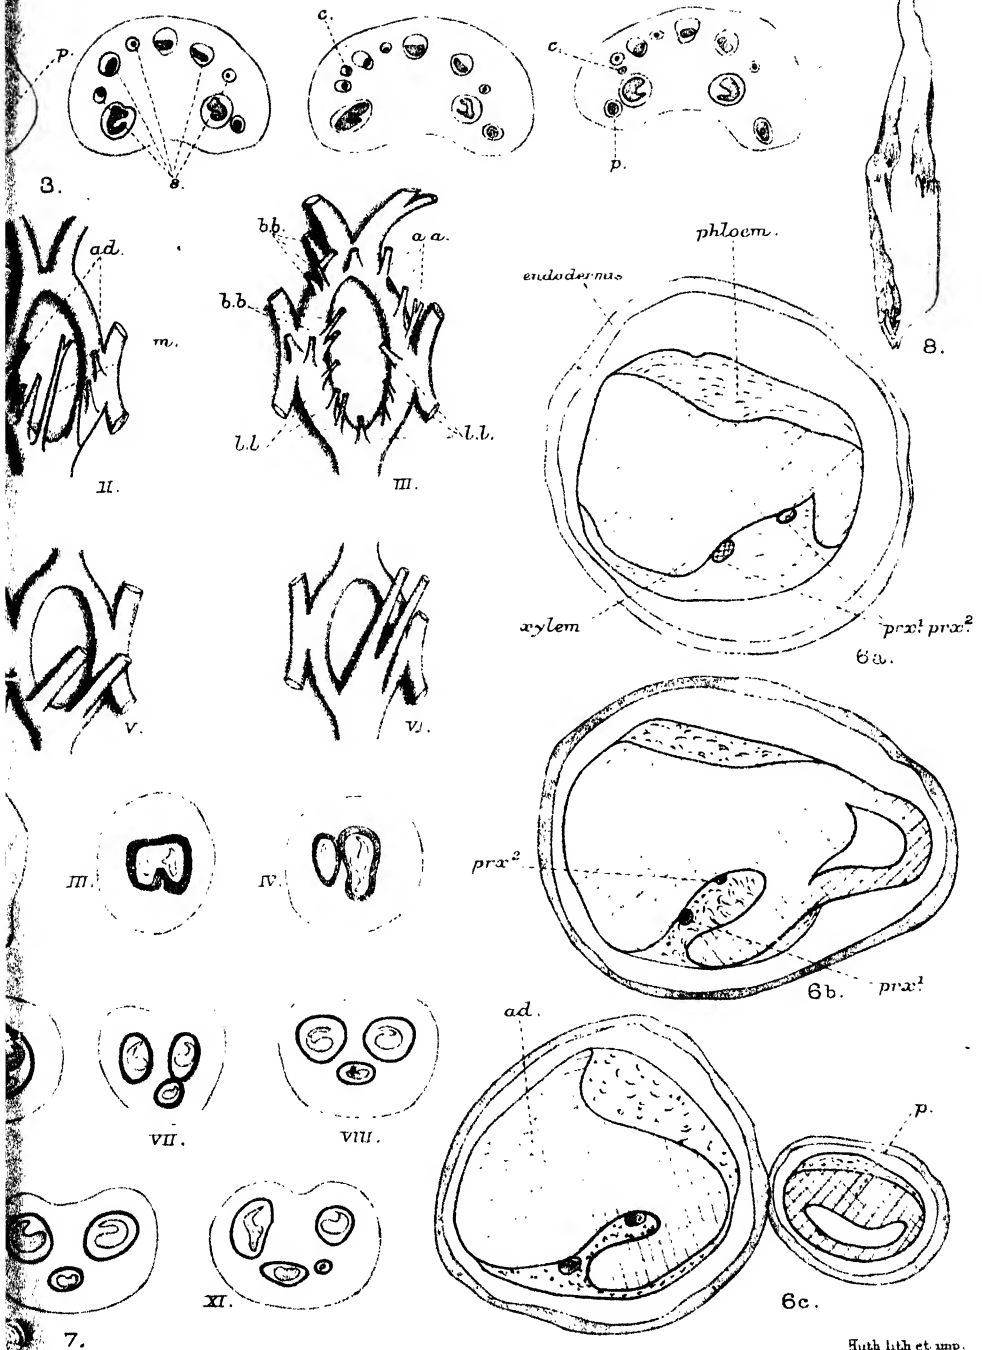

Fig. 22. Section through a mature sporangium of *Diacalpe*, showing the insertion of the annulus and the markings on the spores. $\times 150$.

Fig. 23. Mature sporangium of *Diacalpe aspidioides*, showing a hair on the stalk. $\times 150$.

Studies in the Phylogeny of the Filicales.

II. Lophosoria, and its Relation to the Cyatheoideae and other Ferns.

BY

F. O. BOWER, Sc.D., F.R.S.

Regius Professor of Botany in the University of Glasgow.

With Plates XXX-XXXVI.

IN my 'Studies in the Morphology of Spore-producing Members, No. IV. Leptosporangiate Ferns' ('Phil. Trans.', 1899, vol. cxcii, p. 122), the distinction was drawn according to the mode of development of their sori between the Ferns designated as the Simplices, the Gradatae, and the Mixtae. These were held to illustrate three steps in the evolution of the sorus. It was specifically stated that there was no intention to assert that the living Ferns of any one of these categories were the actual ancestors of those of any other. Nor was it suggested that the progression was by any single line of descent. Parallel development along a multiplicity of lines was distinctly contemplated, involving in any one of them progressions from the Simple to the Gradate, or from the Gradate to the Mixed state. It was even held as possible that a progression might have been effected directly from the Simple to the Mixed state (l. c., p. 124), a transition which has since been demonstrated to have occurred within the genus *Dipteris* (Miss Armour, 'New Phytologist', 1907, p. 238), and it is highly probable that it has occurred also in the descent of *Plagiogyria* ('Annals of Botany', vol. xxiv, p. 438).

Perhaps the most obvious suggestion of transition from the Simple to the Gradate sorus that could be made is that from some Gleicheniaceus type to the Cyatheaceae. Already in 1899 it was pointed out (l. c., p. 123) that '*Gleichenia dichotoma* has a naked sorus' differing 'little in general construction from that of *Alsophila atrovirens*'. This case was not quoted then as indicating a true line of descent, but as an illustration how near one type may be to another in point of arrangement within the sorus. The widening of the basis of comparison, especially in respect of the vascular anatomy, led in 1908 to a more explicit statement ('Land Flora', p. 610), that 'there seems good reason to see in the Cyatheaceae a series having

probable genetic relations with the Gleicheniaceae, but advanced on the one hand to the basipetal succession of the sori, and on the other to a high complexity of the vascular system'.

The degree of closeness of those 'genetic relations' was left undefined, though certain species were indicated as outliers on either side of the gap separating the two families. On the one hand are *Gleichenia linearis*, Clarke (= *dichotoma*, Hk.), and *pectinata*, Pr., distinguished as relatively advanced species, both by their soral and their anatomical characters; on the other hand, *Alsophila quadripinnata*, C. Chr. (= *Lophosoria pruinata*, Pr.), and *A. (Metaxya) blechnoides*, Hk., were indicated as lying anatomically at the base of the Cyatheaceous series. It seems desirable, as material is at hand, and as some further advance has already been made in the anatomy of the more complex Gleichenias, to examine more closely the probable relations of the two families, and to widen as far as possible the basis of the comparisons. For it is only in this way that a dependable conclusion can be arrived at. In discussing such genetic relations in Ferns, soral characters are not sufficient, nor are anatomical data sufficient. Nor should we be satisfied even with a combination of them. To obtain a fully trustworthy result the characters of external form, of the superficial appendages, and of the gametophyte and sexual organs should be also used, together with the details of the ontogeny, while some attempt at seriation of the species within the genera will also assist in giving point to the comparisons. Many phyletic conclusions which are generally accepted fall short of this comprehensive foundation, and it will not be possible in the present case to carry out the programme fully. But it is well at the outset to visualize what is to be aimed at, even though a complete demonstration may not be actually attained at the moment. As the comparisons to be drawn will centralize themselves round the species above named, though with general references from time to time to these and to other genera as a whole, it will be well at the outset to become acquainted with the history, systematic position, and characteristics of them. Often it happens that plants which have a peculiar interest from a comparative point of view have in the past been given diverse systematic places by various authors. This will be seen to have been the case with one at least of the Ferns in question. Such a history at once suggests that the systematist has encountered a synthetic type. In fact the puzzles of the earlier systematists will often provide the opportunities of the phyletic morphologist.

GLEICHENIA.

The two species *Gleichenia linearis*, Clarke (= *Gleichenia (Mertensia) dichotoma*, Hk.), and *Gleichenia (Mertensia) pectinata*, Pr., have long been regarded as outstanding in the genus to which they belong, and recent anatomical observations have accentuated their aloofness from the

rest. But they share the general characteristics of *Gleichenia* so fully that there is no question of their real affinity with it. Both have the creeping rhizome, bearing upon it at intervals leaves which are endowed with the continued apical growth so characteristic of the genus. As in other species, the circinate apex of the leaf rests from active growth at intervals, appearing as a bud dormant between the last developed pinnules, and then resuming again its activity (Goebel, 'Organography,' ii, p. 318). In the disposition and development of the ultimate branchings of the leaf, these species have been recognized by systematists as forming each a separate section of the genus. Their segregation has also been based upon the fact that in the number of sporangia in the sorus they exceed the rest. Of *G. pectinata* Sir Wm. Hooker wrote that 'it is the only species of this section (§ 3), and not to be confounded with any other'; while he further remarked of his § 4, that 'as *G. pectinata* is a solitary species in its section, so is *G. dichotoma* of the present one' ('Syn. Fil.', p. 15).

Branching of the axis may be in *G. pectinata* either dichotomous in a horizontal plane, or monopodial in a vertical plane. Of the former branching Boodle and Hiley remark that 'it appears not to be known to occur in the rhizome of any other species of the genus' ('Ann. of Bot.', 1909, p. 426). It is true that collectors and systematic botanists have commonly neglected to provide evidence of, or to describe such features. But I have specimens of very perfect dichotomy of the axis in *Dicranopteris fulva*, Desv. Underw. (= *Gleichenia pubescens*, H. Bk.), and the same branching exists also in *G. flabellata*. Probably dichotomy of the axis is frequent within the genus. In the leaf, on the other hand, it is stated by Goebel ('Organography', ii, p. 319, footnote) that 'no species in *Gleichenia* has a dichotomous leaf', and these species appear to be no exceptions. Moreover, as Campbell has observed ('Ann. Jard. Bot. Buit.', 2^e série, vol. viii, p. 98), 'the cotyledon in *G. pectinata*, *G. dichotoma*, and *G. laevigata* shows a prolonged apical growth like that found in the adult leaves of the young sporophyte'. He notes (l. c., p. 94) that 'the cotyledon of *Gleichenia*, especially in the section *Mertensia*, differs from that of most Ferns. In the majority of Ferns the cotyledon is fan-shaped, the result of an early dichotomy. In *Gleichenia* the original apex seems to persist.' The complex leaf-forms of the genus are the result of repeated pinnation, modified, but not in any genetic sense altered, by unequal development of the parts, varied distribution of intercalary growth, and periodic arrest of apical activity. In *G. linearis* the unequal development of parts of the leaf makes itself apparent in the specialization of certain pinnules as a protection to the resting apex of the leaf. Goebel points out that these are neither 'adventitious structures' nor 'vestiges', but only pinnules which are developed for the protective function; and that they vary in different species according to the size of the resting apex, being absent where it is small, or

where scales or hairs form an efficient covering. In *G. linearis* (= *G. dichotoma*) they are highly specialized for the protective function (Goebel, 'Organography,' ii, p. 319, Fig. 206). In general form the leaves of these two species are very widely expanded, and are among the largest of the *Mertensia* division of the genus. They are thus in strong antithesis to the leaves of the *Eu-Gleichenia* division, which have the leaf-area reduced, probably in relation to a xerophytic habit.

The surface appendages have been too much neglected as a basis for comparison in Ferns. In many systematic treatises they are ignored. Even in the excellent work on the Filicales by Diels (Engler u. Prantl, 'Nat. Pflanzenfam.,' i. 4) their occurrence and peculiarities are often left unnoticed in cases where, as in *Gleichenia* and *Alsophila*, they have a comparative value. Long ago, however, the value of surface appendages for phyletic comparison was noted by Prantl ('Schizaeaceen', p. 37), who concluded that simple hairs were the primitive type, but that in many circles of affinity they developed in a flattened form. The ramentum or scale is thus derivative or secondary. This distinction of hair and scale was adopted by Max Kühn as the basis of a classification of the Polypodiaceae, which he divided into *Chaetopterides*, with hairs, and *Lepidopterides*, with flattened scales. Against the use of this as a leading criterion, which resulted in an unnatural juxtaposition of genera, Prantl protested ('System der Farne', 'Arb. K. Bot. Gart. z. Breslau,' p. 13). But, nevertheless, he adopted the existence of the scale as an expression of a progressive step of organization. This is the way in which the hair-scale criterion should be used as an indication of a relatively primitive or of a relatively advanced condition, which may be brought with other progressive features into a general argument; but with the full knowledge that the advance from hair to scale has probably been made in various phyletic lines, and that it does not necessarily progress coincidentally with other features of advance.

An examination of the dermal appendages of *Gleichenia* brings some interesting results. Of the section *Eu-Gleichenia* three species have been examined, viz. *G. polypodioides*, Sm., *G. dicarpa*, R. Br., and *G. circinnata*, Sw. In all of them broad scales were found protecting the dormant leaf-apices, as also on the leaf-bases and the rhizomes. But with them are associated hairs. In the first two species these were pale and soft, but in *G. circinnata* they were stiffer, and very beautiful transitions can be found between simple brown hairs and those which are branched and tufted, and finally to broadened scales, with stiff hairs projecting from their margins. It is as though the bases of the hairs had broadened to form the scales, and this is their probable origin. The hairs and scales fall off early from rhizome and leaf. It appears thus that both hairs and scales are present, probably with constancy, in *Eu-Gleichenia*, and this is biologically in accordance with their xerophytic habit.

In the *Mertensia* section observations were made on *G. Bancroftii*, Bl., *glauca*, Hk., *flabellata*, Br., *Cunninghamii*, Hew., *furcata*, L., *owhyhensis*, Hk., *flagellaris*, Spr., *vestita*, Bl., and *hirta*, Bl. In all of them both scales and hairs were present, the former especially upon the circinate leaf-apices. The scales vary, being large and broad in *G. Bancroftii*, but only narrow in *G. flagellaris* and *vestita*, while in the latter the hairs are soft and fluffy, of the type to be described in *G. linearis*. Thus, though *Mertensia* is, as a whole, of less xerophytic habit than *Eu-Gleichenia*, both hairs and scales are general, especially on the circinate leaf-apices.

But in § 3, *Gleichenia pectinata*, and § 4, *Gleichenia linearis*, no scales are found. They stand in this character apart apparently from the whole of the rest of the genus. Hairs are present in both, and they are of the tufted type, branching near to the base. In *G. linearis* these are of a softer texture, but in *G. pectinata* they are stiff and brown, with their peg-like branches often reflexed. These hairs, especially those near the insertion of the leaf on the axis, are long and curved, and coarse in texture. Each of them with its tuft of stiff branches is borne on the end of a rather massive emergence, which is a firm multicellular outgrowth. But the hair is readily broken away from its tip; the emergence then remains as shown in Pl. XXX, Fig. A, in the case of the two lower emergences. And as these are numerous and relatively large, they give to the rhizome and the base of the leaf that prickly character which is often seen about the base of the leaf in *Alsophila*, *Hemitelia*, and *Cyathea*, though here it is on a smaller scale. The prickles in these latter plants bear each a ramentum when young, and this may be seen with special clearness in the case of the large, more or less isolated scales borne on the young leaf of *Hemitelia horrida* (Pl. XXX, Fig. B). There can be little doubt that the structures in question in *Gleichenia pectinata* and in the Cyatheaceae are essentially comparable one with another; in that case, those of *Gleichenia* may be held as a prototype of the larger emergences of the Cyatheaceae. See Pl. XXXIII.

It appears from the above observations that the two species of *Gleichenia*, which are outstanding in other characters from the rest of the genus, are also exceptional in showing the more primitive type of dermal appendages only, viz. hairs and no scales. Their aloofness from the rest of the genus is further indicated by their anatomy. It will suffice here to quote briefly from the conclusions which have been arrived at on the basis of comparison of their vascular tissues.¹ Tansley sums up his discussion of the anatomy of *Gleichenia* thus (l. c., p. 46): 'We are therefore led to the conclusion that such a form as *G. flabellata*, on the whole, represents the most primitive type of the genus.' As regards *G. linearis* he remarks (p. 41) that it 'stands apart from the other *Mertensias*', being 'intermediate

¹ Tansley: Lectures on the Evolution of the Filicinean Vascular System, iv, p. 40, &c. Boodle: Ann. of Bot., xv, p. 703, and xxiii, p. 419.

between the *Mertensia* and *Eu-Gleichenia* types'. The latter are generally accepted as being forms showing reduction from the typical *Mertensia* type, as represented by *G. flabellata*; they are in fact a side branch. Thus, as Boodle points out (l. c., p. 432), *Mertensia* includes not only the species of *Gleichenia* which is held to be the most primitive anatomically, viz. *G. flabellata*, but also the most advanced, viz. *G. pectinata*. The solenostelic structure which it shows is to be regarded as derived from a protostelic *Mertensia* type, like that of *G. flabellata*. And thus it appears that, putting *Eu-Gleichenia* aside as a line of xerophytic specialization, *Mertensia* illustrates a sequence in which *G. linearis* takes an intermediate place, leading from a protostelic to a fully solenostelic structure of the axial stele. It will be seen that this runs parallel with certain soral characters.

The structure of the sorus in certain species of *Gleichenia* has been described elsewhere (Studies, IV. Leptosporangiate Ferns; 'Land Flora', p. 555, &c.), and the conclusion is drawn that the sorus and sporangium of *G. flabellata* are probably the most primitive of the forms examined, a conclusion based partly upon the construction of the sorus, which is radiate and uniseriate with about 3-5 sporangia ('Land Flora', p. 554, Fig. 309), partly on the large output of spores from each sporangium. The species of the *Eu-Gleichenia* section show a diminution in number of the sporangia, and in their individual output of spores, as compared with *G. flabellata*, and they present no feature of special interest for our present comparison. But the two species which are outstanding from the rest of the genus in other respects, viz. *G. linearis* and *G. pectinata*, both show indications of advance beyond the condition normal for the *Mertensia* section. This is apparent in the larger number of sporangia in the sorus, in their arrangement, and in the diminished output of spores per sporangium. The facts have already been observed for *G. linearis*, where the number of sporangia in the sorus may be as large as ten, and the central area of the sorus, which is usually vacant in other species, is occupied by sporangia (Pl. XXX, Fig. C). Hooker ('Species Filicum', i, p. 13) mentions 'capsules 10-12'. The sorus being thus more crowded than in the usual *Mertensia* type, the question of dehiscence of the sporangia becomes a critical one. In *Gleichenia* the dehiscence is by a split in a median plane of the sporangium, and in order that the opening may be effective elbow-room is required right and left of each sporangium, and it is therefore only suitable for a laxly arranged sorus. The difficulty will be appreciated by examination of the sori in Fig. C, or better of the detailed drawing (Fig. D). From this it appears that even in a sorus with seven sporangia their close juxtaposition has led to an oblique opening of one of them. But the question is not here one of acute difficulty. As regards the spore-output the number of spores per sporangium counted in specific cases for *G. flabellata* were 794, 695, 838, 634, all these figures lying between the typical numbers 512-1024. For *G. linearis* the numbers

were in two specific cases only 251 and 319. This smaller number is in accord with the smaller size of the pear-shaped sporangia of the latter species, but it is nearly matched by the output in species of *Eu-Gleichenia*, where the relatively large sporangia produce large spores, but their numbers are in near proximity to the typical number 256.

A more special interest, however, attaches to the case of *G. pectinata*, which is sorally, as it is also anatomically, the most advanced species. It has long been known that the sori of this species contain the largest number of sporangia in the genus. Hooker ('Syn. Fil.', p. 15) mentions '8-10 capsules'. The drawing (Pl. XXX, Fig. E) shows that this is clearly under the mark, for the numbers vary from 10 to 15 in this specimen from Jamaica not specially selected. The sporangia, being long-stalked and all seated upon a central and slightly raised receptacle, are obviously crowded. They form two tiers, the upper tier fully occupying the central space, which in *Mertensia* is usually vacant. The enlarged drawing of a single sorus (Pl. XXXI, Fig. F) shows that the sporangia are even flattened against one another, a fact which is readily seen in their flattened sides when the sporangia lie separate and free. They are also far from uniform in size, and the orientation of the annulus is occasionally reversed. It is plain that shedding of the spores will here be a matter of difficulty if the median dehiscence is maintained. That the difficulty is a real one is shown by the fact that, though the sporangia arise and mature all simultaneously, many of them remain full long after other sporangia of the same sorus have been emptied. It appears then that in *G. pectinata* the Gleicheniacean type of sorus has reached the point of ineffectiveness in its increase in number of the sporangia. There are four possible ways out of the difficulty, and they may be adopted singly or in combination: (1) by increasing the length of the sporangial stalk, (2) by adopting a lateral in place of a median dehiscence, (3) by extending the area of the sorus, and (4) by elongating the receptacle. But none of these has been adopted by the genus *Gleichenia* itself. Other Ferns have, however, adopted them, and have succeeded.

The development of the sorus of *G. pectinata* has been followed out for comparison with that of other species. The receptacle is present as a considerable upgrowth before the development of the sporangia begins (Pl. XXXIV, Figs. 1, 2). The sporangia themselves are almost simultaneous in their appearance, but not perfectly so. In Fig. 3 the middle sporangium is just dividing off its cap-cell, whereas those right and left have them complete. There is still more discrepancy in the state of development of the three sporangia in Fig. 4. But there does not appear to be any rule or method of succession. The sporangia themselves show a segmentation which, though variable in detail, conforms to that already described for other species of the genus.¹ In most cases it ranks most nearly with the type seen in the Schizaeaceae

¹ Compare Studies. IV. Phil. Trans., vol. cxcii, pp. 32-8, and Plate II.

('Land Flora', Fig. 349, *d*), but some show relations also with the types *c* and *e* of Fig. 349. In any case the segmentation is more massive than that of the Polypodiaceae. The result is a relatively bulky sporangium, with a stalk of several rows of cells (Pl. XXXIV, Fig. 5). When mature it closely resembles that of *G. linearis* both in shape and in average size. But there appears to be a smaller number of spore-mother-cells in each sporangium than in this species, and considerably less than in *G. flabellata*. Fig. 6 shows the definitive sporogenous group as seen in a section transverse to the axis of the sporangium, and the number of spore-mother-cells is fifteen, arranged roughly in four plates. Fig. 7 shows a section of a similar sporangium in a median longitudinal section, and the number of the spore-mother-cells traversed is twenty. Fig. 8 shows the condition where the spore-mother-cells have separated and rounded off. These drawings provide an interesting comparison with my drawings for *G. flabellata* and for *G. linearis* (Figs. 24-26, Pl. II of my Studies, V, and Figs. 27-30, Pl. III). From a comparison of such sections as those shown in Figs. 6 and 7 the total number of spore-mother-cells in *G. pectinata* may be estimated at some figure probably in excess of 64, which if all were matured would lead to an estimated output of spores something in excess of 256 per sporangium. Actual countings for sporangia of *G. pectinata* gave the result of 422 and 429 for large sporangia, and 228 and 236 for small sporangia. The larger are thus seen to approximate to the typical number 512, though falling a good deal short of it; the smaller approximate to, but fall short of the typical number 256.

A comparison of these facts with those for *G. linearis* and *G. flabellata* indicates clearly a sequence of reduction from the large sporangia of *G. flabellata*, which are few in a sorus, each with an individually large spore-output approximating to the typical number 1,024, through *G. linearis*, with its smaller sporangia, more numerous in each sorus, and with spore-output approximating to or exceeding 256, to *G. pectinata* with sporangia variable in size, but still more numerous in the sorus, and with a variable spore-output, approximating in large sporangia to 512, but in smaller falling to below 256. The variability in size of the individual sporangia makes precise statement precarious. An important point is that the variability exists in the species which is in various respects the most advanced in the whole genus.

Turning to the gametophyte of *Gleichenia*,¹ it presents characters of importance as indicating affinity with relatively primitive types. The massive form of the prothallus with a marked midrib is characteristic, and suggests comparison with *Osmunda*. It bears in some species 'marginal

¹ Rauwenhoff: La Génération sexuée des Gleicheniacées. Arch. Néerland., 1890. Campbell: Mosses and Ferns, 2nd Ed., p. 336; also The Prothallium of *Kaulfussia* and *Gleichenia*. Ann. Jard. Bot. Buit., 2^e sér., vol. ix, p. 80.

leaf-like lobes', seen especially in *G. laevigata*. These are compared by Campbell with those of *Fossombronia*, or *Dendroceros*. But the most important characters for comparison are provided by the sexual organs. Campbell has shown that the neck-canal-cell of the archegonium (except in *G. polypodioides*) commonly divides into two cells. This is regarded as a primitive character. As regards the antheridium, Rauwenhoff examined various species of *Eu-Gleichenia*, but of the *Mertensia* section only *G. flabellata*, and found in all that he examined a general correspondence of the antheridium with that of the Polypodiaceae. But other species belonging to the *Mertensia* section examined by Campbell are characterized by the much larger size of the antheridium, this being especially marked in *G. laevigata* and *G. pectinata*.

The number of spermatocytes traversed in a median longitudinal section gives a numerical basis for comparison. From Campbell's published drawings the numbers appear as follows: *G. polypodioides* (§ *Eu-Gleichenia*)—19. *G. (Mertensia) laevigata*—95, 35, 76. *G. (Mertensia) linearis*—30, 42. *G. (Mertensia) pectinata*—46, 23, 60, 62. From this it appears that there is considerable variability not only within the genus, but also in specimens of the same species. It is a criterion which must be used with caution. The chief point is that the numbers are high compared not only with those of other Ferns, but also with Pteridophyta at large. From published figures (mostly taken from Campbell's 'Mosses and Ferns') it appears that typical numbers of spermatocytes seen in section are for *Ophioglossum* 87, *Kaulfussia* 61, *Marattia* 31, *Osmunda* 32, *Onoclea* 21, *Nephrodium* (Kny) 16, *Woodsia* (Schlumberger) 17, 18, 16, 14, 14, 13. In other Pteridophytes the numbers are for *Equisetum* 56, and *Lycopodium* 46.

From a comparison of these figures it follows that the antheridia of *G. laevigata* are exceptional in showing in specific cases a larger number of spermatocytes in median section than any of the Pteridophytes quoted. On the other hand, the figures for the *Mertensia* section of *Gleichenia* as a whole are in excess of those for the Leptosporangiate Ferns. *Nephrodium* with about 16, and *Woodsia* with an average almost the same, may be taken as typical for the Leptosporangiate types. And so it is seen that the *Mertensia* section of *Gleichenia*, together with the two outstanding species *G. linearis* and *G. pectinata*, occupy a position altogether exceptional among Ferns, while the latter species are extremes even among Pteridophytes at large, in respect of the number of their spermatocytes. This, going along with the large output of spores in the *Mertensia* section, and other relatively primitive characters, indicates in an unmistakable way that it is among the most primitive types of the living Filicales.

But the characters upon which this general conclusion is based do not always run parallel. Thus *G. flabellata*, which in its anatomy, its sorus, and its spore-output appears as the most primitive species, has not the

largest antheridia (cf. Rauwenhoff). Unfortunately, the extreme type in the latter respect (*G. laevigata*) has not been examined as regards its spore-output. *G. linearis*, which anatomically and sorally is more primitive than *G. pectinata*, is on the antheridial criterion more advanced. These discrepancies find some explanation in the irregularity of size of the individual antheridia of *G. pectinata*, which shows that this criterion must not be pressed too hard. It has long been a matter of note that the extent of projection and the bulk of sporangia and antheridia show some degree of parallelism, the more bulky and deeper sunk being held as the more primitive condition. It has also been pointed out at length elsewhere ('Land Flora', p. 641, &c.) that the numbers of spores produced in a sporangium give a rough numerical measure of the relative bulk of the sporangium for comparative purposes. It is also the fact that there is a parallel between these characters and the segmentation of the apices of axis, leaf, and root in the plants in question. To these criteria is now added that of the spermatocyte-production of the antheridium. But while we recognize these points, they must not be driven to the length of exact numerical comparison. It is becoming apparent that while such parallels are true in general, indicating conditions of relatively greater or less bulk of fundamental organization, still they are not invariably exact, and are open to exceptions.

From the details and comparisons advanced in the above pages the conclusion may be drawn with some degree of certainty that the Gleicheniaceae occupy a place among the most primitive of the Filicales; that *Mertensia* is more primitive than *Eu-Gleichenia*; and that in many characters, though not in all, *G. flabellata* is a central and an early type. Perhaps it may share this position with *G. laevigata*, which is as yet imperfectly investigated. From such forms as central, lines of specialization appear to have led, resulting on the one hand in *G. linearis*, which show various features of advance; on the other hand there is *G. pectinata*, which may be held as the most advanced species of the genus. This appears especially from its vascular anatomy, and from its sorus, the latter having arrived at the limit of development which can be practically effective in the Gleicheniaceae type of soral construction. This species shows, however, in its hairs (scales being absent), in the relatively large spore-output of its larger sporangia, and in the large number of spermatocytes of its largest antheridia, traits that are primitive. But the variability of size of both its sporangia and of its antheridia indicates the readiness with which the type might advance progressively to characters shared by most Leptosporangiate Ferns. The question of genetic relations between the Gleicheniaceae and the Cyatheaceae is thus centred definitely upon *Gleichenia pectinata* above all other species of the genus. The next step will be to consider the question from the other side, and to see whether any outstanding species of the

Cyatheaceae show primitive characters, such as compare in any degree with those of *G. pectinata*.

LOPHOSORIA PRUINATA, PRESL.
(= *Alsophila quadripinnata*, Gmel.).

The Fern so named has passed under various designations, and has commonly been regarded as an outstanding species. It was called *Polypodium griseum* by Schkuhr. Swartz named it *Polypodium pruinatum*. In 1848 Presl isolated it as the only species of a distinct genus, under the name of *Lophosoria pruinata*, but Sir William Hooker reduced it to *Alsophila*, and it appears in the 'Species Filicum' (vol. i, p. 47) as *A. pruinata*, Kaulf. It is, however, there remarked that 'in habit and appearance this is extremely distinct from any other *Alsophila*, and the receptacles are very slightly elevated, so that it must be considered but a doubtful species of the genus'. It bears the same name in the 'Synopsis Filicum', where as species 34, not only is it not accorded the dignity of a special section of the genus, but it is ranked indiscriminately among the ordinary species. Diels ('Nat. Pflanzenfam.', i. 4, p. 135) treats it in somewhat the same way, but remarks that it is a peculiar species. Christ ('Farnkräuter', p. 236) passes it under the name *Alsophila pruinata*, Kaulf., but places it in the section *Lophosorus*, Presl. Grisebach ('Flora of the British West Indies', p. 703) names it *Lophosoria pruinata*, Pr., and goes so far as to place it as a substantive genus, with *Cyathea* intervening between it and *Alsophila*. Finally, in Christensen's Index it appears as *Alsophila quadripinnata*, (Gmel.) C. Chr.

The best description hitherto given is that by G. S. Jenman, in his 'Synoptical List of Jamaican Ferns'. Ranking the plant under *Alsophila*, as species 6, *A. pruinata*, Kaulf., his description is as follows:—

Stem short, rarely 3 ft. high, clothed densely with laniferous scales (*sic*); stipites 3-6 ft. long, or more, arching, faintly impressed, rather polished, naked, except at the base; fronds 4-6 ft. long, 3-5 ft. wide, subdeltoid, tripinnate, pale green above, frost-coloured beneath, coriaceous, costae and costulae pubescent above, the pinnulae lanate on the ribs beneath; pinnae large, apart, petioled, lowest pair deflexed and a little reduced, next above $1\frac{1}{2}$ -2 $\frac{1}{2}$ ft. long, 6-10 in. wide; pinnulae lax, petiolate, 3-6 in. long, 1-1 $\frac{1}{2}$ in. wide, serrate-acuminate, the lowest segment situated on the superior side; tertiary segments $\frac{1}{2}$ - $\frac{3}{4}$ in. long, 1 $\frac{1}{2}$ -3 in. wide, acute, deeply cut into deltoid lobes in which the veins are pinnate; sori at the base of the lobes, at the apex of the lowest venule on the upper side near the crenulated sinus; sporangia few, rather large, roundish, mixed with copious lanate scales (*sic*). *Polypodium*, Swartz, *Lophosoria*, Presl, Plum-Fil. t. 33.

Very plentiful in forest shade from 3,000 ft. alt. to the highest ridges. The caudex, which is 3-4 inches in diameter, buds and throws up from the base a number of minor stems about half the size of the primary one. The petioles are sometimes as much as 10 ft. long, giving the fronds an immense

spread. In shape of frond, character of vestiture, and scant number of capsules, it differs materially from all the other species.

There has never been any question of the identity and distinctness of the plant, the uncertainty has been how it should be treated systematically; and this is an indication of its aloofness, which gives it an added interest in relation to the present inquiry.

As regards the details, beyond such facts as are used by descriptive botanists quoted above, little is known of this Fern, except what has been stated by H. Karsten ('Vegetationsorgane d. Palmen', p. 123). He described and figured transverse sections of the stem and leaf-bases, and of the adventitious buds. From his drawings and description it is clear that the axis is solenostelic, and that the leaf-trace is at its base a continuous horse-shoe (compare 'Land Flora', p. 605, where Karsten's figures are reproduced). This relatively primitive anatomical structure is so clearly divergent from that usual in the Cyatheaceae that the facts fix the attention still more forcibly upon this outstanding type.

Lophosoria is a widely spread Fern of the Western Tropics. It is found on the West Indian Islands as well as on the mainland, where it extends southwards as far as Patagonia. Its general characters, its habit, and large dimensions will be sufficiently gathered from Jenman's description, above quoted. Associated with each leaf is usually a bud, which may be only initiated in the case of the upper leaves, or it may be developed in the case of the leaves at the base of the plant; the bud takes then the form of a runner, which after growing horizontally, for a distance usually short, then turns upwards. The leaves on those parts that are underground may be arrested, but those at the distal end of a runner develop in the full form typical for the plant. The position which the buds hold is median at the base of the leaf that bears them, and on its abaxial side. There is in this way a very profuse provision for the vegetative expansion of the individual (Pl. XXXI, Fig. G).

As implied by the name '*quadripinnata*' which has been given to the species by some authors, the leaf is highly divided, and of the Cyatheaceous type, with a clean rachis without either basal pinnae or thorny emergences; except that in large leaves some low emergences may appear at the extreme base (Fig. G). The rachis, together with the axis, is covered by a dense felt of hairs—not 'scales' as Jenman described them. They persist till maturity on both axis and the base of the leaf-stalk, as shaggy rufous masses. They are present also on the under side of the pinnae and pinnules, giving a rusty appearance to the veins, while the rest of the under surface is glaucous. The upper surface of the mature pinnule is free from hairs. Numerous hairs are also associated with the sori. There are no scales on any part of the plant, though such appendages are

a marked feature of the Cyatheaceae. In this *Lophosoria* resembles *Gleichenia pectinata* and *linearis*.

The pinnules themselves are narrow, with crenate margin curved downwards, and their texture rather stiff. The venation is forked, without fusions (Fig. H), just as is the case in *Gleichenia*.¹ The sori are circular and compact, inserted with great regularity upon the lowest anadromic veinlet of the ultimate pinnule. It will be noticed that this corresponds to the position of the sorus in *Gleichenia linearis* (Pl. XXX, Fig. C), and also in *G. pectinata*. The number of sporangia in the sorus is small; they are seated upon a circular and slightly raised receptacle, and show a regularity of orientation of their sporangia, indicated by their oblique annulus, which resembles that in *Gleichenia* (Pl. XXXI, Fig. I). The actual numbers as shown in Fig. H range from 7 to 10, and their arrangement is more or less obviously in two tiers: a lower tier of about 6 or 7, which form a circular series, and are so orientated that the annulus is in a plane almost vertical to the surface of the leaf, or forming an angle with it by sloping outwards from the centre of the sorus. In fact, the orientation is as in *Gleichenia*. The upper tier of sporangia, consisting it may be of only one or of more sporangia, shows less regular orientation, much as is seen in *G. linearis* or *pectinata*. But in *Lophosoria* the crowded nature of the sorus presents no difficulty in dehiscence, for it will be seen later that the slit is not here in a median plane, but lateral.

It thus appears from the external characters that *Lophosoria* holds a peculiar position between the Gleicheniaceae and Cyatheaceae types. The internal structure and development will now be described, with a view to testing the validity of these indications.

Anatomy of Axis.

The axis and leaf-bases of *Lophosoria* are covered externally by a dense band of hard black sclerenchyma, without any of those lenticel-like perforations which are so marked a feature in the dendroid Cyatheaceae (Fig. G). There is also a sclerotic tissue within the solenostele, which in the young plant is a solid core as in *Gleichenia pectinata*, but in larger plants it expands into a hollow cylinder filled with softer pith, and lining the tubular stele internally. At the leaf-gaps it extends outwards in close relation to the leaf-trace, and a portion separates with it as a supply of mechanically effective tissue into the leaf-base. The gap in the sclerotic ring is then closed by a commissure, and the ring is thus completed again before the closing of the foliar gap. In fact, the sclerotic tissue accommodates itself to the conformation of the vascular system (Pl. XXXIV, Fig. 9).

¹ The figure of *G. pectinata* (Pl. XXX, Fig. D) appears to suggest fusions of the veins; but an examination of the pinnule from which the drawing was made, after removal of the sporangia, showed that no fusions were present.

Karsten's drawings and description of the structure, so far as they go, accurately represent the facts (see 'Land Flora', p. 605, and Fig. 336, where reference is made to the original paper). *Lophosoria* shows in certain sections a perfectly solenostelic state, the vascular ring opening in the usual way to give off a broad segment of the ring as a foliar strand. This is shown in Pl. XXXIV, Fig. 10, in which it is seen that the separation of the strand is not effected synchronously on both sides. One margin separates as a rule before the other, and this is in fact usual in Ferns with a creeping axis. After both are clear, a wide gap is left in the solenostele, which ultimately closes again. Sometimes the leaf-gaps almost overlap. A case is shown in Fig. 9 in which in a very large axis a foliar gap is seen still open, while on the obliquely opposite side the solenostele is already thinning out in preparation for the formation of the next succeeding leaf-trace. A clear idea of the behaviour can be obtained by comparison of a succession of sections, such as those shown in Fig. 11, which are similarly orientated, and are ranged in succession from below upwards. Fig. 11, i, shows the solenostele open on the side opposite to a leaf-trace which has just come off; the internal sclerotic ring has already closed, but not the stele. It may be noted that the leaf-trace shows the unusual state of having joined its margins, so as to form a complete ring; it may be remarked, however, that the leaf was a stunted one, the axis being a pushing adventitious shoot. Fig. 11, ii, shows a point higher up, where the foliar gap is closed, but the stele is still thinner there than the average. On the side almost opposite, the stele is thinning out for the formation of the next leaf-trace, but it is still a complete solenostele. In the next section, Fig. 11, iii, the leaf-trace thus prepared for is just separating at one margin, but connected by the other. In Fig. 11, iv, that leaf-trace is quite separate, and it shows again the closing in on the adaxial side, so as to form a complete ring. In the last section of the series, Fig. 11, v, the solenostele has closed completely, though two thinner points are seen, the one marking where the ring has closed after the departure of the last leaf-trace, the other showing where the next will come off, and this is already indicated also by the slight outgrowth of all the tissues on the side obliquely opposite to the preceding leaf. It is thus evident that the leaf-gaps do not actually overlap, though they may follow in rapid succession, and the structure is accordingly solenostelic, but with a rather compact arrangement of the leaves, which is specially marked where the plant has settled down to its normal vertical growth, with a terminal tuft of leaves.

The validity of these results is shown by Pl. XXXII, Fig. K. This does not represent any idealized conception of the vascular system, but it is an accurate delineation of an actual dissection of a large axis, from which the cortex has been removed, and the vascular system laid bare. The outer surface represented in the drawing is the solenostele itself, and it

is shown of the natural size. The leaves are at considerable distances apart, so that in transverse section the leaf-gaps do not overlap, and transverse sections of the parts lying between them would show the complete solenostele. It may be noted that in this case the adventitious buds are absent from the leaf-bases.

It has been pointed out that roots and adventitious buds are borne by the axis. The attachment of the roots is shown in Pl. XXXIV, Fig. 11. Their vascular supply comes away from the outer margin of the stele in the usual way. The adventitious buds are placed with regularity below the leaf-bases. Frequently there is one at the base of each, but their presence is not constant. In order to trace the vascular connexion of the bud and its related leaf, sections were cut transversely to the parent shoot, as in Fig. 12. Of these (i) is the lowest; it shows a foliar gap of a preceding leaf just closing, while almost opposite the thinning out and extension of the stele is beginning preparatory to the departure of the next trace. But already the related bud (*b*) is traversed, though the section was below the level of its vascular supply. In Fig. 12, ii, the bud is traversed in median section, and it is seen that not only does the vascular tissue extend directly out into it, but the sclerenchyma also; in fact, the vascular tissue of the bud arises as a diverticulum of that at the base of the related leaf. Closely above it, as shown in Fig. 12, iii, the leaf-trace itself comes off in the usual way. These results were checked by tangential sections, as shown in Fig. 13. Of the sections there shown (i) is a transverse section of the bud close to its base, showing its solenostelic structure, with numerous roots. A tangential section just below its insertion is seen in (ii), which shows the continuity of the sclerenchyma and pith of the main axis with that of the bud. It is also seen how the vascular supply of the bud arises from the leaf-trace strand itself. A section still lower is seen in (iii), where the ring has widened out, and merged into the curved strand of the trace.

It is thus seen that the adventitious buds may be solenostelic from the first. It is not improbable that small and weak runners may be protostelic at their base, but none have been observed. Unfortunately the youngest plants available from those collected in the open forest showed already the solenostelic structure; and as the cultures from spores did not come through to the formation of sporelings, the ontogenetic origin of the solenostelic structure in the plant must for the present remain in doubt.

Pl. XXXII, Fig. L, represents the vascular skeleton of a shoot of moderate size, showing the relation of the supply to the adventitious buds to that of the leaves. In this case most of the leaves bear an adventitious bud, but in some cases the bud was absent.

As regards the details of structure, the solenostele is of a very usual type. It is limited on either side by an endodermis with brown coloured walls, succeeded by a pericycle of two or three layers, and the broad band

of phloem on either side of the xylem presents no characters for remark. The xylem varies in its thickness, thinning off especially where a leaf-trace is about to depart. It consists of tracheides mixed with parenchyma. The tracheides are of uniform character, and, as is often the case in the Cyatheaceae, there appears to be no protoxylem. Not only is this absence of protoxylem seen structurally, but it is also shown in sections of young stems by the fact that the tracheides mature almost simultaneously over the whole transverse area.

Though the axis is often very bulky, no medullary vascular system has been seen.

Anatomy of the Leaf.

The leaf, which is slightly dilated at the base, is continued upwards with an almost cylindrical stipe, marked on either side by pale lines similar to those in the Bracken, and often accompanied by dark streaks of sclerenchyma. These are interrupted, just as in the Bracken, at the first pinnae, which are inserted in large leaves at two or three feet from the base.

The leaf trace has been seen to come off as a simple meristele, which soon assumes a complicated horseshoe outline, with lateral involutions. In small leaves it may remain throughout as a single continuous strand; but in large leaves it commonly divides close to the leaf-base into three distinct portions, which in very large leaves may be widely separated (Pl. XXXIV, Fig. 9). In leaves of smaller size the margins of these several portions may remain in close relation, or the strands may even fuse with one another from time to time. But sooner or later they finally join again to form a single band. This was found to be completed in a specific case within nine inches of the base of the leaf (Fig. 13 *bis*, *a*, *b*).

Very soon after leaving the axis protoxylem-groups make their appearance in the vascular strand, which had previously been without them. They are characterized in the usual way, but are very numerous, forty-seven being counted in a specific case. Each protoxylem acts as the centre of a 'divergent', and lies apparently nearer the periphery of the section than the metaxylem; but in actual fact the protoxylem elements, accompanied by cavity parenchyma, are really on the adaxial face of the xylem of the meristele. Since this arrangement impresses itself on the whole contour of the strand, a characteristically corrugated outline results (Pl. XXXIV, Fig. 13 *bis*; Pl. XXXV, Fig. 14). This condition is continued with little change in form of the trace, or even in number of the protoxylems, up to the level of the first pinna.

Opposite the involutions of the horseshoe-shaped strand a break in the continuity of the band of sclerenchyma which bounds the section may be seen on either side. The epidermis is there thin, with numerous stomata, while a lacunar ventilating tissue lies below it. This structure constitutes those lateral lines already observed from without (Fig. 13 *bis*).

The origin of the pinna-trace from the rachis has been followed. For purposes of description reference must again be made to the strand of the rachis. It is in outline like the Greek omega (Fig. 13 *bis*, δ), thus corresponding to the chain of separate strands so characteristic of the leaf-trace in the Cyatheaceae. There are two internal bays on each side: these may be designated according to their position as the adaxial and abaxial bays. It is in relation to these that the pinna-trace arises. An example is seen in Pl. XXXV, Fig. 14, i-vii (left-hand side). The first sign is a deepening of the abaxial bay on the side where the pinna arises (Fig. 14, i). The xylems then come together a little short of the extreme curve and fuse, forming a loop of xylem, with conjunctive parenchyma enclosed (Fig. 14, ii). A constriction then takes place, so as to nip off the xylem-ring with its attendant tissues, while the phloem and sheaths close in so as to abstrict off an island of vascular tissue from the angle of the bay. Meanwhile the sheaths at the angle of the adaxial bay begin to widen out towards the island, and, joining with its sheaths, receive it as it separates from the abaxial bay (Fig. 14, ii, iii). After the junction has thus been made with the adaxial bay the xylem-ring connects with its xylem, and then opens out; the conjunctive tissue and the sheaths curve into the cavity, and the island thus takes its place as part of the adaxial bay of the trace (Fig. 14, iv, v). But meanwhile a constriction, and finally an interruption, appears further along the bay, on the adaxial side (Fig. 14, v); enlargements then appear facing one another upon the two sides of the adaxial bay: these meet and fuse (Fig. 14, vi), but shortly the bridge of fusion divides down its middle; when that is completed the pinna-trace becomes isolated, while the trace of the rachis resumes its original form (Fig. 14, vii). These successive steps are illustrated on the left-hand side of the sections seen in Fig. 14. It will be seen that similar steps are initiated on the right-hand side also; these are for the next pinna, which is seated almost opposite to the first, but slightly higher.

A comparison of these steps in the formation of a pinna-trace may be made with the description and drawings given by Tansley for the secondary pinna of *Cyathea excelsa* ('The Filicinean Vascular System', p. 118 and Fig. 97). There are differences of detail, partly in relation to the interrupted nature of the vascular tracts in *Cyathea*. But the essentials are the same, and the chief point is that in either case the pinna-trace is connected with both bays of the folded trace of the rachis. The median part of the pinna-trace is derived from the abaxial bay, and the lateral parts of it from the adaxial bay.

On the other hand, a comparison should be drawn with what is seen in *Gleichenia*, and a series of sections has been made from the rachis of *G. linearis*, at the level of insertion of a pair of pinnae. At first sight there does not appear to be much similarity. But in any such comparison

allowance has to be made for the habit. In *Gleichenia* there is a more restricted area of the transverse section, and consequently a greater compression of the vascular tract. This is evident in the absence of the lateral involution between the adaxial and abaxial bays, as well as in the stronger curving inwards of the hooks of the horseshoe, which actually meet and fuse (Fig. 15, i). Thus the changes which lead to the separation of the pinna-traces start from a simpler and more compact state than in *Lophosoria*.

The first changes are the separation of the hooks from one another, while the loops formed by them are completed (Fig. 15, ii). Each of the loops then becomes constricted in the middle, and a C-shaped vascular tract is separated off from its distal end (Fig. 15, iii-v). Meanwhile, two projections arise from the concave side of the main bundle, opposite to these C-shaped tracts (Fig. 15, iii-v), while the latter alter their form by producing processes opposite to these (Fig. 15, v). The pairs of processes then fuse, and subsequently each bridge of junction splits down its middle into equal halves (Fig. 15, vii). The result is the formation of three C-shaped tracts of vascular tissue lying in a row, which supply respectively the main rachis and the two pinnae. Putting aside the differences of detail, the points of similarity with *Lophosoria* are, (i) that the pinna-trace is intra-marginal in its origin, and (ii) that its separation is effected by the splitting down the middle of a bridge of junction between the internal faces of the curved trace. On the other hand, as points of difference may be noted, (i) the greater simplicity of the initial steps in *Gleichenia*, consequent on the absence of the lateral involution, (ii) the difference of behaviour of the margins of the trace, consequent on its constriction, and (iii) the equality of size of the traces of the rachis and the pinnae. Thus the comparison brings out fundamental similarities, while the differences which appear may be attributed to the peculiar habit of the Gleicheniaceae leaf, and the extreme contraction of its vascular supply.

It may not be out of place here to remark that notwithstanding the well-known contraction of the meristele at the base of the leaf in *Gleichenia*, which is correlated with its continued apical growth and straggling habit, the meristele may open out above into a widely curved horseshoe. Sections from the upper regions of the leaf of *G. flabellata*, and especially of *G. linearis*, show this clearly. In them the xylem widens out into a dilated curve of one to three layers in thickness, while the protoxylems, with their cavity parenchyma, lie on the adaxial face. The structure is in essentials like that of *Lophosoria*; the chief difference is in the much lower number and less prominent identity of the divergents.

Hairs.

The only dermal appendages found on the shoot of *Lophosoria* are simple hairs, composed of a single row of cells. They are thin at the base,

becoming thicker upwards, and narrowing suddenly near to the apex. They do not bear any glands, and are not branched (Fig. 16). Such hairs are of a very primitive type, and the absence of any broadening into ramenta or scales is in strong antithesis to what is seen in many related genera, and especially those of the Cyatheaceae. But the condition here seen compares in essentials with the condition of those species of *Gleichenia* (*G. linearis* and *pectinata*) with which comparisons have been drawn on other grounds.

The Sporangium.

It has been seen that the sorus of *Lophosoria* consists of about 7–10 sporangia, seated upon a slightly raised receptacle. Not only does observation of young stages show that the sporangia of a single sorus arise simultaneously, as in the relatively primitive *Simplices*, but there is an extraordinary simultaneity of development of the sporangia on the same pinnule, and even on the whole leaf. This condition, so different from what is usual in the more advanced Ferns, was entirely unexpected when the collection of material was made. The result was that only certain stages were at first secured, and those did not include the earliest. The difficulty as to material was, however, surmounted through the kindness of Mr. Harris, of the Hope Gardens, Jamaica, who made a second collection for me so as to secure the earliest stages of the sorus and sporangium. It is to be remembered that the condition thus shown by *Lophosoria* is characteristic rather of the lower than of the higher Filicales, and is conspicuously the case in the Gleicheniaceae.

The mature sporangium is of large size, and of almost spherical form. It is attached by a short stalk, which in transverse section shows six or more cells (Fig. 17). This corresponds to what is seen in *G. linearis* (Studies, IV, Fig. 9), and is distinctly more complex than is seen in *Alsophila excelsa* (l. c., Fig. 89). There are no internal cells such as are seen in the massive stalk of *Todea* (l. c., Figs. 48–50), or in *Lygodium* as clearly indicated by Binford's drawing ('Bot. Gaz.', vol. xlv, Fig. 18, p. 217), or in *Gleichenia circinnata* (l. c., Fig. 5), or in *Matonia* (l. c., Fig. 59), and occasionally seen in *Mohria* (Prantl, 'Schizaeaceae,' Fig. 143). In this detail, which is in itself an indication of the massive character of the sessile sporangium, *Lophosoria* takes a middle position between the larger sporangia of some *Simplices* and the smaller sporangia of the *Gradatae*.

The external form and structure of the sporangium is shown in Figs. 18–20, from three different points of view. The oblique annulus is well marked, and continuous past the stalk, thus marking off two areas of thin-walled cells, corresponding to those described as the 'peripheral' and 'central' faces in the case of *Gleichenia* (Studies, IV, p. 34). The peripheral face is shown in frontal view in Fig. 18, and is the face of the

sporangium which is directed obliquely outwards from the centre of the sorus in the normal orientation; this orientation we have seen to be habitual in those of the lower tier in *Lophosoria*. The central is the opposite face, which is directed obliquely inwards, to the centre of the sorus, just as in *Gleichenia*. It is shown for *Lophosoria* in Fig. 19. In Fig. 20, where the sporangium is seen from the side, showing clearly its turgid form, the two opposite faces are indicated by words. The annulus consists as a rule of a single row of cells of regular sequence; but in the neighbourhood of the stomium irregularities appear. In Figs. 19, 20, certain cells are divided, while in close proximity there appears a break in the regularity of the sequence. It is as though the distal part of the annulus were more nearly vertical than the proximal part. Such facts indicate an instability of exact position of the annulus such as might be anticipated in a case where that structure is in course of change from an inherited to a novel position; in fact, swinging from an oblique towards a vertical position.

The stomium is lateral in position—a marked difference from the case of *Gleichenia*, where the dehiscence is median. It is not exactly differentiated, and appears to be variable in the number as well as in the exact position of its cells. It serves, however, as a structural definition of the lateral dehiscence, though not with the constancy of structure seen in more advanced Ferns. Such a condition is what might have been expected in a type in which a recent change of the point of dehiscence from a distal to a lateral position had occurred.

The number of tabular cells covering the faces of the sporangium is relatively large, and it is markedly so when a comparison is made with the sporangia of the Cyatheaceae. Thus, over fifty cells are shown on the peripheral face of Fig. 18 of *Lophosoria*. In Studies, IV, Fig. 83 of *Cyathea* there are only six, in Fig. 86 of *Hemitelia* there are eight. The correspondence is, however, a closer one with the large sporangia of *Gleichenia*. Having noted thus the large size of the sporangium, and its complexity of structure, it was a matter of some surprise to find that the output of spores is low. Several countings gave figures closely approximating to, but not exceeding sixty-four, which appears to be the typical number in each sporangium.

The development of the sorus and sporangium has been studied in sufficient detail for bringing out the points that are essential for comparison. As in *Gleichenia* the receptacle makes its appearance on the lower surface of the pinnule, at some distance from the margin, as a multicellular upgrowth of rounded form (Figs. 21–2). Certain of its superficial cells begin to grow out as hairs (Figs. 24–6), while others become soon recognizable as the parent cells of sporangia (marked x in Fig. 23). These undergo divisions by walls inclined to one another, leaving a pyra-

midal cell at the apex of the upgrowing sporangium. From this by a periclinal wall the cap-cell is cut off. The number and relations of the cells which thus go to form the stalk of the sporangium do not appear to be precisely the same in all cases. The stalk which results is of a massive type (Figs. 25, 26). The whole segmentation of the sporangia, as well as their position on the receptacle, and the structure of the latter are strongly reminiscent of what has been demonstrated for *Gleichenia linearis* (= *G. dichotoma*) some years ago (Studies, IV, Pl. II, Figs. 15-17). In both cases the relatively thick stalk is indicative of a primitive sporangial type. On the other hand, a comparison may be instituted with the young sporangia of the Cyatheaceae, as shown for *Cyathea* (l. c., Figs. 78-80), for *Alsophila* (l. c., Fig. 87), and for *Onoclea* (l. c., Fig. 90). It is, however, to be remarked that in these the sporangium is of a rather more attenuated form, and projects more in its early stages of segmentation, which is an indication of its more advanced state.

A later state of the sorus and sporangia is shown in Figs. 28, 29, the former being cut so as to follow the course of the vein over which it is seated, while in the latter the vein is cut transversely. From the convex surface of the receptacle arise numerous hairs, which show a basal intercalary growth. The sporangia are few, and are always of uniform age in the sorus. There is no evidence of any succession in their appearance. Thus *Lophosoria* would be properly ranked, as *Gleichenia* is, among the Simplicies. It may be noted that the sporangia in *Lophosoria* are raised further from the surface of the leaf than in *Gleichenia* (compare Figs. 28, 29 with Figs. 22, 24 of Studies, IV). This is owing to the greater height of the receptacle, a fact which accords with its relation to the Cyatheaceae, where the receptacle is higher still.

As regards the sporangia, their position when young naturally corresponds with that which they hold when mature. In Fig. 28 two are traversed in positions corresponding to those of *Gleichenia linearis*, as seen in Fig. 15 of Studies, IV. In Fig. 29 three are seen corresponding in their disposal to those of *G. linearis* shown in Studies, IV, Fig. 16. The sporangia themselves have their short massive stalk segmented in a way that would lead to a structure as seen in Fig. 17. It corresponds to that of *G. linearis*, rather than to the more massive structure seen in *G. circinnata*. The sporangial head has as usual the single peripheral layer of cells that will form the sporangial wall, lined with the tapetal layer, which surrounds the single sporogenous cell. The structure and proportions thus seen for *Lophosoria* are of a type common for the more primitive Ferns where the sporangium is large, such as *Gleichenia linearis*, *Matonia*, or *Loxsonia*, but not of the very largest size. As it grows older the annulus begins to be differentiated by enlargement of certain cells of the wall (Figs. 30-2), the tapetal layer divides in the usual way into two, and the sporogenous cell

divides into usually sixteen cells. These are as a rule arranged in two tiers of eight, so that in transverse sections that number is shown (Fig. 32). In one case, however, nine were found (Fig. 33). It would thus appear possible that a larger number than sixteen spore-mother-cells were present. But as this was an isolated example among many others, and as the countings of the spores showed consistently figures not exceeding sixty-four, stress should not be laid on this single divergent fact. Moreover, it is possible that a division may have been left out in the other tier of cells, so that the total of the spore-mother-cells would still be only sixteen. Then follows the tetrad division, and maturing of the spores in the usual way. The result is shown in a section from an almost mature sorus in Fig. 33. Here the position of the sorus relatively to the curved surface of the pinnule is seen, with the mass of tracheides which enters the receptacle. Of the four sporangia traversed, those right and left show the regularity of orientation characteristic of the Gleicheniaceae type. A comparison of these with the sporangia as seen from outside (Figs. 18–20) explains the relation of the large cells of the annulus to the body of the sporangium, and to its peripheral and central faces. But the two sporangia which occupy the centre of the sorus show irregular orientation, as would be anticipated from the drawing of the sorus as a whole (Pl. XXXI, Fig. I).

It has been seen that the stomium is lateral, and therefore the annulus on dehiscence behaves in the manner characteristic of the Gradatae, as seen in the Cyatheaceae. This makes no demand for 'elbow-room' as in the median dehiscence of the Gleicheniaceae. It is an arrangement which is practically effective in closely crowded sori, and it is evident from the relation of the sporangia, as seen in Fig. 33, that the mature sporangia of *Lophosoria* are in close contact.

It appears from the data thus given that the sorus of *Lophosoria* presents features of correspondence with, as well as of strong divergence from, that of the Gleicheniaceae type. The points of similarity are: (1) the superficial position, (2) the insertion on the anadromic branch of the forked veins, (3) the raised receptacle with vascular supply, (4) the simultaneous origin of the sporangia, (5) the disposition of the sporangia after the type of *G. linearis* and *pectinata*, (6) the segmentation of the sporangia, and (7) the oblique annulus. The points of difference are: (1) the lateral dehiscence, and (2) the smaller spore-output from the individual sporangium. As to the latter, the condition seen in *Lophosoria* is in some degree approached by the smaller sized and less prolific sporangia of *G. linearis* and *pectinata*, while in the last-named species a marked degree of variability of size of the individual sporangium is seen. There is, however, an obvious break in the series, leaving *Lophosoria* isolated. As to the dehiscence there is little evidence on either side of transition from the median to the lateral type. The want of strict definition of the stomium in *Lophosoria* may, however, be

held as some indication that shifting of its position had occurred. It is, on the other hand, quite possible that the Cyatheaceous type of dehiscence may have existed *ab initio*. This, however, seems to me to be the less probable reading of the facts.

Taking all the points of correspondence and of difference into account, it appears probable that *Gleichenia* and *Lophosoria* are genera which are descendants of a common stock which had a superficial sorus, of the type of the Simplicies; that in certain of the forms a departure was made from the originally radiate uniseriate type by formation of sporangia in the centre of the sorus, as in *G. linearis* and *pectinata*, the latter of which reached the limit of crowding of the sorus which could secure effectiveness of dehiscence by the median rupture; that this difficulty was avoided by another related stock, represented in its simplest form by *Lophosoria*, in which, either as an original character, or more probably as a result of later adaptation, the lateral dehiscence is now seen.

Spore and Prothallus.

The mature spore of *Lophosoria* is a very characteristic one. It is tetrahedral, and shaped like a kettle-drum. There are three flattened faces, separated by lines which converge to the central apex and marked by irregular spots. These represent the skin of the drum. The margin of the drum-head is expanded into a projecting circular band, while the rest of the rounded body of the spore is covered by a thick wall, marked by minute rounded bosses (Fig. 34).

On germination the rupture takes place along the three converging lines, and the three apical flaps of the outer wall come apart. The prothallus is at first filamentous, and in crowded cultures may continue so for some length. But sooner or later the apex widens out into a spatulate form, with its lobes ill-defined and unequal, as is usual in *Alsophila* (Fig. 35). My cultures have progressed to the stage of producing antheridia, which are of a usual type. They rupture by the extrusion of a single cell. Unfortunately, the first cultures at this stage damped off. But attempts are being made to raise fresh cultures from spores kindly supplied from Jamaica by Mr. Harris. A fuller statement on the gametophyte and observations on the young sporophyte will have to be deferred to a later communication.

Morphological Discussion.

A considerable number of characters have been mentioned in the above pages, according to which the Fern described as *Alsophila* (*Lophosoria*) *pruinata* occupies a peculiar position of aloofness; characters which were for the most part unknown to Sir William Hooker, or at least not regarded by him as important when he merged it as a species of *Alsophila*.

It will be shown that these characters indicate that *Lophosoria* is a more primitive type than the true species of *Alsophila*, and point with all the strength of parallel comparison to its position at the base of that series, where in point of fact it has been naturally placed by most systematists.

On the other hand, a somewhat similar aloofness has been indicated within their own genus for two species of *Gleichenia*, viz. *G. linearis* and *G. pectinata*. This has been commonly recognized by writers. It has been shown that their peculiarities mark them off as an advance upon the genus *Gleichenia* in general. By further comparisons between this advanced guard of the ancient genus *Gleichenia* and the *Lophosoria* type as the most primitive of the Cyatheoid Ferns, it appears that the two large groups approach one another. In fact, on the basis of the foregoing observations, together with other considerations now to be advanced, the conclusion may be drawn that the primitive and creeping Gleicheniaceae resembled the ancestry of the Cyatheoid series, and that of living types they most nearly represent the forerunners of that great body of dendroid Ferns.

The criteria which may be used for the purpose of this comparison are the following :—

- (i) The position and branching of the axis.
- (ii) The form and pinnation of the leaf.
- (iii) The dermal appendages.
- (iv) The characters of the vascular system.
- (v) The sorus, its position and constitution.
- (vi) The sporangia and spores.
- (vii) The prothallus and sexual organs.

Each of these will now be examined with a view to an opinion on the phyletic relation of the Ferns named.

1. In chapter xvi of the 'Land Flora' I have dealt broadly with the question of symmetry in the sporophyte, and drawn the conclusion that 'the radial mode of construction was primitive for the sporophyte at large, and that where dorsiventrality occurs it is a secondary condition'. If this were accepted in its baldest form, one might proceed to classify all radial types as relatively primitive, and all dorsiventral types as derivative. But that could only be done by making the quite gratuitous assumption that changes of symmetry could only occur once in any phyletic line. For this there is no warrant. It would seem probable rather that according to circumstances the change from radial to dorsiventral, and also from dorsiventral back to the radial condition of the shoot, may have occurred repeatedly in the course of descent. This subject has been already broached by Prantl in relation to the Hymenophyllaceae and the Schizaeaceae, and similar suggestions have been advanced by Boodle as explaining the anatomy of certain Hymenophyllaceae ('Annals of Bot.', xiv, p. 482). He contem-

plates it as probable for them that though the original ancestry may have been radial, all the living members of the order may have been evolved from creeping forms; some species retaining that character, and others having changed to the upright habit, and back again. It is necessary to keep an open mind on such questions, and to let opinion follow fact and comparison.

Applying this point of view to the present case, though we may contemplate the ultimate origin of the Gleicheniaceae from more primitive Ferns with radial upright axis, we see them to-day as characteristically a creeping family, with dorsiventral shoot. But if the facts indicate that any derivatives from them became in the further course of descent upright, and attained to a radial axis, there seems no reason to dissent from such a conclusion. On grounds especially of their sori reason has been found to contemplate the derivation of the Cyatheaceae from a source resembling the Gleicheniaceae. Our point now is, that if a careful examination of widespread character indicates that that was so, there is no inherent reason to doubt that the columnar upright axis, which is the most striking feature of the Cyatheoids, was itself a secondary character.¹

The question will largely turn upon the existence of intermediate types. There are no relatively advanced Gleichenias which have adopted a definitely upright, self-supporting habit. The two most advanced species, viz. *G. linearis* and *G. pectinata*, are both creepers. But on the other side, though the more advanced genera *Hemitelia* and *Cyathea* show no creeping species, such are seen in the more primitive *Alsophila*, in the species *A. (Metaxya) blechnoides*, and in less pronounced degree in *A. (Lophosoria) pruinata*. Moreover, both of these proclaim themselves as primitive by other characters. A detailed account of *Metaxya* will be held over to a later memoir of this series. It may suffice here to say that with its creeping habit go a solenostelic structure of the axis, an undivided leaf-trace, and hairs only as dermal appendages; all of these being relatively primitive features as compared with other Cyatheaceae. The same may be said for *Lophosoria*, which, however, as regards the mature plant has an upright, though short axis. But the buds which originate at the bases of many of the leaves give rise to runners, which at first take a horizontal course, with their leaves coming off at intervals right and left. The creeping habit with isolated leaves is thus actually shown in the early condition of these shoots. Thus, as regards position of the axis, *Metaxya* pronouncedly, and *Lophosoria* in a less degree, bridge over the gap between

¹ The question here considered, of the upright habit in the Cyatheoid Ferns being a secondary derivative from the creeping habit, has already been stated briefly (Ann. of Bot., xxv, pp. 567-8). The detailed evidence for the opinion is here stated, and it is essential that it should be, for the theory of medullation stated in the paper above quoted could not hold, if the vertical character were primitive. But the comparative evidence from external form, from dermal appendages, from anatomy, and from sorus and sporangium alike, as stated in the above and in the succeeding paragraphs, indicates that it was not.

the creeping habit of the Gleicheniaceae and the upright dendroid types of the Cyatheaceae.

In this connexion it may be noted that terminal branching occasionally is seen in the dendroid Cyatheaceae. An example of this is shown in Pl. XXXII, Fig. M, in a plant in the Glasgow Botanic Garden. Here there is an apparent dichotomy, the two resulting branches having continued their development equally. Anatomical examination would be necessary to prove that the branching was really dichotomous in this case, and naturally that cannot be undertaken. So it must suffice for the present to state that all the external indications are favourable to the branching having been a true dichotomy. If this were really the case, it would be a further point in common with the Gleicheniaceae, in which it has been shown that dichotomy is frequent.

2. As regards the form of the leaf the Gleicheniaceae and Cyatheaceae seem at first sight widely divergent, and *Lophosoria* does not appear to help any transition. But if a comparison be made between the ultimate pinnules of *Lophosoria* (Pl. XXXI, Fig. H) and those of some species of *Gleichenia* (Pl. XXX, Figs. C and E) a similarity of outline, of venation, and even of texture is apparent; the soral similarity is, however, the most important feature of all. The divergence is then in the general habit of the leaf rather than in the details. But even in general habit there are features which link the two families together. The most marked characteristic of the leaf of *Gleichenia* is its apical growth, which may be continued indefinitely though interrupted at seasonal intervals. Looked at broadly, however, the leaf is constructed upon the ordinary pinnate type, and its peculiarities depend upon irregularities in time and extent of the intercalary growth of the rachis, and of the branches of higher order. For the most part the intercalary growth between the pairs of pinnae is strong, so that they are far apart, and usually uniformly removed from one another. In the Cyatheaceae it is less strong, and the pinnae are more closely aggregated. But as a rule the pinnac stop short at some distance from the base of the mature leaf, intercalary growth having been strongest below the lowest pinnae. A special interest, however, for comparative purposes lies in those cases where this rule is not maintained, with the result that basal pinnae are left behind at the base of the leaf, the intercalation of the petiole having taken place above them. These basal pinnae have long been known as the so-called 'aphlebiae', and the example commonly quoted is that of *Hemitelia capensis*. But as a matter of fact it is a feature which exists sporadically in all the three genera of the Cyatheaceae. Pl. XXXIII, Fig. N shows a very pronounced example of *Hemitelia setosa*, Mett., from the Edinburgh Botanic Garden. Fig. O shows the case of an *Alsophila* from Jamaica, growing in the Glasgow Botanic Garden; and Christ has figured a very marked case of basal pinnae in a species of *Cyathea* ('Geographie der Farne', Fig. 24). It thus appears

that the existence of basal pinnae, left behind owing to the higher localization of intercalary growth having produced the petiole above them, is a feature in all the genera of the family of the Cyatheaceae. But in other Ferns it is virtually unknown. It seems to me that the existence of 'aphlebiae' thus exclusively in this family of upright Ferns is strongly reminiscent of an ancestry where the localization of intercalary growth between the pinnae and not exclusively below them was the rule. The unlimited growth and vigorous intercalation seen in the Gleicheniaceae would be impossible features in plants of dendroid habit. But, supposing these dendroid types to have sprung from an ancestry of Gleicheniacous habit, what more probable than that they should still retain some traces of that unusual distribution of intercalary growth? The absence of basal pinnae in other Ferns to which a near relation to the Gleicheniaceae is not ascribed gives strength to this interpretation of the 'aphlebiae' of the Cyatheaceae.

3. Comparisons based upon dermal appendages have mostly been neglected in the phyletic treatment of Ferns, or they have been put to too strenuous a use. The latter was the case when Kühn proposed to divide the Polypodiaceae into two groups on the basis of the simple hairs, as against flattened paleae ('Die Gruppe der Chaetopterideen unter den Polypodiaceen'). A middle course is, however, gradually coming into use, having been initiated by Prantl, who indicated very clearly in the Schizaeaceae how the hair is the more primitive, and the flattened scale, ramentum, or palea the derivative and later type. Other characters being in accord, the presence of hairs only may be held to indicate a relatively primitive condition; the existence of scales, with or without simple hairs as well, may be held to indicate a derivative or later condition.¹ There is reason to believe that a parallel transition from hair to scale was effected in several distinct phyletic lines.

Applying this criterion in the present case, the facts show that *G. linearis* and *G. pectinata* bear hairs only, whereas scales are widely present in other Gleichenias, and especially among the xerophytic types. Now *Lophosoria* and *Metaxya* also have hairs only, and no scales, whereas the genera *Alsophila*, *Hemitelia*, and *Cyathea* are characterized by scales, often of very large size. This superficial feature thus brings together in a very striking way those species upon which our comparison specially turns. But there is a further point to be noted in this connexion. The scales in many of the larger species of the Cyatheaceae are often borne each upon a massive conical emergence, which may persist after the scale itself dries and falls away, as one of those large spines which are specially developed about the bases of the leaves. A like condition has been found in *Gleichenia pectinata* (Pl. XXX, Fig. A), and the existence of such conical

¹ This line of comparison, based on dermal appendages, is being carried further into detail by C. Christensen (On a Natural Classification of the Species of *Dryopteris*, Biologiske Arbejder, Nov. 1911).

emergences about the leaf-bases justifies the comparison of the branched hairs which they bear with the broad scales of the Cyatheaceae. Similar emergences also exist in *Lophosoria* (Pl. XXXI, Fig. G). The progression of characters from the Gleicheniaceae to the Cyatheaceae through *Lophosoria* is in this case based upon a minor detail; but the existence of such a detailed progression supports all the more strongly the comparisons based upon more important characters.

4. By a general consensus of opinion the non-medullated stele is recognized as the primitive stellar type. The characteristic elaboration of this in Leptosporangiate Ferns was connected with the formation of foliar pockets, which intruded above the insertion of each leaf. This led to complete solenostely, with leaf-gaps. When the latter overlap one another the complete dictyostele is the result. No better illustration of these successive steps is to be found than in the Ferns under consideration. The sequence of stages of the elaboration is as follows: In *Gleichenia* in general the stele of the rhizome has a solid xylem-core; it is a protostele, from which the leaf-traces come off in some cases without any disturbance of the underlying tissues. The types of the genus described fall into a rough series, as regards their vascular characters, extending from the simple forms of *Eu-Gleichenia*, through *G. linearis*, to the typical Mertensias, and finally to *G. pectinata* (Tansley, 'Lectures,' p. 44). There is, however, reason to think that the first named owe their simplicity of structure to reduction in connexion with their xerophilous habit, and that *G. flabellata* may be regarded as a central and primitive example. It has a solid protostele, which gives off to each leaf a C-shaped trace, with a pocket of internal phloem, endodermis, and sclerenchyma, which is continued into the stele, but does not intrude far. *G. pectinata* is, however, a solenostelic form, which shows certain complications noted by Boodle and Hiley ('Ann. of Bot.', xxiii, p. 419). From the known facts it seems still uncertain what the exact steps were which led to the solenostelic structure there presented. This, however, is not the present question. What interests us is that, however produced, the solenostely exists in *G. pectinata* with a centrally placed sclerenchymatous pith, surrounded by endodermis and internal phloem. The internodes are long, so that the solenostelic structure is only interrupted by leaf-gaps at long intervals. Passing to *Lophosoria* the solenostelic structure is essentially the same as in *G. pectinata*, but the whole axis is on a more bulky scale. Though in the young plant of *Lophosoria* the sclerenchyma within the solenostele is at first solid, as in *G. pectinata*, in the older plant a parenchymatous core replaces the central region of that sclerenchyma, the remainder of which appears as a dark shell lining the solenostele internally, as is usual in the Cyatheaceae. The latter shows the usual amphiphloic structure, but there is no marked protoxylem: in this it differs from *G. pectinata*, but it shows a condition

which is common in the Cyatheaceae. The internodes are longest in the creeping lateral buds of *Lophosoria*, while in the upright shoots the leaf-gaps sometimes overlap, giving an elementary state of dictyostely. This is exactly what would result if a shoot of the type of *G. pectinata* were to adopt an erect habit. The leaves themselves, being of necessity mechanically self-supporting, must have relatively broad bases of insertion. The axis would necessarily be shortened, and become more bulky to accommodate the more crowded and relatively broad bases of the leaves. That condition is already seen in *Lophosoria*, but the leaf-gaps do not usually overlap. But they do overlap in the typical species of *Alsophila*, which are thus dictyostelic. *Lophosoria* forms accordingly, in the vascular characters of its axis, an intermediate step between the two types, as it does also in habit, and in other features.

The leaf-trace of *Lophosoria* comes off as a single broad strap, and often passes undivided up the leaf. But where the leaf is large it commonly divides up into three parts, though this separate course does not continue far, the three joining again into a single strand below the lowest pinnae. A very similar condition is seen in *Plagiogyria semicordata* ('Ann. of Bot.', xxiv, p. 431), and in some other Ferns. Such cases have their interesting bearing upon general views of the leaf and the relative primitiveness of its parts, a subject which will be held over for the present. From the comparative point of view *Lophosoria* in this detail again takes a middle place between *Gleichenia*, in which no such partition of the trace has been recorded, and the Cyatheaceae, where the dissolution of the trace into separate strands is present in much higher degree, and extends much further along the leaf than in *Lophosoria*. Further, in the horseshoe form of the trace, with its deep lateral depressions, as well as in the origin of the pinna-trace, *Lophosoria* also takes an intermediate place, but with a decided leaning to the Cyatheaceae. This comes out particularly in the large number of the 'divergents', and in the corrugation of the trace in accordance with their position. Thus the general conclusion from an anatomical comparison is that while the affinities of *Lophosoria* are distinctly with the Cyatheaceae, it shows in a number of anatomical features, which may themselves be held as primitive, a condition intermediate between that family and the Gleicheniaceae type. And among the latter it approaches most nearly to *G. pectinata*.

5. But it is upon the characters of the sorus, its position and its constitution, that the most frequent comparisons have been made. In the Gleicheniaceae, as in the Cyatheaceae, the venation of the fertile pinnule is without any fusions, except occasionally in *Hemitelia*. The veins fork, but not very profusely, and the branches run out free to the leaf-margin. In fact, in both the venation is of the primitive, Pecopterid type. In *Lophosoria*, as also in *G. linearis* and *pectinata*, the sorus is constantly seated upon the anadromic veinlet of the ultimate pinnule. This uniformity in position, com-

bined with the similarity of circular form, the absence of any indusium, the approximate uniformity in number of the sporangia, the simultaneity of their origin, and the likeness of their relation to the slightly raised receptacle, are characters that at once establish a sound basis of comparison between the plants named. Moreover, the two species of *Gleichenia* stand out from their genus in the arrangement of their sporangia in the sorus. There is little doubt that the 'radiate uniseriate' type of sorus, as it is seen in *G. flabellata*, is a primitive one—comparing as it does with what is seen in the Marattiaceae on the one hand, and in *Matonia* on the other. Here the centre of the sorus is unoccupied by sporangia. But *G. linearis* has the centre of the sorus occupied by one or more sporangia, while in *G. pectinata* it is habitually crowded with them, so that they are flattened against one another. The constitution of the sorus of *Lophosoria* is very like these, while in point of time of origin of the sporangia those of each sorus are in both cases simultaneous. Both belong technically to the Simplices, while *Lophosoria* is the only case hitherto recorded of this from the Cyatheaceae, which are typically Gradatae.

6. Turning to the sporangia themselves, both the Gleicheniaceae and Cyatheaceae have an oblique annulus, but they differ in that the dehiscence in the former is in the median plane and distal, while in the latter it is lateral. It has been pointed out above (p. 275) that *G. pectinata* with its median dehiscence, which requires lateral space to be effective, has in its crowded sorus reached fully to the limit of possible efficiency. A modification of its type of sorus or of its sporangium is necessary if any larger number of sporangia is to be accommodated, and each is still capable of dehiscence. One modification would be the adoption of a lateral dehiscence. Another would be an elongation of the receptacle. The best result would be by a combination of both. In *Lophosoria* the lateral dehiscence is adopted, but not the elongation of the receptacle. In the rest of the Cyatheaceae both modifications are carried into effect, together with a basipetal sequence of sporangia, which the elongation of the receptacle makes possible. A circumstance which is an indirect support of the view that the sorus of *Lophosoria* is a modification of the Gleicheniaceae type is that, though all the sporangia are simultaneous, the lower sporangia retain the orientation seen in *Gleichenia*. This orientation is of no practical importance where the sporangia are all simultaneous in origin, and the dehiscence is lateral. It may be held as one of those useless survivals which are on that account all the more cogent as phyletic evidence.

From the above considerations it would appear probable that, in the production of *Lophosoria* from some Gleicheniaceae source, a phyletic shifting of the point of dehiscence of the sporangium from the distal to a lateral position has taken place. This suggestion is supported by the fact that the stomium of *Lophosoria* is not highly differentiated, while there is inconstancy in the numbers and relations of the cells which compose it.

In this respect it shows a marked difference from other Cyatheaceae, in which the stomium shows a high degree of differentiation. In point of size also, and in the number of tabular cells forming its lateral walls, the sporangium of *Lophosoria* corresponds rather to the Gleicheniaceae than to the Cyatheaceae. But in the spore-output it is otherwise. The number per sporangium in the Gleicheniaceae is large. In *Lophosoria* it is only 64, a number which tallies with that of *Alsophila* and *Cyathea medullaris*, though that in *C. dealbata* is much lower. Taking all these soral characters together it seems clear that *Lophosoria* holds a very interesting middle position between the Gleicheniaceae and Cyatheaceae, and the characters are such as accord with the view that its sorus and sporangium were originally of the Gleicheniaceous type; but that while the plant has retained the sorus of the Simplices, it has parted with the primitive mode of dehiscence, and the originally large spore output of the individual sporangium is here represented on a greatly reduced scale.

7. The details of the prothallus and sexual organs of *Lophosoria* being still deficient, comparison on these points must be deferred.

OTHER GENERA OF FERNS WITH SUPERFICIAL SORI AND BASAL INDUSIUM.

There are a number of genera of Ferns, containing each relatively few species, individually of moderate or small size, which share with the Cyatheaceae the possession of a superficial sorus with a basal indusium; some of these prove even to have also like them a basipetal sequence of origin of their sporangia upon the receptacle. They have been ranked by various systematists as related to the Cyatheaceae, and they are placed by Diels immediately after them (Engler u. Prantl, 'Nat. Pflanzenfam.', i. 4, p. 159). They are as follows: *Struthiopteris* and *Onoclea*, *Peranema* and *Diacalpe*, *Woodsia* and *Hypoderris*, *Cystopteris* and *Acrophorus*. Their characters show that these genera are naturally grouped together in pairs, as above, each of these being more nearly related to one another than the pairs themselves are *inter se*. In order to arrive at some conclusion as to the phyletic relations of these pairs of genera to the Cyatheaceae, and to one another, comparisons must be instituted so far as possible on the basis of those criteria which have been employed above. None of these Ferns, however, are essentially primitive types. This is indicated by the fact that they all show a more or less advanced state of dictyostely in the stock, in some cases with the peculiar basket-like structure owing to deep involutions of the superficial tissues. Their leaf-trace is divided, but not usually in an advanced degree. The venation is in most cases open, but in *Onoclea* and *Hypoderris* it is reticulate. Broad scales are common, in place of or in addition to the more primitive hairs. Some of them have a mixed sorus, while the sporangia usually have the annulus interrupted at

the insertion of the stalk. The sum of these characters indicates that we are dealing with Ferns of a middle position in the phyletic scale, a fact which makes the question of their suggested relation to the Cyatheaceous series all the more interesting. It will be convenient to take first the genera *Struthiopteris* and *Onoclea*, for they have for long been regarded as having some near relation to the Cyatheaceae.

Struthiopteris and Onoclea.

The genus *Struthiopteris* (= *Matteuccia*) includes two species, *S. germanica* and *S. orientalis*, which have obliquely ascending or upright stocks covered with the bases of the closely grouped leaves, and *Onoclea* with its single species, *O. sensibilis*, L., having a creeping rhizome bearing isolated leaves.¹ Of these three species *Struthiopteris orientalis* is the least familiar. It shares the leading characters of them all. It will be briefly described here, from observations made partly on plants obtained from India through the Calcutta garden, and my thanks are due to the Director for them; partly from plants living in the Glasgow Botanic Garden, originally obtained from Messrs. May of Edmonton. The points in which this Fern differs from the other two better known species will be noted as they arise.

S. orientalis is a rather coarse-growing Fern, which may attain about the same dimensions as *S. germanica*. It has an obliquely ascending, or upright stock, which is completely covered by the bases of the densely tufted leaves. There were no runners on any of the plants examined, such as are a conspicuous feature in *S. germanica*. The leaf-bases are enlarged as they are in the other species, and in *Plagiogyria*, while they bear rough brownish, rounded outgrowths, mostly along their margins, in appearance like the pneumatophores of that Fern. The leaf-bases and stalks are thickly covered by broad, brown, chaffy scales. The simply pinnate leaves are dimorphic, the broad pinnae of the sterile leaves being deeply pinnatifid, and showing the Pecopterid venation without any anastomoses (cf. Engler u. Prantl, i. 4, Fig. 90 B, of *S. germanica*, which it strongly resembles). But in *Onoclea* the venation is reticulate, a condition which is held to be one of phyletic advance. Frequent middle forms occur between the sterile and fertile leaves. The latter are also simply pinnate, but the segments are narrow, and their margins strongly turned downwards so as to protect the sori, just as in *Blechnum capense*, L., a plant which this species closely resembles.²

The massive stock is solid, and does not show that basket-like structure, due to deep pockets immediately above the insertion of the leaves, described by Gwynne-Vaughan for *S. germanica*, and in less degree for *Onoclea sensibilis* ('New Phyt.', vol. iv, p. 211). It is traversed by a dictyostele

¹ Dichotomy of the axis may be observed in *O. sensibilis*.

² It may be remarked that several species now placed in the genus *Blechnum* have from time to time been ranked in the genus *Struthiopteris*, a clear evidence of the similarity which the genera bear to one another. The significance of this will appear in a subsequent paper of this series.

with proportionately large meshes, from the lower margins of which are given off two large strap-shaped strands to the subtending leaf. There is a central pith which is very voluminous in proportion to the other tissues, so that the ring of meristeles lies very near to the periphery. It is to be noted that sclerenchyma is absent from it, in marked contrast to what is seen in the Cyatheaceae. In fact, the structure of the stock is strikingly similar to that of those species of *Nephrodium* which have a binary leaf-trace, such as *N. Oreopteris*.

The general character of the fertile leaf of *S. orientalis* resembles that of *S. germanica* and *Onoclea sensibilis*. The venation of the fertile pinna is on the same plan as that of the sterile pinna, but the branches of each vein from the midrib are only 5-6 as against 10-12 in the sterile. Anastomoses are again entirely absent in *S. orientalis*. The lowest branch of each vein is katadromic (Pl. XXXVI, Fig. 36). Each branch may bear a single sorus, as in *S. germanica*, but whereas there the sori of the lower branches are slightly nearer to the midrib than those of the upper, in *S. orientalis* they are all at an equal distance, so as to constitute a regular intra-marginal row. This will be found to be matched by *Blechnum capense* (see Mettenius, 'Filices Horti Lipsiensis,' Pl. IV, Fig. 21). Each vein is continued a short distance beyond the insertion of the sorus, but stops short where the margin of the pinna curves over as a continuous protective flap, which in this species is firm, and coloured brown. In addition to this protection each sorus is, as in *S. germanica* and *Onoclea*, covered by a shell-shaped indusium, attached at the side next the midrib. It is structurally of the nature of a ramentum or scale. A section through a sorus from one of Messrs. May's plants shows how the leaf-margin overlaps the scale indusium, the protection of the sorus being a very efficient one (Fig. 37). But in the specimens from India the indusium does not appear to be present.

The receptacle in *S. orientalis*, as seen in specimens from the Glasgow Garden, is a rather flat one, being hardly raised beyond the general level of the leaf-surface (Fig. 37). A tract of tracheides rising from the vascular strand which underlies it brings supplies to the sporangia. These are relatively few in number, as seen in the Glasgow specimens; but in the normally grown specimens from India the sori are larger, the receptacle more raised, and the sporangia more numerous. There is an evident basipetal succession of the sporangia, as has already been demonstrated for *Onoclea sensibilis* and *S. germanica* (Studies, IV, Pl. V, Fig. 90). This is apparent even from the drawings from garden plants, for the central sporangium at the apex of the convex receptacle is the most advanced, and the lateral sporangia younger.¹

¹ The absence of an indusium in the specimens from India, together with the much larger receptacle and more numerous sporangia, suggests further inquiry as to specific identity of the specimens. The Glasgow plants correspond most nearly to the specific descriptions for *Struthiopteris orientalis*.

The mature sporangium of *Struthiopteris orientalis* is long-stalked, and it is specially worthy of note that in the Indian specimens a glandular hair is, as a rule, attached to the stalk of each. This corresponds in character and position to the gland which accompanies the sporangium of *Nephrodium filix-mas*. These glands are absent in *S. germanica* and most of the other related Ferns. The annulus is nearly vertical, and it is interrupted at the stalk, being in this point similar to what has been shown for *S. germanica* (Studies, V, Fig. 91). It consists of about fifty cells, a larger number than is shown in *S. germanica*. It is to be noted that frequent cases occur where the series of cells of the ring is irregular, taking sometimes a zigzag or contorted course in place of the usual regular hoop-like series. Such irregularities may be expected in those forms where a transition between the oblique and the vertical annulus is in progress, according to our general hypothesis. It is in such Ferns that these irregularities have been observed.

The characters of *Struthiopteris orientalis* thus described correspond in essentials with those of *S. germanica* and *O. sensibilis*. The differences are in details, and there is no doubt of the naturalness of the group. But in *O. sensibilis* the venation is the most advanced, being reticulate, while in the rest it is an open, Pecopterid venation. The Onocleae appear to be nearly related on grounds of habit, of venation, of anatomy, and of sorus to the Cyathea, and probably *Struthiopteris*, with its upright habit and open venation, is the nearest. These Ferns have, however, adopted the dimorphic frond, though the existence of middle forms in both genera shows that the distinction has not been definitely impressed. The fertile leaf has rolled up its margin, as in *Plagiogyria* and the Pterideae, for the better protection of the sori. These, however, are all distinct, and have the *Hemitelia*-like indusium present in addition. This, with the gradate, superficial character of the sorus, stamps the relationship with the Cyatheoid Ferns. They may be held to be a series which has carried the Cyatheoid type into boreal and alpine climates, where additional protection is required. Further, *Onoclea* shows in its reversion to the creeping habit, and all of them in their deciduous foliage, evidence that they are the outstanding colonists of the family which have become modified in order to meet the conditions of the habitats to which they have spread.

Cystopteris, Bernh.

This genus was founded by Bernhardt in 1806, and includes thirteen species. Presl ('Tentamen', p. 93) recognized its affinity with *Aspidium* and *Asplenium*, and placed it in close juxtaposition with *Acrophorus* in his Aspleniaceae. Hooker ('Syn. Filic.', p. 103) places it between *Davallia* and *Lindsaya*, but remarks that it is 'allied to *Woodsia* and *Microlepia*'. Diels (Engler u. Prantl, i. 4, p. 163) places it in his 'Woodsiinae', in close

relation to *Acrophorus*. Christ ('Farnkräuter', p. 280) ranks it next to *Woodsia*. Influenced by the example of Sir W. Hooker, and after insufficient personal observations, I had in 1899 assented to the relation with *Davallia*, § *Leucostegia* (Studies, IV, p. 76, and 'Land Flora', p. 655). It will now be shown, on the basis of wider comparisons, that the relation is rather with *Struthiopteris* and other Ferns which have a superficial sorus, basal indusium, and a basipetal succession of sporangia.

The anatomy of the stock of *Cystopteris fragilis* has been examined by Gwynne-Vaughan, who found it to have, like *Struthiopteris*, a dictyostelic structure. The leaf-trace also consists of two vascular strands which arise separately from the dictyostele ('New Phytologist', vol. iv, p. 215). He remarks, with regard to the peculiar involutions above the insertion of the leaves, that its stem furnishes almost as good an example of the development of epidermal pockets as *Struthiopteris* (*Onoclea*) *germanica* itself, although the whole structure is on a smaller scale. Thus there is a substantial anatomical similarity with the stock of *Struthiopteris*. If the pockets be left out of account the structure corresponds also with that of *Woodsia*; though in *Cystopteris* the meristeles are smaller and further apart, the disposition of them is essentially the same.¹

Sections of the young sorus of *Cystopteris* show conditions resembling those of *Struthiopteris*, but on a reduced scale, and modified in relation to the flattening of the receptacle under an indusium which lies parallel to the leaf-surface. The formation of the sorus begins slightly back from the apex of the leaf-lobe, as an upgrowth subtended below by the scale-like indusium. The first sporangium, which Schlumberger (l. c., p. 408) describes as being prior to the indusium, appears with regularity on the middle of the convexity (Fig. 38, *a*), several large cells intervening between it and the insertion of the indusium. Transverse sections show that the first sporangium occupies also a median position in relation to the indusium (Fig. 38, *b*); in fact, it occupies the apex of the small flattened receptacle. A comparison may be made with what has been seen in *Struthiopteris* (Fig. 37). Later other sporangia appear right and left (Fig. 39), while the cells which intervene between them and the base of the indusium give rise also to a regular gradate succession in basipetal sequence (Fig. 40). A comparison of the latter drawing with Fig. 90 of my Studies, IV, shows how similar this condition of the sorus is to that of *Onoclea sensibilis*. A comparison with *S. orientalis* also shows correspondence, due allowance being made for the relatively small number of sporangia shown in the garden-grown specimens on which the observations were made. But whereas in these Ferns the

¹ This account does not accord with that of O. Schlumberger (Flora, 1911, p. 410), who states that only a single strand enters each leaf. His observations seem to have been made on a young plant ('Keimpflanze'), and it may be true for the first leaves; but the leaves of mature plants are supplied by two distinct strands, as in *Struthiopteris* and in *Woodsia*. This is already recorded by Luerssen (Rab. Krypt.-Fl., iii, p. 447.)

receptacle rises symmetrically from the leaf-surface, here it is compressed below the indusium, and develops its basipetal sequence as a rule only on the side away from the leaf-surface. None the less is it a gradate sorus, and, contrary to my statement of 1899 (l. c., p. 76) (which was made from old sori), irregularly intermixed stages of sporangia have not been observed in the young state. The segmentation of the sporangia is also a matter for note. It will be seen that the stalk is a relatively massive one with irregularly inclined walls (Fig. 38, *b*). This corresponds closely with what is seen in *Onoclea sensibilis*, and with the Cyatheoid series, and is in sharp contrast to the simple transverse segmentation of the stalk seen in *Davallia* (Studies, IV, Figs. 134, 135). In form the mature sporangia of *Cystopteris* correspond to those of *Struthiopteris* in having their annulus continued to the stalk, but there interrupted; while the stalk itself is relatively massive, and consists of three rows of cells. But the number of cells of the annulus is smaller than in *Struthiopteris*, being only about thirty. The conclusion is, then, that sorally *Cystopteris* is in near relation to *Onoclea* and *Struthiopteris*, and is essentially of the Gradate type; while the characters of anatomy and of habit support the alliance with the Cyatheoids, and especially with certain of their derivatives. Schlumberger, however, considers that the facts of development of the sorus indicate a relationship of *Cystopteris* to the Davallieae ('Flora', 1911, p. 408), rather than with the Cyatheoid series. This opinion I do not share, preferring to regard the peculiarities of the sorus as a consequence of a flattening of the receptacle between the indusium and the leaf-surface, together with an absence of the sporangia on the side of it next to the leaf-surface.

The characters of the prothallus of *Cystopteris*, as described by Schlumberger (l. c., p. 386), are of some importance in considering the relation of the genus to the other Ferns mentioned above. The hairs which it bears are only unicellular glandular hairs, as in the 'Polypodiaceae', not multicellular as in the Cyatheaceae. Further, the lid-cell of the antheridium is undivided, which is again a Polypodiaceous as against a Cyatheoid feature. These characters, together with the flattened type of the sorus above alluded to, accentuate the aloofness of the genus. But its gradate sorus and its anatomy and habit all indicate a relationship to the Ferns with a basal indusium. It may be held to occupy a middle position linking the Woodsieae, especially *Struthiopteris*, with the Aspidieae.

Acrophorus, Presl.

This genus was founded by Presl in 1836, to receive the single species now designated *A. stipellatus*, (Wall.) Moore. It was placed by him in close relation with *Cystopteris*: but the species had previously been styled *Aspidium nodosum* by Blume. Sir Wm. Hooker merged it in *Davallia*, but evidently with some doubt, as it stands in the 'Species Filicum', vol. i, p. 157, under

the name *D. (?) nodosa*, Hook. In the 'Synopsis Filicum', however, the query is dropped, and it appears (p. 92) as *Davallia (Leucostegia) nodosa*, Hk. Diels (Engler u. Prantl, i. 4, p. 164) upholds its generic distinctness, and names it *Acrophorus nodosus*, (Bl.) Presl, giving it a place in close relation to *Cystopteris*. Christ (Farnkräuter, p. 285) also upholds the genus, but places it in near relation to *Struthiopteris*.

It is clear from these diverse opinions that this isolated species shows characters apparently in common with two widely different affinities, both characterized by superficial sori, protected by an indusial structure attached on the side of it nearest the midrib. The *Davallia*-type is, however, a derivative of the Dicksonioid stock, with marginal sori, while the affinities of *Cystopteris* and *Struthiopteris*, as long recognized and as specially indicated on the widened basis of comparison in the above pages, are with the Cyatheoid stock with superficial sori. The former approaches the latter in appearance by a gradual phyletic shifting of the sorus from the margin to the surface of the leaf, a process clearly indicated by the comparative study of *Davallia*. Consequently the position of the sorus, supported merely by the comparison of habit, will not serve to determine the true affinity in any critical case. A careful examination of the anatomy, the superficial appendages, and especially of the structure and development of the sorus and sporangia will be required for a decision in any given example.

This seems specially necessary in the case of *Acrophorus*, and in the absence of material for detailed study I am not prepared to express an opinion whether its relation is truly with *Cystopteris* or with *Davallia*. There is, however, one feature which seems to make the former affinity doubtful. In all the Gleicheniaceae and Cyatheaceae, as well as in the other allied genera with basal indusium, the sorus is seated on a vascular strand, which is continued beyond its insertion. In *Acrophorus*, as its very name implies, the vascular strand stops at the sorus, which is described as being on its tip. This is the usual, though not invariable character of Ferns with marginal sori (Hymenophyllaceae, Dicksonieae, &c.), and is mostly retained, at least in cases with relatively simple venation, even where the sorus has become superficial. This fact appears to strengthen the Davallioid alliance of *Acrophorus*, but no definite expression of opinion on the point is here given.

This is an example of many like questions which must necessarily arise in the phyletic treatment of the more advanced Ferns; for they, perhaps as frequently as any well-represented group of plants, show converging lines of specialization. So that the most advanced representatives of stocks quite distinct in origin assimilate closely to one another, and can only be disentangled by minute comparative study, bringing all possible criteria which may serve to guide a final decision.

Peranema and *Diacalpe*.

I have left the detailed examination of these genera to Mr. Davie, whose paper on these Ferns precedes this (p. 245 above). I would merely remark here that the position which has been assigned to them at the base of the Aspidieae appears to be justified on the ground of their dictyostelic structure, divided leaf-trace, open venation, abundant chaffy scales, mixed sorus, with indusium of the nature of a highly modified scale covering the vascular receptacle. Lastly, the sporangia have an annulus, at least partially interrupted at the insertion of the stalk, but showing some indications of obliquity. These features, combined with the general habit of each, so like that of certain types of *Nephrodium*, indicate a relationship which has been already recognized on less extended grounds of observation by various writers, and specially by Christ (Farnkräuter, p. 286, and preface, p. vii).

On the other hand, the character of their sorus has from their first description been held to relate the Ferns to the Cyatheaceae, and this view is stereotyped in the name *Peranema cyatheoides*, D. Don. Though the detail of the correspondence now proves not to be so close as it was earlier thought to be, still there is sufficient indication that it is in the neighbourhood of the Cyatheaceae that their natural place is to be found. This follows from the position and general character of the sorus, and especially of the indusium; from the vascular receptacle, and from the indications of a basipetal sequence in *Peranema* in the appearance of the sporangia, as described by Mr. Davie. But perhaps the most convincing evidence of a Cyatheoid affinity lies in those characters of the gametophyte which have recently been described for *Diacalpe* by Schlumberger ('Flora', 1911, p. 385). In the first place, hairs of the Cyatheoid type are present upon its prothallus, while further, the lid-cell of the antheridium is divided as it is in the Cyatheaceae, but not in the 'Polypodiaceae'. These indications, in characters which are apparently isolated and not of any great biological importance, may on that account be held to be all the more important as evidence of the Cyatheoid affinity.

Woodsia, R. Br.

This genus was founded by Robert Brown in 1815, and now includes twenty-five species, which mostly inhabit cold or temperate zones of the Northern Hemisphere, and are of small size. The axis is short and ascending, the leaves show an open Pecopterid venation, and the shoot bears superficial scales, which are a specially prominent feature in *W. polystichoides*, var. *Veitchii*. Supplies of this Fern were given from the Edinburgh Botanic Garden. The superficial sori have a basal indusium, which is often reduced to mere hairs united at their base to form a Cyatheoid cup. The details of the indusium are, however, variable in different species.

The anatomy of the stock is on the same plan as in the preceding genera. It is traversed by a dictyostele. In *W. polystichoides* the foliar gaps are relatively narrow, and from the lower region of each two leaf-trace strands arise.¹ A distinct involution of the outer surface is found just above the insertion of each leaf, similar to those in *Struthiopteris*, *Onoclea*, and *Cystopteris*.

The leaves are densely covered with broad chaffy scales; these almost hide the sori, which form regular series near the margin. Vertical sections through them show that, as in other Ferns of this relationship, the vein does not terminate in the receptacle, but may pursue a further course towards the leaf-margin. This may be quite clearly seen in sections of *Woodsia obtusa*. It is a point of difference from *Acrophorus*. The receptacle itself is only slightly raised above the leaf-surface, and from its base springs the indusium; this consists of usually four overlapping scales, which may be separate down to their very base. They are similar in structure and origin to the protective scales of the leaf-surface. Upon the receptacle the sporangia are seated. They are not numerous. Such evidence as is available goes to show that the sorus is essentially a gradate one. This conclusion coincides with the observations of Schlumberger ('Flora', 1911, p. 407, Fig. 13) on *W. ilvensis* and *W. obtusa*; for though he makes no mention in his text of the order of succession of the sporangia, his drawings show the centrally lying sporangia as the earliest and the most advanced, while the peripheral are the lower and smaller. This is also indicated by Fig. 42, which represents a drawing of the sorus of *Woodsia ilvensis* in surface view, kindly sent me by Prof. Goebel.

In my Studies, IV, p. 59, the statements as to the condition of the sorus in the genus were rather indefinite. It was stated that 'some species (*W. mollis*, J. Sm.) suggest that the central sporangia mature first, and the peripheral ones later, but this is not borne out by *W. obtusa*, Torrey, from the Edinburgh Garden'. And in a later passage the sorus of the genus was held to be a 'mixed' one. Examination of a large number of sections from *Woodsia obtusa*, of which additional material was obtained from the Edinburgh Botanic Garden, has convinced me that the sorus of that species is a gradate one. No interpolation of sporangia has been seen. But the receptacle is not raised far beyond the general leaf-surface, and the basipetal sequence of sporangia is very short (Fig. 41). It thus appears that my earlier statements with regard to this genus were incorrect, being based on insufficient observation. The sorus is probably a gradate one throughout the genus. The sporangia themselves show no special point of interest, and have the usual structure of stalk, with three rows of cells.

Observations have lately been made by Schlumberger on the prothalli

¹ See Schlumberger, *Flora*, 1911, p. 409, and Fig. 14, where the vascular skeletons of *W. ilvensis* and *obtusa* are described. Compare also Luerksen, *Rab. Krypt.-Fl.*, vol. iii, p. 498.

of *Woodsia*, which bring forward some welcome characters for comparison from the gametophyte generation. In particular he draws attention (l. c., p. 385) to the characteristic multicellular hairs on the under side of the cushion in the Cyatheaceae, and shows that similar hairs are present in *Diacalpe*, and also in *Woodsia*. A still more interesting point is that the antheridia both of *Woodsia* and of *Diacalpe* have a divided lid-cell, which is the condition shown by the Cyatheaceae, while the 'Polypodiaceae' have the lid-cell undivided. When these separate and apparently immaterial features of correspondence are put in relation to the characters of the sporophyte, which also indicate a Cyatheoid affinity for these Ferns, the evidence of such a relation appears to be very strong indeed. *Woodsia* may in fact be held to be a boreal and alpine type, derived from, but closely connected with, the Cyatheoid stock. In relation to its less favourable habitat we may note the small size of the plants themselves, and the small number of sporangia in the sorus. The latter fact carries with it the flattened receptacle. But still the basipetal sequence characteristic of the Cyatheaceae is retained.

Hypoderris, R. Br.

Hypoderris is a genus founded by Robert Brown in 1830. Mettenius included it in the genus *Woodsia* ('Fil. Hort. Lips.', 1856, p. 98), from which it is, however, properly separated by its habit, and by the copious anastomosis of the veins. It is represented by three species, of which the best known is *H. Brownii*, J. Sm., a Fern which grows upon damp and shaded rocks in the Antilles. The rhizome is creeping, and bears solitary leaves right and left, while leaves and axis are invested by soft brown scales. The leaf is broadly lanceolate, with two lateral lobes at its base, which are variable in their proportion to the central lobe. The venation is reticulate, and the numerous sori, with basal indusium, are 'inserted in lines or series parallel with the primary veins upon the confluent angles of the reticulate veinlets' (Hooker, 'Sp. Fil.', vol. i, p. 57). The general habit and appearance resembles that of *Aspidium trifoliatum*, while a comparison may also be drawn as regards habit with another shade-loving Fern, viz. *Kaulfussia oesculifolia*. As in the latter Fern, the sori of *Hypoderris* show frequent and various examples of fission (compare 'Land Flora', Fig. 281).

The vascular system of the rhizome of *Hypoderris* has been examined by Schlumberger ('Flora', 1911, p. 409, and Fig. 14, 5). He found that it is traversed by a dictyostele, with large leaf-gaps and additional 'perforations'. Four vascular strands pass from each leaf-base to the subtending foliar gap, while the upper and under strands between the laterally placed leaf-gaps show wide-meshed perforations. But Schlumberger's account leaves open the relation between the four-stranded leaf-trace of *Hypoderris* and the two-stranded trace of related Ferns. I have examined the vascular system

of *Hypoderris* in material kindly supplied to me by Professor Goebel. Tangential sections of the leaf-base make it clear that the two larger strands, which are inserted higher up upon the foliar gap, represent the margins of the trace as seen in *Woodsia* or *Struthiopteris*, for they show the hooked xylems characteristic of that position. The strands inserted lower down upon the foliar gap represent the more median portions of the trace. In fact, each pair of strands right and left is representative of one of the two strands of *Woodsia*, which has become divided, and its two parts have in *Hypoderris* widely diverged. This condition, which is an advanced one, harmonizes on the one hand with the stele of the axis, with its numerous 'perforations'; and on the other it occurs together with the profuse reticulation of the veining of the lamina. In all these respects *Hypoderris* shows evidence of phyletic advance on the related genera, an advance which is also matched by the condition of its sori.

An analysis of the sorus of *Hypoderris* was published by Sir W. Hooker in his 'Genera Filicum' in 1842, Tab. I. The drawings show its characters, with the cup-like basal indusium surrounding a dense mass of sporangia. Individually the sporangia are of small size, and long-stalked. A feature which is clearly brought out by the drawings 3 and 4 of his Plate is that the sporangia of different sizes are intermixed without order, a fact which has since been frequently ignored.

The sorus of *Hypoderris* is seated with a flat receptacle upon a vein of the reticulum which is so marked a feature of the leaf in this genus. The position of the sorus relative to the vein-endings is variable. Commonly it is seated upon an arch of the reticulum. At other times it may be seated upon a twig of the reticulum, which is not terminated at the receptacle. Occasionally, however, the vein appears to end below the receptacle. But the common rule appears to be that the vein does not terminate in the receptacle of the sorus. At first the receptacle is almost even with the general surface of the leaf, and it is never much raised above it. It is shielded by the cup-like indusium before the sporangia appear. These arise sporadically, and without any obvious order, upon the receptacular surface. But as fresh sporangia continue to arise, the sorus becomes crowded. The heads of those sporangia which mature first break away from the stalk just below the capsule, leaving the lower part of their stalks as a protection to the sporangia which follow. A section through an old sorus shows accordingly a crowded condition quite similar to that of certain *Mixtae* of quite different affinity from *Hypoderris*.

The sporangia themselves are relatively small and long-stalked. Vertical sections through the sorus show that the stalks are not of uniform structure, and when the sorus is cut transversely the sections of the stalks may show three cells, or only two, or one (Fig. 43). A comparison of young developmental stages of sporangia shows that this is connected with

the initial segmentation. Three different types of segmentation are illustrated in Fig. 44, *a, b, c*. In *c* there is a relatively massive stalk, such as might be found in any of the related genera above described. But in *b* the whole sporangium is more attenuated, while at the very base of the stalk it consists of a single cell-row with transverse segmentation. In *a* this condition is still more pronounced, and doubtless the three sporangia of Fig. 44 would correspond roughly in stalk-structure to the three sections shown in Fig. 43. But the condition does not appear to be uniform throughout the length of the stalk of any given sporangium; thus in Fig. 44, *b*, the stalk would consist at its base of a single cell-row, and in its upper parts of two or even three rows. Examination of sporangia dissected out separately from a sorus show that this is actually the case, one or two of the cell-rows stopping short before the base of the stalk is reached. In fact, the condition is closely similar to that shown by Müller's drawings of *Asplenium trichomanes*, quoted by Engler u. Prantl, i, 4, p. 81, Fig. 57.

The sporangium itself is of relatively small size. The annulus is indurated on one side of the sporangium right down to the insertion of the stalk, but there interrupted. On the other side is the stomium, composed of the usual group of four cells. Attached to the stalk of most sporangia is a hair, which often shows a glandular terminal head, similar to what is seen in *Nephrodium*. This fact acquires greater point when it is remembered how like *Hypoderris* is in habit to *Aspidium trifoliatum*.

The interest of the facts thus related for *Hypoderris* lies in the comparison of like conditions in other Ferns. No one has doubted that the natural place of *Hypoderris* is with *Woodsia*, and in less near relation with other Ferns with a basal indusium. But it stands apart from them in its relatively disintegrated vascular system of stock and petiole; its broad leaves with reticulate venation; in its mixed sorus, and reduced type of sporangium. The progression has been parallel along these distinct lines of character, and the changes from type thus shown here in an isolated genus of a well-defined affinity are matched very closely by similar progressions in other types of Ferns believed to be phyletically distinct. The more frequently such parallel progressions are traced the greater is the confidence in believing them to be indications of true phyletic advance. But the question why they should run so strictly parallel remains awaiting its full physiological explanation. As to *Hypoderris* itself, it may be held to be a member of the *Woodsia* affinity, modified as a tropical shade-form. The broad reticulate leaf follows on this habit; but not so clearly the disintegration of the stele, or the mixed character of the sorus. The reduction seen in the sporangium is, however, to be related with the continued production of sporangia in the mixed sorus.

Discussion of the Phyletic Relations of the Ferns described above.

Comparison has now been made between *Lophosoria* and those Ferns with which its relationship has habitually been recognized by earlier writers in respect of various leading characters, external and internal. The result has been in the first place to confirm on every count the recognition of its place at the base of the Cyatheaceous series, while the newly acquired facts have materially strengthened the relation of these Ferns with the Gleicheniaceae. It is not necessarily to be concluded that any present Cyatheaceae were directly derived from any Gleicheniaceae ancestors such as we now see them. What is concluded is that a stock of Ferns with the creeping habit, vascular structure, and soral characters essentially like those of the living Gleicheniaceae gave rise on the one hand to the Gleicheniaceae themselves, and on the other to the Cyatheaceae.

Among the living species of *Gleichenia*, we have concluded that *G. flabellata* represents a central type, with its protostelic creeping axis, its deeply pinnate *Mertensia*-type of leaf, and its superficial, uniseriate sorus, of few, laxly-grouped sporangia, each with a large spore-output. A line of xerophytic specialization resulted in the *Eu-Gleichenia* section of the genus, still with protostelic axis, and with sorus of the same type, but with the ultimate pinnules much smaller, like shells concave downwards, protecting the sori. There is, moreover, a profuse protection of the young stems and leaves by scales, shared in less degree by *G. flabellata*; this is probably a further sign of xerophytic adaptation.

But another line of specialization was without these xerophytic signs, while it retains the more extended pinnule, and shows only hairs and no scales as dermal coverings. It is represented by *G. linearis* and *G. pectinata*. The former is anatomically and sorally the nearer to the central *Mertensia*-type. But *G. pectinata* shows complete solenostely, while it has been pointed out that its sorus had reached the practicable limit of elaboration, so long as the receptacle remains short, and the sporangium retains the distal dehiscence in a median plane. This circumstance probably blocked further progress of an otherwise successful line; in fact, *G. pectinata* may be held to represent the ultimate realization of its own type. On this view, then, the Gleicheniaceae in their modern developments represent a blind evolutionary branch.

But either an extension of the receptacle or a lateral dehiscence of the sporangium, or better, a combination of both these factors, would make further advance possible.¹ The latter only is realized in *Lophosoria*, but both are combined in the typical Cyatheaceae. All these Ferns have, however, the same position and general type of sorus as the Gleicheniaceae,

¹ A third possible factor would be an enlargement of area of the receptacle. This was probably realized in *Metaxya*, a Fern to be specially investigated later, together with other phyletic consequences believed to have eventuated along this line of advance.

as well as many other characters of structure and conformation above noted, which clearly point to a relationship. The nature of this relationship has probably been that they sprang from a common stock. But while *Gleichenia* was conservative in its sorus, it specialized in its foliar development, so as to rival even *Lygodium*. On the other hand, the Cyatheaceae adopted an extension of the receptacle, and lateral dehiscence of the sporangium, combining these advantages with reduced spore-output per sporangium. In point of habit they became upright, and many of them definitely dendroid.

It is here that the phyletic interest of *Lophosoria* comes in. Its features mark it out as a synthetic type, both anatomically and sorally. Its solenostelic structure and creeping adventitious rhizomes link on with the similar structure seen in the most advanced Gleichenias. Its undivided leaf-trace comes off like theirs from the stele. But its internodes are short in the upright axis, though the leaf-gaps rarely if ever overlap, so that there is not actual dictyostely. Further, the meristele of its larger leaves may show a simple but temporary division into three parts, which anticipates the greater subdivision of the leaf-trace in *Alsophila* and *Cyathea*. The dermal appendages of *Lophosoria* are hairs only, like the most advanced Gleichenias. Scales are associated with the hairs in the definitely dendroid Cyatheaceae. There is thus a parallel progression in this apparently trivial character also. But it is most clearly in the sorus that *Lophosoria* shows its synthetic character. For while retaining the simple sorus of *Gleichenia* without extension of the receptacle in height or in area, it shows the lateral dehiscence of the sporangia. Thus anatomically and sorally it occupies an intermediate position.

It may accordingly be held that *Lophosoria* is a synthetic type, and represents a phyletically early condition of Cyatheoid development. In relation to it the three leading genera are readily seriated phyletically, *Alsophila* being the nearest to *Lophosoria*, *Hemitelia* taking a middle position, and *Cyathea* representing the most advanced type. This conclusion may be based partly on the sorus, partly on the anatomy, and the following brief statement will show that there is a parallelism in the progression in both of these respects.

The description given by Gwynne-Vaughan of the anatomy of the young plant of *Alsophila excelsa* shows that certain stages of structure believed to indicate a natural phyletic progression are passed through with varying rapidity by the young plant of that species ('Annals of Botany', xvii, pp. 709-11). It is at first protostelic; it then becomes solenostelic; this again merges into the dictyostelic structure by overlapping of the leaf-gaps; and finally the first indication of the internal vascular strands makes its appearance 'at about the tenth leaf'. Comparing this ontogeny with the vascular structure in the series we are contemplating, the first stage finds its correlative in *G. flabellata*; the second in *G. pectinata*, and also in

Lophosoria, with a nearer approach in the latter to dictyostely; the third stage, that of dictyostely, is not reached in this plant, though it is rapidly arrived at by *Alsophila* and both of the other genera of Cyatheaceae. These also show the fourth stage of complexity, viz. the addition of internal vascular strands, which are absent in the solenostelic *Lophosoria*. Gwynne-Vaughan remarks (l. c., p. 712) that 'it should be noted that in this plant (i.e. *A. excelsa*) the internal strands do not appear at all until the ordinary stelar cylinder has become more or less dictyostelic'. The fact that they are absent in *Lophosoria*, but present in the mature axes of *Alsophila*,¹ of *Hemitelia*,² and in *Cyathea*, appears to indicate that where the stem is massive and dictyostelic there accessory strands are liable to be present; where the leaf-gaps do not overlap, accessory strands are absent, even though the axis may be of large bulk as it is in *Lophosoria*. It thus appears that the phyletic progression we are contemplating is in direct accord with the progress in complexity of the vascular structure of the plants involved.

A similar phyletic progression, which shows parallel steps to those of anatomy, is to be traced in the sori, which are throughout superficial in position. And this will be specially evident in the details of their protection. In the protostelic *G. flabellata* the sorus is radiate-uniseriate, with 3-5 sporangia, and a spore-output of typically 512-1,024. In *G. linearis*, which is still protostelic, the sporangia are more numerous (10-12) and smaller, the centre of the sorus being usually occupied by one or more; the spore-output is 236 or more. In *G. pectinata*, which is solenostelic, the sorus is crowded with 10-15 sporangia, which are variable in size, and the output of the larger approximates to, but does not reach 512, while that of the smaller approximates to 256. In none of these are hairs a feature of the sorus. The reduction of the spore-output runs roughly, though not with numerical exactness, parallel to the increasing number of the sporangia in the sorus, and to the anatomical advance.

There is a marked break in passing to *Lophosoria*. Its axis is solenostelic as before, but much more massive, while after a short horizontal course the buds become upright and subdendroid. The sorus is constructed on the same plan as that of the more advanced Gleichenias, and all the sporangia are simultaneous in their appearance. But the sporangia have lateral dehiscence, and their spore-output is only 64, while numerous simple hairs are associated with the sporangia. *Alsophila* is the Cyatheaceous genus which is most nearly allied to *Lophosoria*. Its sorus has no protection, excepting numerous hairs which resemble those of *Lophosoria*. It has, however, a more or less pronounced basipetal succession of its more numerous sporangia, which are individually smaller, have lateral dehiscence, and

¹ This has been observed in *Alsophila crinita* in addition to "cases" already recorded.

² This has been observed in a large specimen of *H. (Amphicosmia) Walkerae* from Ceylon.

a spore-output of approximately 64. *Alsophila* has a definitely dendroid habit. The protostelic and solenostelic stages are quickly passed over in the young axis, and a dictyostelic structure is adopted, with internal accessory bundles. Superficially it bears broad scales as well as hairs, and the former at the leaf-bases are, as in *G. pectinata*, borne on peg-like emergences. These characters collectively indicate for *Alsophila* a state of advance upon what is seen in *Lophosoria*.

Hemitelia shares in the main the anatomical and soral characters of *Alsophila*, but its distinguishing feature is the 'indusium'. Christ ('Farnkräuter', p. 329) describes the genus appositely as a small one, 'which as regards the indusium is midway between *Cyathea* and *Alsophila*, since the sorus is in fact naked above, but is provided at the base with a scale-like rudimentary indusium'. This indusium is described as variable in size by various writers. In form and structure it is very similar to the scales found on the surface of stem and leaf, and the probable view which follows from this fact is that it simply represents one of these scales turned to a special protective use.

In *Cyathea* the most specialized type of the series is seen, with lofty dendroid habit, complex structure of the axis, profuse covering of the surface of axis and leaf with chaffy scales. The sori are gradate, and are protected and sometimes completely covered in by the basal, cup-like indusium. This is clearly comparable with that of *Hemitelia*, but it has lost its scale-like character, and is usually developed equally all round the sorus. The sporangia are of the same type as in the other genera, but in *C. dealbata* they are of specially small size, and show a spore-output reduced to the unusually low figures of 16, or even 8. These characters collectively indicate that *Cyathea* is the most specialized genus of the whole series.

When the parallelism of the external, the anatomical, and the soral facts for the sequence of Ferns thus laid out is fully taken into account, it seems impossible to doubt that in essentials it illustrates a true phyletic progression which has taken place. It is not asserted that any modern *Gleichenia* was the progenitor of *Lophosoria* or of any other Cyatheoid Fern. Probably the *Gleichenias* as we know them are a blind branch. What is concluded is that from an essentially *Gleichenioid* type long ago the Cyatheoid type of Ferns originated, and an essential link in the progression is supplied by *Lophosoria*. The progression involves a gradual change of habit from a creeping type with isolated leaves borne by an elongated rhizome, to an erect type which includes the largest of the Tree-Ferns. It necessarily follows that here at least the upright axis is a secondary result of evolution. A similar comparison applied among the members of the quite distinct sequence of the Dicksoniaceae leads to a like result; this will be taken up in detail on a subsequent occasion. From

both sources the result is arrived at that the dendroid character is secondary for the Gradate Ferns.¹

It also appears from the sequence in question that a natural progression is illustrated from the protostelic to the solenostelic, and finally to the dictyostelic type of vascular arrangement. Lastly, there is the further step to a dictyostelic state with accessory strands in pith and cortex. There is probably no series of nearly related Ferns which shows such progressions as these so clearly.

It is also indicated that while the hair is present in the lower members of the sequence, broad scales become a later feature, and that though these at their first appearance in *Alsophila* do not form an 'indusium', in the more advanced types they become specialized for that duty.

Finally, the sequence illustrates the progression from the simple to the gradate sorus, and from sporangia with large spore-output and median dehiscence to those with greatly restricted output and lateral dehiscence. It is the consistent parallelism of all these progressions, in characters physiologically quite distinct from one another, which gives them their special cogency as evidence, and forbids any of the progressions being read in converse.

Unfortunately the evidence from the fossils, which would be so valuable an adjunct to comparison, and especially in deciding whether or not the sequences contemplated were really progressive, is not of a distinctive character. As to the Cyatheaceae, Seward states ('Fossil Plants', vol. ii, p. 366) that 'it is not until we reach the Jurassic Period that trustworthy data are obtained'. The evidence as to the existence of the Gleicheniaceae, such as we at present know them, earlier than the Jurassic Period, where they are certainly represented, is not convincing. It turns upon the interpretation of specimens of *Oligocarpia*, which bear sori with a small number of sporangia, and have been referred by some authors to the Gleicheniaceae. But opinion as to their Gleicheniaceae character is divided. Zeiller and Scott (see Seward, l. c., p. 352) uphold the presence of an annulus such as would be indicative of a Gleicheniaceae affinity. But this is not admitted by Solms-Laubach, Stur, or Schenk. It cannot therefore be used as direct evidence here. Nevertheless the comparative considerations which have been advanced would make the occurrence of ancestral representatives of the family earlier than the Jurassic Period seem probable. And the character of the sorus of *Oligocarpia* suggests at least some such ancestral form, whether or not the sporangia have the exact type of annulus now recognized as characteristic of the Gleicheniaceae. There is no doubt that they had the median dehiscence; this is clear from specimens shown me by Dr. Kidston. There is, however, reason to think that the annulus in these early types may not have consisted of a single row of

¹ Compare footnote on p. 293, above; also Ann. of Bot., xxv, pp. 567-8.

cells, as is the case in the modern Gleicheniaceae, but of several rows. This has already been suggested by Dr. Kidston ('Les Végétaux houillers', Bruxelles, 1909, p. 35).

As regards the remaining genera with superficial sori and basal indusium, the details described above have only served to strengthen their relation to the Cyatheaceae, a relationship which has never been in doubt except in the case of *Acrophorus* and *Cystopteris*. The position of the former must remain uncertain until it has been properly re-examined. But of the Cyatheoid affinity of *Cystopteris* there can now be little doubt. Its sorus is superficial in origin, as it is in all of these Ferns. The demonstration of its basipetal sequence of sporangia upon the receptacle, which has itself become lop-sided in accordance with the lateral attachment of the indusium, combined with the superficial position, is distinctive; while the anatomy of the stock and petiole, so like that of *Struthiopteris*, gives independent and cogent support to the relationship suggested.

The importance of this conclusion lies, however, in the consequences which follow from it. The comparison of *Cystopteris* with the Aspidieae dates back to the time of Swartz and of Presl. The similarity of habit is unmistakable; in point of vascular structure *Struthiopteris* and *Cystopteris* compare very closely with such a type as *Nephrodium Oreopteris*. The sori of these Ferns are alike in position, and in their indusium, to those of the Aspidieae. Both have also a vascular receptacle. The similarity of the young sorus of *Nephrodium Filix-mas* when cut in median section to that of *Cystopteris* appears clearly from a comparison of Figs. 45, 46 of the former Fern with Fig. 38, *b*, of the latter. But while we thus compare its sorus with that of *Nephrodium*, it is to be borne in mind that the one is gradate in the sequence of its sporangia, the other mixed. The conclusion which naturally follows on such considerations is that there has been a further phyletic progression—the recognition of which is facilitated by the living genera *Struthiopteris* and *Cystopteris*—from Cyatheoid derivatives to certain Aspidieae, by the assumption of a mixed character of the sorus. Such a progression has already been recognized within this very sequence, in *Hypoderris*, while *Peranema* and *Diacalpe*, which are shown in Mr. Davie's paper (p. 245) to have mixed sori and a vascular system closely resembling *Nephrodium*, have in the form of the sorus and in the basal indusium clear Cyatheoid characters. As Mr. Davie justly points out, between them *Peranema* and *Diacalpe* seem to unite all the intermediate features between the Cyatheaceae and the Aspidieae. A similar transition from gradate to a mixed type of sorus is believed to have occurred in several other evolutionary lines. This change appears in the present case to have gone along with a flattening of the receptacle between the indusium and the leaf-surface. A further step was the lateral extension of the sporangium-bearing surface right and left, in the direction of the midrib of the pinnule,

so that it took a horseshoe form, the indusium following suit. And so the characteristic Nephrodioid sorus may be held to represent a flattened modification of the Cyatheoid type. A further step is seen in *Polystichum*, by the junction of the two lateral arms of the receptacle on the side next the midrib of the pinnule to form a complete ring. The indusium again following suit, it now appears in the well-known shuttlecock form. The last step is in the abortion of the indusium in certain derivative forms, giving again a 'Polypodioid' sorus of simple circular outline, almost like that of *Alsophila*. It would be out of place here to attempt to trace the various evolutionary lines within the Aspidieae.¹ It must suffice to have recognized the probability that they constitute a great group of Filicales, phyletically related with the Cyatheaceae, and ultimately with the Gleicheniaceae.

The biological advantages of the Nephrodioid type of sorus over the Cyatheoid are obvious. First there is the general advantage which a mixed sorus has over a gradate one, that while it spreads the physiological drain over a long period, it makes the best possible use of a limited length of receptacle. But a second advantage not hitherto recognized is the greater convenience in packing during the circinate condition of the young leaf. In the gradate sorus pressure of the next outer coil of the spiral on the apex of the sorus would tend to crush the first formed sporangia, and evidence of this is sometimes to be seen. This is avoided by the flattened form assumed by the sorus, as seen in *Cystopteris* or *Nephrodium*. But a sacrifice of sporangial space is made in *Cystopteris*. This is amply made up for by the ring-like extension of the receptacle in *Nephrodium* and *Polystichum*, as well as by the continued production of sporangia in their mixed sorus. Thus it appears that the modifications, which are believed to have been phyletic advances, show that physiological advantage is gained by them. This increases the probability that they are rightly so recognized.

The relation of *Hypoderris* to *Woodsia* has always been admitted, and the facts here given tend to strengthen the affinity. But *Woodsia* has a gradate sorus, though the sequence is not long continued, while *Hypoderris*, which is more advanced in vascular structure, in venation, and in foliar character, has a mixed sorus. There can be little doubt that a like soral progression from the gradate to the mixed state has occurred here to that in *Peranema* and *Diacalpe*, or in *Nephrodium*. There is, however, no reason to think that any of these genera had any place in the descent of *Hypoderris*. The conclusion must then be that *Hypoderris* illustrates another and a distinct progression from the gradate to the mixed sorus. It is, in fact, becoming plain that this transition has happened not once only, or twice, but by many parallel progressions.

There does not appear to be any sufficient reason for holding that any

¹ Compare C. Christensen, *Biologiske Arbejder*, Nov. 1911.

two of the pairs of genera discussed above, viz. *Struthiopteris* and *Onoclea*—*Peranema* and *Diacalpe*—*Woodsia* and *Hypoderris*—*Cystopteris* and *Acrophorus*—were related in the sense of being successive steps in a simple phyletic line. That is to say, no one of these groups can be held as the actual ancestors of another. It has been remarked above that none of these Ferns is really primitive. All show indications of a middle position in the general scale of the Filicales. The source from which they spread has without doubt been related to that of the Cyatheaceae, as shown by habit, by anatomy, by sorus, and in some cases by the details of the gametophyte. But in view of the anatomical and soral characters combined, it is difficult to relate any of them to any definite genus of the Cyatheaceae as we see them now. These Ferns with basal sori appear collectively to form a brush of separate minor lines of descent, related one to another by common origin, but separately specialized according to their habitat. The Cyatheaceae are essentially the intertropical forest representatives, showing increasing specialization in soral protection, in accordance with their dendroid habit. *Struthiopteris* and *Onoclea* are forms with still more special protection of the sori by incurving leaf-margins, in relation to their northern and mountain habitat. Similar circumstances have probably influenced *Peranema* and *Diacalpe*, and led to specialization of their sori along a distinct line of their own. *Woodsia* is a boreal dwarf type, and *Hypoderris* a type of tropical shade. *Cystopteris* is a world-wide type, but with its head-quarters in the temperate zones of both hemispheres. It is specially marked by its hardihood and resistance to alpine extremes. Most of the smaller genera are deciduous according to season, a character clearly indicating their specialization for life under marked seasonal change. This is in contrast to their larger and more successful correlatives, the intertropical Cyatheaceae, which maintain their constant tuft of leaves.

The Cyatheaceae are clearly the most successful, as measured by size, as well as by number of species. They were probably also the earliest type. The smaller genera show by their paucity of species, and in some cases by their limited spread, that they have met their external circumstances with only partial success. But indirectly in relation to two of them great phyletic developments have probably arisen. In near connexion with *Cystopteris* (and probably also in some relation with *Peranema* and *Diacalpe*), the great sequence of the Aspidieae has come into existence. Similarly, in relation to *Struthiopteris* has arisen the successful sequence of *Lomaria*, *Woodwardia*, and *Doodya*. Here it must suffice merely to suggest these lines of further progress, and the full discussion of them must be left over for a future occasion. The object here is to indicate that the Cyatheoid type, with gradate sorus and basal indusium, was not a blind or final evolutionary line, though very likely the genera of Cyatheaceae, as we see them to-day, were the ultimate exponents of it. Modifications, and espe-

cially the introduction of the mixed sorus, seem to have given a new phyletic impetus to some of the derivative forms, which has eventuated in the great Aspidioid sequence.

Returning lastly to the criteria above cited, we find the following progressions illustrated in our series:

(i) The dichotomous branching is frequent in the Gleicheniaceae, but becomes rarer in the higher types. The creeping axis of the earlier becomes in certain later types ascending or erect.

(ii) The peculiarities of the original Gleicheniaceae type of leaf are shown in reminiscent details in the Cyatheaceae, but lost elsewhere.

(iii) There is a progression from primitive hairs to scales, the former being characteristic of the lower, while all the higher terms of the series show the latter.

(iv) The vascular system, starting as a protostele in the *Mertensia* section of *Gleichenia*, becomes solenostelic in *G. pectinata* and *Lophosoria*, but is dictyostelic in all the rest. Special accessory strands occur in the Cyatheaceae. The foliar trace is correspondingly broken up into separate strands in the higher terms of the series.

(v) The sorus is superficial in all these Ferns, and is not distal on its supporting vein (the case of *Acrophorus* being left in doubt). It shows progression from a simple type in *Gleichenia* and *Lophosoria* to the gradate in Cyatheaceae, *Struthiopteris*, *Onoclea*, *Woodsia*, and *Cystopteris*. Finally, it becomes mixed in *Hypoderris*, *Peranema*, and *Diacalpe*, a condition leading probably to that of the Aspidieae.

(vi) The sporangia are large in the Gleicheniaceae, few in number, with large spore-output and median dehiscence. The size and spore-output fall in *G. pectinata*. In *Lophosoria* it is already of the number 64, and the dehiscence is lateral. In the Cyatheaceae the spore-number may fall to even lower figures, with oblique annulus and lateral dehiscence. But finally the annulus becomes almost vertical, and interrupted at the stalk in all the highest terms of the series.

(vii) The antheridium shows reduction in number of the spermatozoids which is roughly parallel with the reduction in the spore-number in the higher terms of the series. This goes with structural simplification, especially seen in the final absence of division in the cap-cell in the most advanced types.

It is believed that the Ferns here treated constitute a true phylum, though they probably include a brush of minor phyletic lines. This view is based primarily upon the constancy in the superficial position of the rounded sorus, borne not distally upon a vein, and the basal insertion of the indusium where present; also upon the characters of the sporangia themselves. A substantial parallelism of progression has been traced within the phylum in respect of the characters of external form, of dermal

appendages, of anatomy, of soral construction, and of detail of the sporangia, together with certain gametophytic features. The constancy of the parallelism in features functionally so distinct is held to give just ground for drawing the phyletic conclusions sketched above. Further, it has been shown that they are in accord with physiological probability, and that the fossil record, so far as the known facts bear upon the question, supports the phyletic story thus reconstructed.

Accordingly it is held that in this phylum, which is believed to be quite distinct from that of the Ferns with originally marginal sori, a progression has been traced which extends from primitive forms showing the simple sorus, the protostelic axis, and undivided leaf-trace, to those with a mixed sorus, a dictyostelic axis, and highly divided leaf-trace; while in a middle position lie examples with a gradate sorus, and showing various conditions of solenostely in the axis, and of subdivision of the extended meristele of the petiole. Starting with the ancient *Gleichenia*-ceous type, we have arrived at the *Aspidieae* as relatively modern representatives of the phylum, while the *Cyatheaceae* and their smaller correlatives take a middle position. No attempt has, however, been made here to trace critically the ultimate phyletic derivatives of the *Aspidieae*. This must be left over for further investigation.

The relationships thus recognized have been more or less clearly indicated by various systematic writers. What has been attempted here has been to widen the scientific basis upon which such conclusions ought to be founded. There is accordingly no striking change in nomenclature, beyond the upholding of *Lophosoria* as a substantive genus, quite distinct from *Alsophila*, but related to it. The conclusions arrived at should, however, have the effect of recommending a grouping of the families involved in their probable phyletic sequence, thus: *Gleicheniaceae*—*Cyatheaceae* (with minor groups, e. g. *Woodsieae*, &c.)—*Aspidieae*.

DESCRIPTION OF FIGURES IN PLATES XXX-XXXVI.

Illustrating Professor Bower's paper on *Lophosoria* and its relation to other Ferns.

PLATE XXX.

Fig. A. Hairs of peculiar form, from the base of the leaf of *Gleichenia pectinata*. Each hair is seated on a massive emergence, from which it is easily detached, the emergence remaining as a hard peg-like projection. $\times 50$.

Fig. B. Part of petiole of *Hemitelia horrida*, bearing prickles, or peg-like emergences, and upon the tip of each is balanced a flattened scale, corresponding to the branched hairs in *G. pectinata*. Slightly enlarged.

Fig. C. Pinnule of *Gleichenia linearis*, showing venation and mature sori. Some of the sporangia are shown to have dehisced. Enlarged.

Fig. D. A single sorus of *Gleichenia linearis* on a larger scale, showing the disposition of the sporangia, several of which have opened by a median slit. Enlarged.

Fig. E. Pinnule of *Gleichenia pectinata*, showing the venation and mature sori. Some of the sporangia are shown to have dehisced. Enlarged.

PLATE XXXI.

Fig. F. A single sorus of *Gleichenia pectinata*, showing the sporangia so closely packed as to be flattened against one another. One has already dehisced. Note the inverted position of one of the outer sporangia on the right-hand side. Enlarged.

Fig. G. Upright stock of *Lophosoria*, after removal of the hairy covering. The erect appendages are all foliar, of which those inserted lower down are abortive, while those higher up are developed. From the base of several of them, but not all, arise the horizontal, solenostelic runners. Note the emergences on the bases of the fully developed leaves. From drawing by Mr. Thompson. Half natural size.

Fig. H. Pinnule of *Lophosoria pruinata*, showing venation and sori. Enlarged.

Fig. I. A single sorus of *Lophosoria*, showing the small number of sporangia, with their regular orientation. Each sporangium has its annulus apparently complete, the stomium being lateral, and therefore out of sight. Enlarged.

PLATE XXXII.

Fig. K. Dissection of a large stock of *Lophosoria pruinata*, showing the vascular solenostele exposed, by the removal of all superficial tissues. It is clear that the foliar gaps do not overlap, and transverse sections anywhere in the internode will show the complete solenostele. From drawing by Mr. Thompson. Natural size.

Fig. L. Dissection of a smaller shoot of *Lophosoria pruinata*, showing the vascular system exposed. The internodes are shorter than in Fig. K. Note the vascular supply to the runners arising horizontally from the bases of many of the leaf-traces. From a drawing by Mr. Thompson. Natural size.

Fig. M. Double-headed specimen of *Cyathea dealbata* in the Glasgow Botanic Garden. It is probably a dichotomy.

PLATE XXXIII.

Fig. N. Plant of *Hemitelia setosa* in Edinburgh Botanic Garden, showing numerous 'aphlebioid' pinnae. From a photograph prepared by the direction of Professor Balfour.

Fig. O. Plant of *Alsophila* sp. in Glasgow Botanic Garden, showing basal pinnae, comparable with the 'aphlebiae' of *Hemitelia*.

PLATE XXXIV.

Fig. 1. Very young sorus of *Gleichenia pectinata*, seen in vertical section, before the sporangia have been initiated. $\times 400$.

Fig. 2. A similar sorus, rather older. $\times 400$.

Fig. 3. A similar section of an older sorus, on which the sporangia have already been initiated. $\times 400$.

Fig. 4. A similar section, showing some difference of age of the sporangia borne upon the same sorus. $\times 400$.

Fig. 5. A young sporangium of *Gleichenia pectinata*, showing a typical segmentation of the relatively massive stalk. $\times 400$.

Fig. 6. Section cut through a sporangium so as to traverse the sporogenous tissue in a plane transverse to the axis of the sporangium. The number of the spore-mother-cells is fifteen. $\times 400$.

Fig. 7. A similar section cut in the median plane of the sporangium, and traversing twenty spore-mother-cells. $\times 400$.

Fig. 8. A similar section, showing the spore-mother-cells separated and rounded off. $\times 400$.

Fig. 9. A large stem of *Lophosoria* cut transversely, and represented natural size. A leaf-trace, subdivided into three strands, has recently been given off, leaving an open foliar gap, while preparation is being made for another opposite the mark \times .

Fig. 10. Transverse section of a runner of *Lophosoria*, showing a leaf-trace being given off from the solenostele. Note that the separation of the two margins is not simultaneous. Slightly enlarged.

Fig. 11. (i-v.) A series of transverse sections through a runner of *Lophosoria*. (i) is the lowest, and the series illustrates the successive stages of separation of a leaf-trace from the solenostele. In (v) the ring is again completely closed. Note that the leaf-traces in (i) and (iv) have their margins united to form a ring: this has only been observed in the traces of arrested leaves. Slightly enlarged.

Fig. 12. (i-iii.) Successive sections from below upwards transversely through an axis of *Lophosoria*, showing the relation of the vascular supply of a runner to that of the axis and leaf. *b* indicates the runner itself. $\times 4$.

Fig. 13. (i-iii.) Tangential sections through the base of insertion of a runner upon the leaf-base to which it is related. (i) shows the runner itself, with its solenostele; (ii) shows the solenostele now connected with the leaf-trace, which being cut tangentially appears as a broad sheet of vascular tissue. Slightly enlarged.

Fig. 13 bis. *a, b.* Transverse sections of the petiole of *Lophosoria*. *a* is from a point near the base, and shows the trace divided into three strands, while opposite the gap between them there is on either side an interruption of the superficial sclerenchyma for ventilation purposes. *b* was taken at a point higher up, and the trace is here a single continuous strand. $\times 4$.

PLATE XXXV.

Fig. 14. (i-vii.) Series of transverse sections of the rachis of *Lophosoria*, successively from below upwards, showing the origin of the pinna-trace. $\times 4$.

Fig. 15. (i-vii.) Series of transverse sections of the rachis of *Gleichenia linearis*, for comparison with Fig. 14, showing the origin of the pinna-trace. $\times 4$.

Fig. 16. Hairs from the sorus of *Lophosoria*, which are unbranched, and not obviously glandular. $\times 100$.

Fig. 17. Transverse section of the stalk of a sporangium, showing its relatively massive character. $\times 200$.

Fig. 18. Sporangium of *Lophosoria* presenting its 'peripheral' face, and showing that the annulus is uninterrupted and the dehiscence lateral, while the area surrounded by the annulus is very large. $\times 150$.

Fig. 19. A similar sporangium presenting its 'central' face. $\times 150$.

Fig. 20. A similar sporangium seen in lateral view, presenting the side which bears the stomium. The lower face, as seen in the drawing, would be opposite the surface of the leaf. $\times 150$.

Fig. 21. Section vertically through a very young sorus of *Lophosoria*, taken so as to include the margin of the pinnule. $\times 400$.

Fig. 22. Section of a similar sorus in a direction at right angles to that of Fig. 21. $\times 400$.

Fig. 23. Transverse section of a similar sorus. The cells marked \times will produce sporangia. $\times 400$.

Fig. 24. Vertical section of a rather older sorus, in which the sporangia and hairs are becoming apparent. $\times 400$.

Figs. 25-7. Longitudinal sections of young sporangia of *Lophosoria*, showing details of their segmentation, and the hairs which accompany them. $\times 400$.

Fig. 28. Vertical section through a young sorus of *Lophosoria*, so as to follow the course of the vascular strand which supplies the receptacle. Two sporangia are traversed, and many of the simple hairs. $\times 200$.

Fig. 29. A similar sorus cut transversely to the course of the vascular strand, showing three sporangia and the hairs as before. $\times 200$.

Fig. 30. Vertical section through a sporangium of medium age. $\times 200$.

Fig. 31. Transverse section through a sporangium of like age, showing the usual number of spore-mother-cells. $\times 200$.

Fig. 32. A similar section, showing the unusual number of nine. $\times 200$.

Fig. 33. Vertical section through an almost mature sorus of *Lophosoria*. The vascular supply into the receptacle is shown, and four sporangia, together with numerous hairs. The spores are still in tetrads. Note that the orientation of the outer two sporangia, as shown by the position of the

large cells of the annulus, is according to the type for *Gleichenia*, but that the inner sporangia do not maintain that regularity. $\times 100$.

Fig. 34. The very characteristic spores of *Lophosoria*, and their germination. $\times 250$.

PLATE XXXVI.

Fig. 35. A young prothallus of *Lophosoria*, which has just begun to form antheridia. $\times 66$.

Fig. 36. The venation of the fertile pinna of *Struthiopteris orientalis*; the dots on the veins indicate the receptacles. Enlarged.

Fig. 37. Vertical section of a sorus of *Struthiopteris orientalis*, from a plant grown in the Glasgow Botanic Garden. It shows the indusium covering the basipetal sorus, and itself overlapped by the leaf-margin. Note that the vascular strand extends beyond the insertion of the receptacle. $\times 160$.

Fig. 37 bis. Another example, showing clearly the basipetal sequence of the sporangia. $\times 160$.

Fig. 38. *a, b*. Vertical sections of the sorus of *Cystopteris fragilis*. *a* cuts the leaf-lobe transversely; *b* cuts it longitudinally, so as to include the leaf-margin. The first sporangium appears in a median position, terminal on the convex receptacle. $\times 250$.

Fig. 39. Section of an older stage cut as in Fig. 38 *a*, or as indicated by the line crossing Fig. 40 vertically. The median sporangia, which are the oldest, have been cut through their stalks only; the lateral ones, being shorter, have been cut through their heads. The indusium forms an efficient covering. $\times 250$.

Fig. 40. Section of a sorus of *Cystopteris fragilis* corresponding to that of Fig. 38, but older. It shows clearly the basipetal succession of the sporangia, but only on one side of the receptacle. $\times 250$.

Fig. 41. Vertical section through a sorus of *Woodsia obtusa*, showing the vascular supply into the receptacle, the basal indusium, and the basipetal succession of the sporangia. $\times 160$.

Fig. 42. Very young sorus of *Woodsia hyperborea*, seen in surface view. *Sp.* indicates the sporangia. *i.i.* indicate the beginnings of the indusium. From a drawing kindly lent by Professor von Goebel.

Fig. 43. *a, b, c*. Transverse sections of the stalks of sporangia of *Hypoderris*, showing the differences which exist in complexity of the stalk, which shows sometimes three, sometimes two, or one cell in section. $\times 250$.

Fig. 44. *a, b, c*. Three types of sporangia, showing different segmentations, which tally with what is seen in Fig. 43. $\times 250$.

Figs. 45 and 46. Vertical sections of young sori of *Nephrodium Filix-mas*, cut in a direction corresponding to that of the figure (38, *b*) of *Cystopteris fragilis*. The similarity of structure is obvious. $\times 250$.

BOWER—LOPHOSORIA AND OTHER FERNS

The Cytology of *Laboulbenia chaetophora* and *L. Gyrinidarum*.

BY

J. H. FAULL, B.A., PH.D.,

University of Toronto.

With Plates XXXVII-XL.

THE Laboulbeniales possess many fundamentally important morphological features that cannot be properly interpreted until their underlying cytological phenomena have been elucidated. This is especially true of their organs of reproduction, including both gametangia and spore-sacs. Thus the latter have been rightly denominated asci by some botanists, but in the absence of any knowledge of their cytology—which recent investigations have shown to be essential to a definition of the ascus—others have advanced different views with regard to their nature, and correspondingly different speculations as to the taxonomic position of the group. By way of illustration it is needless to go farther afield than Engler's 'Syllabus' ('07), in which they are classified as Laboulbeniomycetes, a class of equal rank with the Ascomycetes and the Basidiomycetes. The gametangia have played an even more prominent part in these speculations. This is particularly true of the female organ, whose striking resemblance to that of the red seaweeds has won for it the name of 'procarp', and given rise to the theory that the Ascomycetes are an offshoot of the Florideae with the Laboulbeniales as the connecting link. But every biologist nowadays realizes the unreliability of schemes of phylogeny, the sole capital of which is external morphology. The true homologies of the gametangia are quite as likely to be expressed by their cellular and nuclear phenomena. Hence, a knowledge of the latter is almost certainly needed before a satisfactory estimate can be made of any phylogenetic hypothesis based on the morphology of the organs of reproduction.

The sexual organs have also been of interest from another standpoint. Because they are well marked and apparently functional they have been cited as proof that the Ascomycetes have not parted with their sexuality. As a matter of fact, it has never been shown whether they are or are not sexually functional, or just how they may function—that remains to be determined by following patiently the fate of their nuclei. It is likewise

noteworthy that, within the limits of the order, bisexual and unisexual species exist, and that, in connexion with the latter, heterospory and dimorphism have arisen, but concerning the associated cytological phenomena we know nothing. These and other matters provide abundant cause and stimulus for investigation. Since up to the present no contributions, apart from two brief articles by the writer (Faull, '05, '11), have been made on their cytology, several forms have been placed under investigation in the hope of discovering an answer to some of the problems that await solution. Some of the results obtained are presented here and some will be published in other memoirs. In this connexion, I wish to express my gratitude to Professor Roland Thaxter, who has most generously placed the rich stores of his intimate knowledge of this group at my disposal, and who has kindly examined some of my preparations and extended many other courtesies.

MATERIAL AND METHODS.

Laboulbenia chaetophora occurs on the edges of the elytra and the free tip of the abdomen of several species of the genus *Gyrinus*, the familiar 'whirligigs' common on ponds and along the quieter margins of streams and lakes. With it is frequently associated *Laboulbenia Gyrinidarum*, though in the two rather remotely separated regions from which the material for the investigations described in this paper was collected, the former species was abundant and the latter rare in one locality, while in the other the conditions were reversed.

L. chaetophora seems to prefer the free tip of the abdomen, on which it often grows in tufts of from two to ten or more individuals, and *L. Gyrinidarum* the margins of the elytra, which are not uncommonly fringed with a growth of the plants of this species.

L. chaetophora is the larger form of the two, sometimes attaining a length approximating a millimetre and a width one-fifth as great, a perithecium up to 400μ long, and a receptacle 525μ or more. The smaller form rarely reaches half a millimetre in entire length and 160μ breadth. There are other well-marked distinctions, all of which are noted by Thaxter in the second volume of his monograph.

Of the available species of *Laboulbenia*, *L. chaetophora* presents the advantages of size, and mode and place of occurrence on the insect, though both lend themselves rather well to the manipulations about to be described. The material was collected in the neighbourhood of Guelph and Ottawa, Canada. While most of it was of the larger species, it was impracticable if not impossible to separate the species, and especially to distinguish the younger stages of the two forms from one another. However, they are so nearly alike and so closely allied that chances of error are practically negligible.

The most serious difficulties in the way of technique, apart from those of obtaining suitable and adequate material, have been the securing of proper infiltration of the reagents used, and the sectioning of the embedded portions of the host. The chitinous external wall of the fungus impedes the ingress of fixatives and often prevents it. Hot fixatives were sometimes employed, and in some instances gave excellent results, but by far the best were obtained by making an incision in each plant in the manner to be next described.

Préparatory to fixing, portions of the insect bearing the fungus were dissected off with scalpel or scissors, as little as possible of the integument of the insect being taken. Immediately after detaching such a piece, it was laid in a drop of the fixing fluid on a slide, and with the aid of a dissecting microscope and a pair of chisel-pointed needles the ends of the perithecia were snipped off. For this purpose needles with the finest points obtainable were mounted in match-stick handles and the points ground down to a sloping chisel edge. The material was then at once transferred to a phial filled with the fixing reagent. In the case of young plants the application of such technique was impracticable, and they were fixed without snipping, with the result that not infrequently fixation was not good. Snipped and unsnipped mature perithecia were sectioned by way of comparison. The former were invariably better preserved, the latter usually so badly as to be unusable. Several reagents were employed, but Flemming's weaker solution proved to be most satisfactory and was finally exclusively employed. As for stains, there is little to choose between Flemming's triple and Haidenhain's iron haematoxylin, the choice possibly resting with the former.

In order to overcome the obstacles offered in sectioning the host, some attempts were made at detaching the plants, usually during the embedding process, and handling them individually. With the larger subjects this can be done successfully, and by improving the methods possibly with all. But on account of their minuteness there is bound to be more or less loss in such a procedure, and as this is a serious consideration where material is none too abundant to begin with, this method was not very extensively employed.

By embedding in paraffin with a melting point of from 57° to 60° C., and cutting with a hard knife, sections from 3 to 5 microns can be obtained, though the chitin of the host almost invariably fractures before the knife. In order to soften this chitin, experiments were made by immersing the material in a solution of eau de Javelle after it had been hardened. This method was useless, however, because, while it dissolved the chitin, it also rendered the plants quite colourless and caused them to loosen from their points of attachment.

CELL-WALLS AND GENERAL ENVELOPE.

The entire plant is enclosed by a thin, homogeneous, extremely tough, and impermeable continuous membrane or general envelope which is independent of the cells of the thallus. According to Thaxter it is the persistent gelatinous envelope which is first formed around the ripe spores just before they come to maturity and while still within the perithecium. Its impervious qualities are obviously of advantage, in that they protect the plant from the danger of desiccation.

This membrane is so thin that if embedded in hard paraffin it offers no serious resistance to the microtome knife. However, it very often checks or cracks and curls from the cut surface just as does a thin sheet of celluloid or hard rubber. It is often a serious hindrance to the fixing of sections to the slide, partly because it does not adhere well to glass, and because of its tendency to break and curl, thus disturbing the rest of the section during the various processes to which it is subjected in the course of staining and mounting.

The wall immediately underlying the general envelope is remarkably thick, and exhibits a curious differentiation, expressed both by structural peculiarities and characteristic reactions to staining media. Figs. 9 and 10 represent its morphological characters, from which it will be seen that it is laminated, and that the outer lamina is of different consistency and structure from the inner. The number of layers may vary, but usually from two to four or five can be counted.

The inner ones consist of a compact, non-granular substance, perfectly homogeneous and structureless, except for occasional radially arranged streaks, and with Flemming's triple or Haidenhain's iron haematoxylin take a light yellow stain or none at all. The streaks mentioned are darker in colour than the matrix in which they occur, since they vary from a smoky to a purplish tint. They have their bases or origin in the outer lamina, radiate more or less regularly inwards, at times branching, and frequently terminate at the inner boundary of a layer. Here they often expand into an irregular disc such as is illustrated in Pl. XXXVII, Fig. 9.

The outermost layer is of very different structure and staining capacity from the inner ones, and in the course of its development undergoes a very remarkable transformation. In the ripe spore nothing of peculiar interest is evident, but at an early stage in the history of the plantlet, after the walls have thickened, but while the substance of their component laminae is yet compact and non-granular, the peripheral layer soon shows its pronounced affinity for stains. The contrast to the inner layers is very marked, though not so much so as later, as at this stage the latter also show a tendency to take up stains. Later the contrast is sharp and complete, heightened so much the more by the circumstance that it adheres to the

general envelope and often bears no apparent relationship to the protoplasts (Fig. 9). At a comparatively early stage the differentiation in structure referred to above becomes evident. At first it is little more than a mottling. The changes in structure, however, vary in different parts of the plant. In some regions there is a more or less uniform granulation of the lamella, in others the appearance of a radially arranged system of deeply stained rays grouped in plates. Reference to Figs. 9 and 14 will make clear what is meant. Viewed in section these plates look like dark, compactly striated bars of varying width, while viewed from the surface they resemble a honey-comb or net. With increasing age the plates disintegrate into granules, until finally the lighter areas, the meshes of the net, composed of the apparently almost unmodified wall substance, stand out as anticlinally oriented strands. In these changes it sometimes happens that one or more of the subjoined layers may become involved, but only secondarily so.

The strands which originate in this curious way are of very common occurrence in species of the genus *Laboulbenia*, and are of very characteristic appearance. Figs. 10 and 12 represent the fully formed strands. By light reflected from their surfaces they appear quite black in stained preparations, but by transmitted light are light-coloured and bright, the latter quality being due to their comparatively high index of refraction. Fig. 11 represents a portion of the general envelope that has been pulled away by the knife, and to which several of them are attached. The surface of such a portion of the plant viewed by transmitted light appears pitted or porous (Fig. 12). Indeed, Istvanffi ('95) described this punctate appearance, but interpreted the punctations as 'pore canals'. Thaxter rightly associated them with these strands or fibrillae, to the existence of which he was the first to call attention. Their formation, as has been seen above, is due to a more or less complete disintegration of the outer laminae, and in particular of the outermost. But as to the cause of this one can only conjecture. Instead of a granulation or degeneration of portions of the substance of the wall, as just described, in some instances there may be nothing more than a shredding, which is either an artifact or due to an unwonted stretching of an inelastic membrane. But shredding is exceptional, and cannot be offered as the cause of the origin of the ordinary type of fibril or the curious differentiation of the wall so early expressed in the life of the plant.

This account of the general envelope and external cell-walls does not apply to those of the trichogyne, the appendages, and the inner cells of the perithecium, all of which remain comparatively thin. Because of this fact the fixation of the appendages is usually good. In passing it may be pointed out that the appendages, in this species at least, appear to be capable of regeneration to a marked degree. New branches frequently spring from injured ones to replace the portions that may have been destroyed. The terminal cells in particular are long and thin walled, and are

covered by a filmy colourless 'chitinous' envelope (Pl. XXXVII, Fig. 2). It is noteworthy, too, that the protoplasm and nuclei of all the cells of the appendages, even in older plants, are apparently well nourished, and that they never show indications of decay. This is in contrast with the larger cells of the receptacle. The protoplasm in the latter often becomes very scanty and loosely reticulate, and the nuclei frequently have every appearance of being in a state of decadence, as is manifested by the fact that they sooner or later lose their sharp outlines, their contents show little or no structure, and sometimes an irregular, densely staining nucleolus accompanied by a greater or smaller mass of equally densely staining débris is all that remains of them. This disorganization is rarely, if at all, seen in the appendages.

The septa in the receptacle are resolvable into several layers, of which the middle lamella stains purplish and the others yellowish. The former is continuous with the darkly stainable layer in contact with the general envelope (Figs. 8 and 9). On it the others are superposed, the younger being less compact and more hyaline than the older. The septa separating daughters of the same mother-cell are single pitted (Fig. 7), so that there is a continuous protoplasmic tract from the base of the plant to the tips of the appendages.

The septa of the appendages are constructed like those of the receptacle, but are rather thicker than might be expected after what has been said of their peripheral walls (Fig. 1). Their pits, too, are surprisingly large. In *L. chaetophora* and *L. Gyrinidarum* the septa are black as seen from the edge, but sections and face views show that the blackening is superficial and mainly restricted to the portion of the general envelope covering the rim of the septum. The septum stains reddish for a short distance out from the pit, then there is a wider yellowish peripheral portion, and then the black rim (Fig. 2, a).

PROTOPLASMIC BRIDGES.

Possibly the most interesting features of the cell-walls are the pits and protoplasmic bridges. They are beautifully demonstrated and figured by Thaxter ('96) in Part I of his monograph, and it is strange that no reference is made to his descriptions by A. Meyer ('02), Kienitz-Gerlöff ('02), Strasburger ('01), and other botanists who have examined various Fungi to discover whether or not they possessed these structures.

De Bary ('84) appears to have been the first to note the existence of pits in the partition walls of the Fungi. He pointed out that they often possessed simple pits, and that those in *Dactylium macrosporum* were strikingly like those of the Florideae, such, for example, as in *Callithamnion*. The first work of any consequence on the subject of protoplasmic bridges in Fungi was done by Wahrlich ('92), who published an account of extensive

investigations on a large range of forms. The extent of his observations may be judged from the fact that he drew his material from the following groups: Mucorini, Ustilagineae, Uredineae, Agaricineae, Polyporeae, Hymenogastreae, Lycoperdaceae, Nidulariaceae, Saccharomycetes, Perisporiaceae, Hypocreaceae, Pezizeae, Helvellaceae, Tuberaceae, Parmeliaceae, and Cladoniaceae. In every instance Wahrlich found that the transverse septa were perforated by a single simple pore. In only one species, however, did he find protoplasmic bridges that closely resembled those of the Florideae, and of the *Dactylum* recorded by de Bary.

A. Meyer ('96) has also examined the Fungi from this standpoint quite independently of Wahrlich's publication, and later ('02) published an extended account of his researches on protoplasmic bridges and cell fusions in the Fungi, in which he fully corroborates the observations of Wahrlich. Baur ('98), Darbishire ('99), Woronin ('00), Strasburger ('01), and Kienitz-Gerlöff ('02), and others have made more or less extensive examinations of the protoplasmic bridges in various Fungi and lichens, and all noted their existence.

It is aside from the purpose of this paper, however, to review the literature on this subject, except in so far as it touches the Laboulbeniaceae, the only account of which is given by Thaxter ('96). Concerning protoplasmic bridges in the Laboulbeniaceae, Thaxter offers the following: 'The protoplasm of adjacent cells, the origin of which is the same, is connected by a strand of the same substance, which passes from one cell to the other through a well-marked perforation of the cell-wall, the connexion being demonstrated with great ease by treatment with potash and subsequent staining (Pl. III, Figs. 11-12; Pl. II, Figs. 16-18). In many instances, also, it may be seen in the living plant without the use of reagents. This protoplasmic connexion is found in all the cells, including those of the trichogyne, when this organ is multicellular. In many cases in which the cells had been separated by potash, and the connecting protoplasmic strand stretched between them, I have seen a slight enlargement like that indicated in Fig. 12, Pl. III, recalling the similar structure through which the strands of protoplasm pass in the Florideae. I have, however, been as yet unable to determine its exact nature.'

Judging from microtome sections of the forms described in this paper, the thickening to which he refers may be the middle lamella, together with the granular accumulations to be found on both sides of it. The rather violent treatment of gross material with potash, followed by maceration, might very well tear out a portion of the middle lamella along with the strands. In this connexion Kienitz-Gerlöff's ('02) 'Neue Studien über Plasmodiesmen' are of interest, as they deal with the bridges of the Florideae.

He was able to verify the observations of Wahrlich and Meyer on

the Fungi, but, surprisingly, was not able to satisfy himself as to the existence of uninterrupted protoplasmic bridges in the red seaweeds, a condition that seems so patent from a low-power examination of almost any filamentous member of the group. Indeed, he doubts the existence of bridges even in such a form as *Polysiphonia*: 'Gleichgültig, ob man die Pflanzen ohne oder nach mehrtägiger Behandlung mit H_2SO_4 oder $ZnCl_2$ untersucht, die beide so gut wie unwirksam sind, gleichgültig ob man mit Jod, Methylviolett oder Hämatoxylin färbt, so findet sich in den meisten Fällen, auch an den günstigsten Objecten, wozu die Haare und einfädigen Zweige gehören, in den Tüpfeln zwischen den Zellen scheinbar eine deutliche Schliesshaut, welcher beiderseits eine halblinsenförmige, dunklere Protoplasmamasse angelagert ist, oder es liegt in den Verbindungen ein stark lichtbrechender Körper, über dessen Natur ich mir nicht ganz klar geworden bin. Mitunter gelang es mir freilich, ihn durch Behandlung mit Eau de Javelle zu entfernen, was für seine protoplasmatische Natur sprechen würde, aber diese Flüssigkeit löst allmählich die Zellen überhaupt aus ihrem Zusammenhange. Manchmal ist dieser Körper auch deutlich doppelt conturirt und linsenförmig. Ab und zu scheint freilich eine ganz homogene Verbindung zu bestehen, die so oft beobachtete Existenz jenes Körpers hat mich jedoch äusserst misstrauisch gemacht. Andererseits ist es auch möglich, dass die Erscheinung auf denselben Ursachen beruht, wie die so oft beobachtete Bildung des Knöpfchens in den Plasmodiesmen der höheren Pflanzen.'

My observations on gross material, stained and unstained, coincide with those of Thaxter, but after an examination of hundreds of microtome sections of *L. chaetophora* I am driven to nearly the same conclusion as that reached by Kienitz-Gerlöff for the Florideae.¹ The pits are easily found, and, as in the Florideae, never more than one in a septum; and so far as could be judged none of these is the result of fusions between cells such as Meyer has described in detail for other Fungi. But the middle lamella or 'Schliesshaut' stretches across the bottom of the pit, as shown in Pl. XXXVII, Figs. 7 and 20, and there is considerable doubt as to the extent to which it is perforated. In a few instances, but very few, I have found a coarse strand of protoplasm, differing in no way from the cytoplasm of the protoplasts, passing from cell to cell, but these are undoubtedly exceptional phenomena.

The pits in the thin walls of young cells and of the inner sheath of perithecial cells are shallow and inconspicuous, but in thick septa are deep, always extending in as far as the middle lamella (Fig. 7). The cytoplasm dips into the pits, and, in the case of the deep ones, forms a coarse strand interrupted only by the middle lamella. The cytoplasm occupying

¹ Connolly's observations on *Rhabdonia globifera* ('11) are not in accord with those of Falkenberg ('01) and Kienitz-Gerlöff ('02), for he reports a large strand of cytoplasm connecting contiguous protoplasts. His material appears to have been treated with strong solutions on the slide.

the pit is usually clearer and more structureless than the rest of the cytoplasm. One of its most striking features, and one by means of which the position of the protoplasmic bridges can always be located, is the presence of rather coarse, deeply staining granules (a brilliant red with Flemming's triple stain), some of which are closely in contact with the 'Schliesshaut' (Fig. 7). These are probably the 'metachromatic' granules observed by Claussen in the mycelium of *Ascodesmis* and by McCubbin in *Helvella*.

In favourable preparations the middle lamella or 'Schliesshaut' can be seen to be perforated by a very fine pore, and in some instances there is the appearance of several minute perforations. But that there are no large openings to accommodate such strands as are obtained by the maceration of entire plants, or that permit of the uninterrupted continuity of the strands that occupy the pits, is absolutely certain. A possible exception is to be made in the case of the appendages, for as judged from end views of their septa, which are easily obtained in almost any section, each is occupied by a comparatively large open pore (Fig. 1). Such an angle of observation is not favourable for the determination of the presence or otherwise of the thin middle lamella, but an occasional lateral view also gives the same impression. The black ring around the septum interferes seriously with observations from the side. The absence of the red granules characteristic of the bridges in the body of the plant lends further support to the possibility that the septa of the appendages are coarsely perforated, and that the protoplasmic bridges here are coarse strands of cytoplasm.

That there is a more or less definite organization of the cytoplasm related to the pitting of the septa is frequently evident, but will be referred to in another connexion.

THE PROTOPLAST.

The protoplasts are typically monoenergid, each cell possessing a single relatively large nucleus. Occasionally in older plants the nucleus in some of the cells may undergo one or more mitotic divisions. This may take place in the cells of the receptacle, especially in the larger ones, and in the cells lining the perithecium, but never in the foot, appendages, or spores. Fig. 19 illustrates an example of a large cell from the receptacle in which as many as ten nuclei were counted, all of uniform size and organization. Where such a proliferation occurs, the number varies from two to ten. Amitosis has not been seen in any instance.

The somatic nuclei are characterized by a large nucleolus and discrete masses of chromatin. There is no reason for believing that any portion of the chromatin is held by the nucleolus, for it is readily distinguishable in the resting nuclei in well-fixed preparations. The chromatin is especially abundant in the nuclei of the appendages. The nucleolus and chromatin

stain bright red and the linin network blue. The chromatin is sometimes in shapeless masses, but most frequently in longer or shorter threads or granules (Fig. 1). Whether or not there is a definite number I cannot say. Now and then only two chromatic elements can be counted; at other times four, while in other instances there seem to be more. Nor can I satisfy myself that they bear any relation to a central body, or, indeed, that a central body is a constant concomitant of the nucleus. It may be. Not seldom a granule that might be interpreted as such lies in contact with the nuclear membrane in the cells of the appendages, but as there are other red-staining granules in the cytoplasm it is difficult to say just what this particular one really is.

Mitotic figures in the hyphae of several Ascomycetes have been observed by a number of cytologists, excellent illustrations, for example, being given by Fraser ('08) for *Humaria*, and Schürhoff ('07) for *Penicillium*. Faull ('05) and Dangeard ('07) have noted them in the spores.

The cytoplasm is finely granular or reticulate, but usually in the larger cells it is of a coarse spongy or reticulate structure. Oil bodies in *L. chaetophora* and *L. Gyrinidarum* are rare, but abundant quite highly refractive granular inclusions are of common occurrence. They may be small or quite large, and often regularly curved. Various sizes are shown in Figs. 3-6. They appear to be formed in the meshes or cavities of the protoplasm. The nature of these bodies was not determined. They make their appearance as the plant approaches maturity and do not show any especial affinity for the stains that were employed, though taking up the safranin and gentian violet to a limited extent, in contrast to the cytoplasm, which has a greater affinity for the orange G. Thaxter ('96) records an interesting fact in this connexion, namely, 'that the contents of the living cells consist of rather dense granular protoplasm, in which, as a rule, certain highly refractive spherical oily masses are conspicuous. In some instances these masses are few in number, one or more of them being often very large (Pl. V, Figs. 4 and 5), while again they may be more numerous and uniform in size, completely filling the cells, as in the case of *Laboulbenia Harpali*, *L. Philonthi*, and many others.' Whether or not the bodies I have described are to be identified as the smaller ones detected by Thaxter I cannot say, but it seems not improbable that they are the same.

There is still another feature to be mentioned, to which reference has already been made, that is, the presence of protoplasmic strands running out from the pits in the septa and from the nuclei. These phenomena have been repeatedly observed. Fig. 20 illustrates a case in point. The strands passing out from a pit in one of the cells intersect those coming from the pit in the opposite septum. The strands are slightly darker, as if of denser substance than the rest of the cytoplasm, but at the points of intersection are several brightly red-staining granules, such as are to be found in the

bottoms of the pits. In another cell the 'fibrils' are shown passing around the nucleus on their way across. It was thought at first that possibly these strands of cytoplasm connected the nuclei of contiguous cells in some way, such for instance as Strasburger found to be the case with pairs of nuclei in the same cell in *Penicillium* (Strasburger ('02), Schürhoff ('07) *contra*), but Fig. 20 lends no support to such a view. It is true, nevertheless, that cytoplasmic fibrils can in some instances be traced from the pits to the nucleus, and that in degenerating cells they appear to be the most persistent parts of the cytoplasm.

That the nucleus bears a very evident relationship to the organization of the surrounding protoplasm at times has been dealt with in some detail by the writer in an earlier paper (Faull, '05). *Hydnobolites* and *Sordaria* furnish indubitable evidence of this contention.

ANTHERIDIA.

Careful and repeated search has been made for antheridia, but no organs resembling either the exogenous or the endogenous types have been discovered in either *L. chaetophora* or *L. Gyrinidarum*. So far as our knowledge goes these species afford examples of forms that have lost their antheridia. Belonging, as they do, to a genus characterized by conspicuous flask-shaped simple endogenous antheridia, it is not likely that they can have been overlooked, though that is not outside the range of possibilities. The cytology of both types of antheridia has been studied in other forms, and an account of the phenomena observed will be very shortly published.

PROCARP.

The procarp has its origin as a uninucleate terminal cell of a lateral branch of the receptacle (Pl. XXXVIII, Fig. 21). The two basal cells of the branch represented in Fig. 21 are daughters of the obliquely septated 'primordial cell of the perithecium', and give rise to the perithecium proper.

The course of development of the perithecium has been very carefully worked out by Thaxter, and so need not be recapitulated in detail here. It may be stated, however, that transverse sections wholly verify his statements that the number of rows in both the outer and inner walls is four, and that the rows of the two walls alternate with one another (Figs. 33-6). The inner is of later origin than the outer; in fact, does not appear until the latter is nearly complete and the procarp fully formed. Both are clearly outgrowths of the basal cells of the perithecium. They have been repeatedly seen in longitudinal sections in all stages of development, and their protoplasmic connexions with the basal cells demonstrated (Fig. 25).

The mature procarp consists of three parts, the carpogonium, the trichophoric cell, and the trichogyne. The trichogyne is very highly developed in *L. chaetophora* and *L. Gyrinidarum*. It is an elaborately branched, frequently septated structure consisting of uninucleate cells (Figs. 30, 31). It, too, has been figured and described by Thaxter, and little further can be added.

The possible functions of trichogynes that appear no longer to serve as receptive organs of spermatia have been recently fully discussed by Vuillemin ('07) and Brooks ('10), but so far as I know no experimental evidence has been adduced in confirmation of any of them.

The sequence of cell-formation in the carpogenic cell is strictly comparable to that described by Thaxter for *L. elongata*. The trichophoric cell undergoes no further division, though its nucleus as described below may play a very significant rôle. The carpogenic cell divides into three superposed cells, the superior and inferior supporting cells (*s.s.* and *i.s.*) and the ascogonium (*am.*) which lies between them. The ascogonium may again divide transversely, the lower half constituting a secondary supporting cell, while the upper usually divides by an oblique partition into the ascogenic cells (*asc.*) from which the asci (*as.*) bud out. In some plants this division does not take place, so that there may be but one ascogenic cell. Two, however, is the characteristic number, and never more than two have been found in the species here described. Two vertical rows of asci now bud out from each of the ascogenic cells. An account of their further development will be given in a subsequent section, and the cytology of the procarp only dealt with here.

The carpogenic cell is at first uninucleate, a relatively large nucleus with a large nucleolus occupying the centre of the cell (Fig. 22). The trichophoric cell is also uninucleate (Fig. 22). The single, centrally placed nucleus of the carpogenic cell now apparently divides; at all events it is succeeded by a pair of smaller nuclei (Fig. 24). I have not observed its actual division, but the nucleus represented in Fig. 23 appears to be in an early prophase stage. The nucleus of the trichophoric cell very soon moves down next to the carpogonium, as shown in Fig. 25, and undergoes a homotypic mitosis. The central bodies of the spindle are large and disc-like, but it is difficult to make sure of the number of chromosomes. At this stage, or even earlier, the partition separating the two cells disappears. Thus in Fig. 26 there is the appearance of a long single cell in which lie four nuclei, A, B, C, D, enumerating from the bottom up. A and B presumably are daughters of the carpogenic nucleus, C and D of the trichophoric. The lower end of this cell with nucleus A is eventually cut off as the inferior supporting cell, and the upper end with D as a 'restored' trichophoric cell. But it was impossible to determine the exact sequence of septa-formation.

The middle pair, B and C, divide after a short period of growth, and

their division is immediately followed by the separation of the superior supporting cell, which receives two of the four daughters, the other two remaining in what is now the ascogonium (Fig. 27). The two nuclei left in the ascogonium again divide, and a secondary inferior supporting cell is sometimes cut off which likewise appears to be characteristically binucleate (Fig. 28). The remnant of the ascogonium is still binucleate, and it may at once begin to bud off asci, or, as usually happens, first divide into two binucleate ascogenic cells (Fig. 28).

So far no nuclear fusions, nor any indications of such, have been observed.

By this time the perithecium has grown beyond the upper end of the receptacle, over which it curves as shown in Fig. 32. The supporting cells are still intact, but they are beginning to show signs of breaking down. This soon happens, and then the ascogenic cells with their asci come to lie free in the cavity of the perithecium, where they are sustained by the cells lining the perithecium. The latter are thin walled and well nourished. The upper cells lining the perithecium and the canal cells of the neck are crushed by the increasing mass of asci and spores soon after the perithecium has attained its maximum size, and eventually the same fate befalls those in the base of the venter.

A general survey of the Laboulbeniales reveals the fact that the procarp is characterized throughout by the constant occurrence of two cells, the carpogonium and the trichophoric cell. There is always a trichogyne, but it is extremely variable. The trichophoric cell is of especial interest since it is not represented in the Florideae or the Uredineae, and, if represented, is not determinable in any other Ascomycetes. Whether it is to be looked upon as a part of the trichogyne or as a part of a two-celled 'scolecite', its history and functions call for closer scrutiny. In the apogamous species investigated in this paper its nucleus joins forces with that of the carpogonium, a phenomenon quite comparable, without any thought of implying homology, to the initial stages of fertilization in certain Uredineae and possibly in such sac-fungi as *Ascobolus*.

Harper ('96) found that the cells of the scolecite of *Ascobolus* are primarily uninucleate, and that subsequently there is a migration of nuclei from cell to cell through perforations in the transverse septa of the scolecite. Welsford ('07) has fully corroborated his observations. Welsford states that 'the transverse walls of the scolecite are perforated medianly by large circular pores. Pores could not be identified in the earliest stages of development, and it seems possible that they may be of secondary formation. The nuclei with the cytoplasm of the several cells pass through the pores till they reach the ascogenous cell, where they fuse in pairs.' Though the history of individual migrating nuclei was not followed, the phenomena described are suggestive of what takes place in *Laboulbenia chaetophora*.

THE ASCOGENIC CELLS.

The ascogenic cells are binucleate at all stages. The rather large nuclei divide simultaneously prior to the formation of each ascus (Fig. 37). This is a conjugate division: one of the daughters of each of the mother nuclei passes into the young ascus and the other remains in the ascogenic cell. The pair left in the ascogenic cell immediately begin to increase in size, and with the advent of the next ascus undergo another division. The divisions of the nuclei are homotypic, and, as has been seen to be the case elsewhere, the central bodies are conspicuous and the chromosomes four in number. In Fig. 39 a metaphase stage is represented in which the chromosomes are especially large and somewhat scattered, so that the count could be made with certainty.

The protoplasm of the ascogenic cells, as of the procarp, is dense and very finely granular, and exhibits a greater capacity for stain than the cells of the perithecium and receptacle, so that they always stand out clearly differentiated from the rest of the thallus.

The ascogenic cells of the Laboulbeniaceae have seemed to be unique among the Ascomycetes in respect to the limited and constant number for each species, and in respect to their capacity for giving origin to an unlimited number of asci. The number of ascogenic cells in *Amorphomyces* and two or three other genera is one, in *Laboulbenia* and several others two, in *Stigmatomyces* four; in *Haplomyces* there are eight, and in *Polyascomyces* there are thirty-two or more. This fixity of number is paralleled, however, by such genera as *Sphaerotheca*, in which there is a single ascogenic cell in every fruiting body, and as to the unlimited capacity of the ascogenic cells for ascus production I have found examples not at all uncommon in practically every order. The cytological details in these examples correspond to those in *Laboulbenia* in that a series of conjugate divisions takes place in the ascogenic cell in relation to a corresponding budding off of asci. Brefeld ('74) long since cited what has often appeared exceptional in the case of *Penicillium*, but theoretically at least his claims may be regarded as perfectly valid. The investigations of McCubbin ('10) and Brown ('10, '11) have shown the same thing expressed in another way for *Helvella elastica*, *Leotia*, and *Lachnea*, namely, that the nuclei of a potential ascogenic cell may undergo many conjugate divisions, and eventually give rise to many asci.

The common underlying principle is that of conjugate divisions, which is undoubtedly a character of the Ascomycetes. In *Laboulbenia* the apparatus involved is extremely simple, since the ascogenous cells correspond to the entire system of ascogenous hyphae and part of the female apparatus in most other groups. They are characterized by

similar series of conjugate divisions, but undergo no considerable growth, no branching, and no septation.

THE ASCUS.

Thaxter was the first to discover that the spores of the Laboulbeniales are invariably borne in sacs, and constantly to the number of four, or in a few species of eight. On these grounds he has unequivocally maintained their ascigerous nature. It has only remained to examine the spore-sacs cytologically (Faull, '06, '11) to prove the correctness of his view, and to prove beyond question that they possess all the essential features of asci.

They begin as basipetally arranged folds or outgrowths of the ascogenous cells. They are never septated off from the latter, but their bases, which at first are very broad, gradually contract until finally the cytoplasmic connexion is broken. In *Laboulbenia chaetophora* the walls of the older asci are not always dissolved nor are the asci always completely sloughed off from the mother-cell (Pl. XXXIX, Fig. 41), though both are common phenomena and are said by Thaxter to be characteristic for the group.

At first small, the ascus grows to a relatively large size, during which time the definitive nucleus also increases enormously in bulk. The cytoplasm is finely granular and fairly uniform throughout. When mature there is a slight vacuolation in both the upper and the lower parts of the ascus (Fig. 51), and sometimes a few insignificant granular inclusions make their appearance.

Two nuclei which we may with good reason assume to be lineal descendants of the pair that occupied the carpogonium in its later stages of development enter the young ascus and fuse with one another. Their chromatin is ordinarily distributed irregularly throughout the nuclear cavity in the form of a thread, an arrangement which persists for some time after fusion (Figs. 43-5). Eventually a synaptic contraction sets in (Fig. 46) and the threads are matted to one side of the nucleus, though their connexion with the nucleolus is probably maintained.

The synaptic stage is succeeded by one in which the threads are again loosely arranged, but this time much more regularly and with a more or less obvious relation to the nucleolus and an appearance of being paired. These features are clearly illustrated in Figs. 47 and 48. It will be seen, too, that there is a more or less regular system of achromatic threads radiating out from the nucleolus and traversing the entire nuclear cavity.

The next stage is characterized by a very marked diminution in the apparent amount of chromatin, and by what may possibly be interpreted as a second contraction. Figs. 49 and 49*a* represent the same nucleus from two consecutive sections, and are designed to show the entire amount and

disposition of the chromatin. It will be observed that the volume has diminished, and that the threads are thicker and more irregularly arranged.

Up to this time a central body has not been conspicuous, though probably present as indicated in Fig. 44. But now it can be found without great difficulty, and as shown in Fig. 50 the chromatin threads are apparently connected with it. Such a phenomenon was first discovered by Harper ('05) in *Phyllactinia*. It will again be noted that the polarity of the nucleus with respect to the nucleolus is still maintained, in which phenomenon the linear threads already described may play some part, since they appear to converge at the side opposite the nucleolus and there stand in connexion with the central body. This stage (Fig. 50) is immediately prior to the first mitosis, and constitutes a part of its prophase. The number of chromatic threads is clearly four, and these are identical with the four chromosomes to be seen on the spindle.

During all this time the nucleolus has been a very conspicuous organ. Each of the initial pair of nuclei contributed a large nucleolus, and these fused to form that of the definitive nucleus. Its growth throughout is steady and remarkable. In the later stages it becomes quite vacuolate and at times even somewhat honeycombed. During mitosis it steadily diminishes in size, but a portion of it still remains almost up to the time the daughter nuclei begin to form (Pls. XXXIX and XL, Figs. 42-54).

The first spindle is in many respects a very interesting structure. It is clearly intranuclear and is terminated at both ends by an extranuclear disc-shaped central body, evidently the products of division of the pre-existing one already noted, from which stream out long astral rays. There are four elongated and curved chromosomes of unusual size for a fungus (Figs. 51-2). The achromatic portion of the spindle consists of two sets of fibrils, such as I have described in *Hydnobolites*, &c. (Faull, '05)—a central system of many rather closely packed threads, and an outer mantle system. The mantle rays bear the chromosomes and appear to be responsible for their transport to the opposite ends of the spindle. After the chromosomes have reached the poles of the spindle the central fibrils experience a great elongation, carrying the daughter chromatic elements far apart (Pl. XL, Fig. 54). In some instances, not figured, the remains of this central spindle have been observed subsequent to the stage represented in Fig. 54, the fibres no longer separable, the whole thing resembling a coarse sharply defined dark cord, and irregularly wavy or crooked as though it had lost its former tension and was incapable of contraction. The daughter chromosome masses had probably moved slightly towards one another after the central spindle had fulfilled its function. This wide separation of the daughters of the definitive nucleus is a characteristic phenomenon of the first mitosis in every order of the sac-fungi.

The chromosomes appear to divide transversely (Pl. XXXIX, Fig. 52) and, as they approach the poles of the spindle, show a tendency to split (Fig. 53). They are not homogeneous, for as seen in cross-section they do not stain uniformly. The centre may be hollow, at all events it is much lighter than the periphery. Fig. 53 presents some interesting features and is interpreted as follows: The chromosome at the extreme right is dividing transversely, the large one in the centre is still entire, the two pieces at the left are segments of the third chromosome, the uppermost is a daughter chromosome splitting, and portions of its sister, also longitudinally split, are on their way to the opposite pole.

The asters in the anaphase stage are even more distinct than earlier. A vacuole gradually forms around each of the chromosome masses, and the daughter nuclei very soon stand out clearly defined.

The second mitosis follows very swiftly on the heels of the first and is essentially different in many details. There is no preliminary synapsis stage, the spindle is sharper pointed, the central bodies are smaller, the chromosomes split longitudinally (Pl. XL, Fig. 55), the spindles are not differentiated as is the first, and there is no subsequent elongation. As a result of this the daughter nuclei lie side by side. Fig. 57 represents a tetranucleate stage of the ascus, showing the two pairs of sister nuclei.

The four nuclei now pass through a brief resting period, during which the chromatin is in the form of threads, and possibly in connexion with the persistent central bodies (Fig. 57).

During the prophase of the last mitosis the relation of the chromatin to the central bodies is more evident (Fig. 58). Presumably the latter divide, constituting the poles of the spindle on which four chromosomes, corresponding to the four threads of the prophase, take up a position in the equatorial plane (Fig. 59). It was not possible to determine just how the chromosomes divide, but they do divide, and there is no reduction in their number (Figs. 60, 61). Nor was it possible to detect a differentiation in the spindle, which, whatever its constitution, is extensible, since the daughter nuclei are carried far apart (Fig. 62). The astral rays are long and tenuous. They are represented in Fig. 62 just before the spores are delimited, and again in Figs. 63 and 64 after this process is completed. That they do not fuse laterally and do not form a part of the limiting membrane is perfectly obvious, even were such a phenomenon as lateral fusion physically possible.

The spores are delimited progressively, beginning always at the central body. Relative to the process nothing more can be added than has already been described by the author and corroborated by Fraser and Brooks ('09) and Brown ('11), and in part by Dangeard ('07). Faull ('05): The spores are delimited 'by the differentiation of a limiting layer of hyaline or finely granular layer of protoplasm that begins adjacent to the

centrosome and continues progressively until completed at the opposite pole.' Possibly there is a cleavage in this layer resulting in the plasma membrane of the spore and a corresponding membrane lining the cavity in which the spore lies. 'The astral rays never appear to fuse, as is stated by Harper to be the case in *Erysiphe* and *Lachnea*.' Fraser and Brooks ('09). These authors describe 'an outward flow of some substance which emanates from the centrosome' in *Ascobolus* and *Lachnea*. 'It has already been suggested', they add, 'that this substance is not improbably an enzyme.' This layer is the seat of a cleavage resulting in the two membranes mentioned above. 'We have, however, obtained no evidence of a lateral fusion of astral rays to form a membrane such as Harper describes, but we hold rather that the rays indicate rather the direction of flow of altered substance from the centrosome.' Berlese ('99) first suggested the possible directive action of the astral rays in laying down the limiting plasmatic spore membrane. 'Il cinoplasma determina poi la formazione dello strato parietale plasmatica dell' ascospora, ed individualizza quindi questa il sen al trofoplasma.' Dangeard ('07) could not differentiate the astral rays in his preparations of *Pyronema*, but he did detect a homogeneous sheet of material that issued from the central body and gradually delimited the spore. 'Il y aurait peut-être lieu de modifier légèrement la description classique donnée par Harper du mode de formation des ascospores dans l'asque et du rôle des filaments de l'aster; ici nous n'avons pas vu de filaments, mais seulement cette substance homogène chromatique qui enveloppe le noyau progressivement.' Brown ('11) affirms that the astral rays of *Lachnea* do not fuse to form the limiting membrane of the spore, and that they constitute no part of it. He also finds a membrane lining the cavity in the epiplasm in which the spore lies. Evidence from these independent sources indicates that Harper's interpretation of the part played by the astral rays of the last mitosis was incorrect. Moreover, from a physical standpoint Harper has affirmed an impossibility, as these long astral rays swinging down and out separate farther from one another (I refer to adjacent rays on the same side of the central body) rather than come into contact. Were they all laid side by side and welded into a ribbon they are so few and so tenuous that they would form a very small portion of the entire protoplasmic membrane of the spore. There is unanimity on one fact in this connexion described by Harper, namely, that the limiting membrane is formed progressively, but this feature is not more important than the determination of the origin of the membrane, as an exact knowledge of the latter must influence our conception of the homologies and phylogeny of the ascus itself.

After the spores are delimited in *Laboulbenia*, the flask-shaped nucleus continues to elongate until the neck is extremely attenuated (Fig. 64). In fact, the venter almost comes into contact with the opposite end of the young

spore. The astral rays are observable up to this time, and in older stages lie much farther inward towards the nucleus and away from the limiting membrane than in the earlier stages, or for that matter in any other asci I have yet seen. They have been found here even more or less twisted about the attenuated neck of the nucleus (Fig. 64). These phenomena in themselves, even were lateral fusion of the longitudinal ribs of a globe physically possible, which is certainly not the case, are sufficient evidence that they do not fuse to form a protoplasmic membrane. The cavities in which the spores lie also appear to be lined by a protoplasmic membrane. The central body finally loosens its connexion at the older pole of the spore and takes up its position on the surface of the now spherical nucleus (Figs. 65 and 69).

The long axes of the spindles of the third mitosis lie in the long axis of the ascus, consequently the asters are directed towards the upper and lower ends of the ascus respectively. Since there is no relative change of position during spore-delimitation it is possible to state with almost absolute certainty that the lower daughter nucleus of each spindle functions as a spore-former. That they lie approximately side by side in two pairs is merely a natural consequence of the disposition of the four nuclei of the second generation (Figs. 57 and 63). The upper daughter nuclei, on the other hand, initiate no spores, and pass at once to the upper end of the ascus (Fig. 65), where they eventually disintegrate.

SPORES.

From the first the spores lie with their long axes parallel to the long axis of the ascus. Almost spherical at the outset, they become broadly elliptical, then continuously more narrowly elliptical until their normal mature form is attained (Figs. 63-6). During the earlier stages of growth the nucleus remains at the upper or younger pole of the spore. At the same time chromatin is distinctly aggregated in proximity to the central body, simulating in a more or less striking manner the phenomenon of synapsis. Later the nucleus moves down well past the middle of the spore and there undergoes an ordinary homotypic mitosis, the chromosomes numbering four (Fig. 70). The spindle elongates somewhat and a thin septum is quickly formed between the daughter nuclei, dividing the spore into two cells. Whether or not a simple plate is formed progressively from the periphery of the spore inward I cannot say. Fibrils, possibly the spindle threads, may be seen passing from the nucleus to the young septum, and often a small plug lies at the centre of the plate, such as is represented in Fig. 67. Presumably there is a protoplasmic bridge, but only special refined methods would bring it out. The spore now completes its growth, and in addition to the ordinary wall, finally clothes itself with a gelatinous sheath which is

strongly developed at the upper end, the future basal cell of the plantlet into which the spore will grow should it find favourable lodgement on a suitable host.

DISCUSSION.

One immediate result of these investigations has been the confirmation of Professor Thaxter's classification of the Laboulbeniales as true Ascomycetes. This recognition is based on the characters of the spore sac, for the only positive diagnostic feature that distinguishes the Ascomycetes from other higher fungi is the ascus. That organ has been submitted to a very searching and successful examination during the past few years, so that our conceptions now concerning it when it is placed in comparison with the phycomycetous sporangium, the floridean tetrasporangium, or any other spore-bearing cell are no longer hazy. Every research has testified to the constancy of its nuclear heritage, and to the sureness with which certain characteristic cytological changes recur in the course of its development, all of which in combination suffice to distinguish it from every other spore-bearing organ known in the organic kingdom. Thus the unfailing inheritance of a pair of nuclei, the regularity of their fusion in the young ascus, the minutiae of the successive three mitoses, and the details of spore-delimitation by a remarkable method of free cell-formation are uniform throughout the group and without a parallel in any other. Precisely the same phenomena characterize the spore sac of the Laboulbeniales, in fact so exceptionless as to throw no new light on the origin of the ascus. This faithful cytological similarity, therefore, affords conclusive proof that the Laboulbeniales can no longer be counted among the doubtful Ascomycetes, or that the Laboulbeniomycetes of the Engler system can be maintained as a class, or that they can rank other than as an order or suborder of the sac-fungi. Unquestionably, in accordance with prevailing definitions, the Laboulbeniales, Thaxter, are rightly regarded as Ascomycetes and as a suborder of the Pyrenomycetes.

Studies on the cytology of the Laboulbeniales have still another and very special interest in that they promise material additions to our knowledge of the sexuality of the Ascomycetes. This is a fascinating subject on its own account, and has also a wide bearing on the difficult problem of the phylogeny of the sac-fungi.

There is a strong tendency at the present time to regard the Ascomycetes in point of sexuality as unique among plants and animals, for it is commonly believed that their sexual phenomena comprise two successive nuclear fusions, one in the female gametangium or its substitute, and the other in the ascus. This, if true, would involve a quadrupling of the chromosomes in the fully fertilized egg and a subsequent double reduction. There is likewise a tendency to deny the existence of normal series of conjugate nuclear divisions in the Ascomycetes, though the subject has not

been more than superficially investigated. Turning to the species described in this paper it will be seen that the observations noted do not bear out either of these views. The fusion of the nuclei in the young ascus is the only nuclear fusion found in the life cycle; there is but one meiosis; and conjugate divisions play an important part.

Relative to the problem of the sexuality of the Ascomycetes it is becoming increasingly obvious that the phenomenon of conjugate divisions must be given serious consideration. The regularity of their occurrence among the Laboulbeniales is certain, and there is a growing body of evidence pointing to the generality of the phenomenon throughout all but one or two other subdivisions of the sac-fungi. That this feature has either been inherited from an earlier stock, or that it has been evolved within the Ascomycetes themselves, is self-evident. In either case, it would not be wholly unexpected to find occasional reversions to the more primitive procedure of a fusion of gamete nuclei directly following the conjugation of sexual cells. Such fusion nuclei would be potentially capable of at once forming spore-nuclei. It is understandable that sometimes, as Claussen asserts is true in *Pyronema*, there might be nothing more than pseudo-fusions in the gametangium, the actual fusions taking place normally in the asci. Such reversions would explain the recorded instances of fusion in the female gametangium, and the fallacy of assuming—what has never been demonstrated—that the sexual act comprises two successive nuclear fusions. The same tendency would also account for pseudo-fusions. In view of the need of research on the nature and extent of conjugate divisions in the Ascomycetes, especially because of the light an exact knowledge of this feature will throw on the problems of their sexuality and phylogeny, I venture to review the field and to explain the grounds taken above at greater length.

Cytological investigations on the higher Fungi in recent years have uncovered the interesting and universal phenomenon of a fusion of two nuclei in the spore mother-cell. An even more remarkable fact has been established for all but the Ascomycetes in this connexion, namely, that the fusing nuclei belong to two distinct lineal series the members of which have lived side by side in pairs, dividing conjointly without fusion for many generations.

Dangeard ('93), Sappin-Trouffy ('93 and '96), Blackman ('04), Christman ('05 and '07), Blackman and Fraser, ('06), and Olive ('08) have cleared the ground in the case of the Rusts. They have shown that a binucleate phase begins with the migration of a nucleus from one cell into another at a definite stage in the life-history, and that the progeny of these initial pairs accompany one another uncombined up to the teleutospores, where fusion ensues, followed at once by a reduction division. These events indicate that a curious type of sexuality has been evolved in the Rusts, one characterized by a long

period of vegetative activity between the initial and the final phases of the sexual act.

Maire ('00-'02), Harper ('02), and Nichols ('04) have investigated a number of species of Autobasidiomycetes and have found that the cells of the lamellae of the Agaricaceae, and of the entire fruiting body and even part of the mycelium of some other forms, are binucleate, though so far no one has determined where or how this condition arises. Fruitful investigation is rendered difficult in most forms because the cells which might be expected to contain two nuclei are ordinarily multinucleate and the number of nuclei is not at all constant. Maire asserts the belief that where more than two occur in such cells the increased number is due to an amitotic multiplication of an original pair. The nuclear phenomena in the basidium have been studied by Wager ('93), Dangeard ('93), Maire ('02), and Fries ('11), and have been found to closely correspond to those in the teleutospore. Thus there is reason to believe that the same type of sexuality is expressed by the Autobasidiomycetes as by the Rusts.

The problems presented by the Ascomycetes have appeared at first sight less complicated in some respects than in the Basidiomycetes, owing to the existence among them of more or less conventional and in some instances apparently functional sexual organs, and the failure to recognize conjugate nuclei. A closer examination has revealed the fact, however, that a nuclear fusion takes place in the ascus just as it does in the basidium, and that the sexual organs exhibit a more perplexing multiplicity of forms than in any other group of plants. Several botanists have reported, too, that they have seen gamete nuclei fusing in the oogonium or its equivalent, and there is increasing evidence of the occurrence of characteristic conjugate nuclei. Indeed, the ensemble of facts has appeared so difficult of reconciliation that so far no view has been advanced that has not called into question the actuality of the existence of some one of them.

Harper ('96, '05), seconded by Blackman and Fraser ('06), Fraser ('08), and Claussen ('05), has contended that there are two successive nuclear fusions within the limits of a single life cycle, one in the female gametangium, the other in the ascus. They have actually seen both—at least, so they have interpreted what they have seen—but, granting the correctness of their interpretation, it is pertinent to insist that their claim that both occur in the same life cycle is a pure assumption. If their contention be correct, then, according to prevailing views regarding chromosomes in conjugating nuclei, there must be a quadrupling of the chromosomes with the second fusion, and in consequence a compensatory double reduction. Harper ('05) has consistently accepted this apparently inevitable theoretical deduction, and locates the site of the two reductions in the ascus. He considers that the double reduction is effected by the three mitoses in the ascus—an alluring hypothesis because of the obviousness of one meiosis and the universality of

the three mitoses. Unfortunately—and here is the crux in this theory, the one direct proof that would establish beyond cavil the correctness of Harper's assumption of two nuclear fusions—he could find no indications of a second meiosis. The claim that there is such is merely the theoretical deducing of one assumption from another. Fraser ('08) and her co-workers, it is true, state that they have detected in certain forms indications of the theoretical second reduction, but Guilliermond ('11) has examined some of the same species and has seen nothing of them. Guilliermond, Dangeard, Maire, Brooks, the author, Claussen, as also Harper, have found no second reduction in the many forms examined by them, and the search has been by no means perfunctory.

Further, it may be added that though the generality of the occurrence of eight spores in the ascus is striking it is not exceptionless, and is no more remarkable and perhaps no more significant than the regularity with which the Laboulbeniales produce two-celled spores, or the Fucaceae eight-nucleated oogonia, or the Angiosperms eight-nucleated embryo-sacs.

While Harper's interpretations have received very general acceptance, there have been dissenters. Most notable among them is Dangeard, who has maintained on the strength of his own researches that the primary sexual organs, except in *Eremascus* and *Dipodascus*, are no longer functional, that they have been abandoned, so to speak, and that the sexual phenomena have been transferred to the ascus, in which the only nuclear fusion in the life cycle takes place. The gamete nuclei, he affirms, must then come from vegetative cells of the thallus, presumably from the peripheral cells of the ascogenous hyphae, and may travel together for one or more generations, dividing conjointly before fusing in the ascus. It seems strange that Dangeard has never observed a fusion of antheridium and oogonium in some of the forms studied by him, for example, *Sphaerotheca*, *Erysiphe*, and *Pyronema*, in view of the joint testimony of several seasoned botanists that such exist. Having failed to do so, however, he has unequivocally challenged the reliability of the observations of Harper, Claussen, *et al.*, in respect to their assertion that they have observed these phenomena.

Maire ('05) has followed Dangeard's lead, and deems from what he has observed in *Galactinia* (cp. also Guilliermond ('05) on *Acetabula leucomelas*) that conjugate nuclei, or in his own terminology *syngarions*, are characteristic of the Ascomycetes, and hence that there is a more evident parallelism or homology throughout the Eumycetes than has been hitherto recognized.

Finally, Claussen ('07), after examining *Pyronema*, has burned his bridges behind him, and in a paper that bids fair to become a classic has championed an hypothesis similar to Maire's and Dangeard's, except that he locates the origin of the gamete nuclei that finally fuse in the ascus in the gametangia. He has observed migrations of nuclei from the antheridium into the oogonium and a pairing up of the nuclei in the latter, followed by

what he takes to be conjugate divisions. What have been designated nuclear fusions in the oogonium he construes to be pseudo-fusions, for he finds a less intimate association between the pairing nuclei after they have entered the ascogenous hyphae. He is thoroughly satisfied in his own mind that all of the reported nuclear fusions in the gametangia (Harper ('96, '05), Claussen ('05), Fraser ('08), &c.) have been misinterpretations of what were really pseudo-fusions—an explanation that lacks demonstration and hence open to some objections.

A perusal of the literature of the last decade or more on this subject cannot but occasion amazement at the enormous amount of energy expended in the effort to determine whether or not nuclei fuse in the female gametangium, and equally so at the meagre positive results that have been attained. Very probably some actual fusions have been observed, but the number is small, and if the theory of synkarions holds they may well be regarded as reversionary. On the other hand, the question of conjugate divisions has not been in the minds of most investigators, and so the subject has not been approached with anything like the same vigour from this angle. In spite of that, part of the ground in that direction has been cleared, and with promise that further effort will lead to a final solution.

The first step in this connexion has long since been taken, for it has been proved again and again that the nuclei fusing in the ascus are not sister nuclei, but that they are daughters of the mother nuclei that undergo a simultaneous division. In other words, they afford an instance of conjugate division recurring with unfailing certainty at a definite stage in the life cycle, and which every one admits. Maire ('05) and Guilliermond ('05) have likewise shown that both pairs of this division remain together in *Galactinia* and *Acetabula*, and that both are presumably capable of fusion. Some attempts to trace the ancestral lines of these nuclei farther back have been made, but as yet, with the exception of Claussen's studies on *Pyronema*, any certain knowledge is fragmentary. Massee ('05) has pointed out that binucleate cells are characteristic of thalli of various Ascomycetes. McCubbin ('10) in a much more definite manner has shown that in *Helvella elastica* there may be several conjugate divisions prior to fusion. Brown ('10, '11) reports the same features in *Leotia* and *Lachnea*. My own observations indicate that not only is this true of *Helvella*, but it is demonstrable for a number of forms belonging to the Exoascaceae, Helvellaceae, Pezizaceae, Plectascaceae, and Pyrenomycetaceae, including the Hypocreales, Sphaeriales, and Laboulbeniales. The repeated proliferation of hooks and the fusion of terminal and antepenultimate cells as observed by McCubbin, and almost simultaneously by Brown, is not an abnormality, as Carruthers ('11) would have it, but is an exceedingly common phenomenon in the Helvellaceae and Pezizaceae. Nor are conjugate nuclei restricted to the penultimate cells. Often, especially in the Plectascaceae and Pyrenomycetaceae, but also in some of the Disco-

mycetes, they occur most abundantly in terminal cells, from which any number of asci may spring, or from other cells which may or may not be definitely located.

In view of these data I am thoroughly convinced that any investigations on the sexuality of the Ascomycetes and any phylogenetic scheme drawn up for the group must take cognizance of the phenomenon of conjugate nuclei or synkarions. It is admittedly manifest in the peripheral cells of the ascogenous hyphae throughout the class, except in a few forms that are marked by great simplicity. Indeed, it ranks here next in the regularity of its occurrence to the intricate phenomena in the ascus itself, and there is increasing evidence that the nuclear divisions in the ascogenous hyphae are of this type. Once having arisen, it is readily understandable how such a variation so favourable to increased sporogenous productivity from a single pair of gametes would persist and develop in one or several directions. The main difficulty arises in discovering just where the beginning was made. At some stage in the evolution of the group the principle must have been adopted. That is self-evident, for, regardless of differences of opinion as to its use, every one admits that this principle is utilized by all so-called typical sac-fungi. But where are these ancestors to be sought?

Many have held that the Laboulbeniales are the living representatives of the first sac-fungi and that they had their beginnings in the red seaweeds. But this phenomenon of conjugate divisions only adds another specialization to the several of which no hint is given by the Florideae, and we know of no connecting links. It is true that our phylogenetic conceptions of the Ascomycetes are in such a plastic state that it is not inconceivable that delay in the fusion of gamete nuclei might have originated in some family of the Florideae, especially as there are good reasons for believing that this phenomenon has originated independently more than once in the Thallophyta. But in the present state of our knowledge it would seem a more reasonable working hypothesis from many standpoints to look to the less specialized sac-fungi for the progenitors of the group. In them the gametes copulate and at once produce a single ascus. In *Eremascus*, for example, there is a fusion of the gamete nuclei followed by the immediate formation of an eight-spored ascus (Stoppel, '07)). By a division of these nuclei before fusion two asci would have been possible, and by repeated divisions, several; and by the elaboration of a system of *synkarion carriers* or ascogenous hyphae, an unlimited number.

It is, of course, to be borne in mind that, starting with the primitive forms, whatever they may have been, in which the phenomenon originated, several parallel lines have probably been worked out in which advantage of this method of multiplying the reproductive powers has been retained and elaborated. At the same time there would have been other changes of importance, such, for example, as an evolution of the sexual organs in more

than one subgroup, resulting in heterogamous and apogamous conditions of varying complexity. In evidence, every one will admit that the sexual organs are among the most striking diagnostic features of such an assemblage as the Laboulbeniales. Simultaneously or otherwise, types of fruiting bodies would have been elaborated, especially with regard to protective and spore-disseminating adaptations. Obviously, whatever our conceptions of their race history may be, there will be agreement in believing that not one character alone but several have been involved in the evolution of the various subdivisions of the Ascomycetes, though there may be differences of opinion as to which, in certain instances, most importance is to be attached.

SUMMARY.

1. The cell-walls are laminated. The layer just below the general chitinous envelope is frequently differentiated into a fibrillar system by what appears to be a process of localized degeneration.

2. Single pits occupy septa separating cells of common origin. The protoplasmic bridges are typically very tenuous.

3. The protoplasts are monoenergid. In older cells the nucleus may repeatedly divide. Up to ten nuclei have been counted in a single cell of the receptacle.

4. No indications of antheridia in *L. chactophora* or *L. Gyrimidarum* were found.

5. The procarp has its origin as a uninucleate terminal cell of a branch of the receptacle. The procarp consists of a uninucleate carpogonium, a uninucleate trichophoric cell, and a branched and septated trichogyne, each cell of which is monoenergid.

6. After the procarp is mature the carpogonium and trichophoric cell become continuous. Meanwhile the nucleus of the carpogonium is succeeded by two, which are apparently daughters of the carpogonial nucleus, and almost simultaneously the trichophoric nucleus undergoes division. Later a uninucleate trichophoric cell and a uninucleate inferior supporting cell are septated off from the now four-nucleated fusion cell. After further nuclear divisions a binucleate superior supporting cell and sometimes a binucleate inferior supporting cell are cut off. The binucleate ascogonium now begins to bud off asci or divides into two ascogonic cells, each of which contains a pair of nuclei. Up to this stage no nuclear fusions have been observed.

7. The nuclei of an ascogonic cell divide conjointly, a daughter of each passing into a young ascus. This process is repeated at the birth of every ascus. The pair entering the ascus soon fuse.

8. The fusion nucleus divides meiotically after a period of growth. The number of chromosomes is the same as in other mitoses.

9. There are two other mitoses prior to spore formation, and both are homotypic.

10. The spores are delimited by the method characteristic for ordinary sac-fungi. The astral rays do not fuse laterally to form the primary protoplasmic spore membrane.

11. Four only of the eight nuclei, the lower on each spindle, are functional in spore formation, the others soon degenerate.

12. The main theoretical conclusions reached are as follows:—

(1) the Laboulbeniales are true Ascomycetes ;

(2) it is probable that the only nuclear fusion in the life cycle takes place in the ascus ;

(3) conjugate divisions of nuclei constitute a significant phase in the sexual phenomena of the sac-fungi.

DESCRIPTION OF FIGURES IN PLATES XXXVII-XL.

Illustrating Professor Faull's paper on the Cytology of *Laboulbenia*.

PLATE XXXVII.

Fig. 1. Part of appendages of a mature plant of *Laboulbenia chaetophora*. All of the septa except the two uppermost are represented in section. The two in black illustrate the septa as they ordinarily appear, because of the fact that the wall at the periphery of the septum is opaque black in nature and so obscures the inner details. $\times 2,700$.

Fig. 2. The apical cell of an appendage. $\times 2,700$.

Fig. 2a. An ordinary septum from an appendage as seen in face view. The black line represents the peripheral black chitinous wall substance, and the opening in the centre the single 'pore' or 'pit'. $\times 2,700$.

Figs. 3-6. Portions of cells from various parts of the main body of the mature plant, showing the structure of the protoplasm with granular inclusions as it appears in sections. Fig. 3 is from one of the lower and larger cells. $\times 2,000$.

Fig. 7. The ordinary type of pit in the main body of plant. Hyaline cytoplasm and intensely staining granules occupy the depressions. The middle lamella is very finely perforated, if at all. $\times 1,350$.

Fig. 8. A very exceptional instance of a wide open pore from the lower part of receptacle. $\times 1,350$.

Fig. 9. A section of outer wall of a young plant, showing the chitinous covering, the fibrous layer in course of differentiation (the unstippled bars are the unchanged wall substance that later constitutes the fibrils), and the inner laminae streaked here and there by fine dark threads. $\times 2,700$.

Fig. 10. A later stage, showing the fibrils. $\times 2,700$.

Fig. 11. A part of the chitin torn away by the knife and to which several fibrils are attached. $\times 2,700$.

Fig. 12. A bit of the outer wall, comprising the chitinous covering and the fibrous layer, shown in three dimensions. The porous appearance of the chitinous covering is due to underlying transparent fibrils. $\times 2,700$.

Fig. 13. The surface of the fibrous layer immediately in contact with the chitin. $\times 1,800$.

Fig. 14. A bit of the fibrous layer in an early stage of differentiation shown in three dimensions. The portions not stippled are unmodified parts of the layer which later give rise to the fibrils. $\times 1,800$.

Fig. 15. From uninucleate stage of spore; the nucleus in division. $\times 2,700$.

Figs. 16-18. Stages immediately following Fig. 15. In Fig. 18 the septum is complete. $\times 2,700$.

Fig. 19. A multinucleate cell from the receptacle of a mature and probably old plant. $\times 900$.

Fig. 20. A portion of thallus, showing pits in walls and cytoplasmic fibrils. $\times 1,800$.

PLATE XXXVIII.

Fig. 21. Part of young thallus. Uppermost cell is the initial of the procarp. The cells just below give rise to wall of perithecium. $\times 600$.

Fig. 22. Section through a young plant. The outer wall of perithecium is complete; one cell

of the inner wall, which is just beginning to form, is shown at the left. The carpogonium and trichophoric cell of the procarp occupy the axis of the perithecium. $\times 600$.

Fig. 23. A slightly older stage. The inner wall of perithecium is now well on the way. $\times 600$.

Fig. 24. A still older stage, although the inner wall of perithecium is not as far developed as in Fig. 23. The nucleus of the carpogonium appears to have divided into two, and the septum between the carpogonium and trichophoric cell is no longer visible. $\times 1,350$.

Fig. 25. A later stage, in which the trichophoric nucleus is seen in the act of dividing. $\times 600$.

Fig. 26. A later stage. $\times 600$.

Fig. 27. An older procarp. The cells in order from the top down are, trichophoric cell, superior supporting cell, carpogonium, and inferior supporting cell. $\times 450$.

Fig. 28. From the bottom up are the inferior supporting cell, secondary inferior supporting cell, ascogenic cells, superior supporting cell, and trichophoric cell. (Drawn from two sections.) $\times 600$.

Fig. 29. In the axis are to be seen an ascogenic cell, secondary inferior supporting cell, and the remains of inferior supporting cell. $\times 600$.

Fig. 30. Upper end of a young procarp, at the stage represented in Fig. 22, showing trichophoric cell and trichogyne. $\times 450$.

Fig. 31. A combination of Figs. 22 and 30, with the trichogyne restored from other sections of same series, and hence in part conventional. $\times 450$.

Fig. 32. An older stage than in Fig. 28. The young asci have begun to grow out. In the axis, from the upper part down, are the trichophoric cell, superior supporting cell, two asci, two ascogenic cells, secondary inferior supporting cell, and inferior supporting cell. Partly conventional. $\times 600$.

Figs. 33-6 are transverse views of the same young fruiting organ taken at successively lower levels, and designed to show the position of the procarp and the relation of the two perithecial walls to one another. $\times 450$.

Fig. 37. An ascogenic cell in which the nuclei are dividing, and an ascus in which the nuclei have not yet fused. $\times 2,700$.

Fig. 38. An ascogenic cell and four of its asci. $\times 1,800$.

Fig. 39. Nucleus of a spore in metaphase stage. $\times 2,700$.

Fig. 40. Photograph of anal plate of host with two attached *Laboulbenia chaetophora*.

PLATE XXXIX.

Fig. 41. Two ascogenous cells with asci, as seen in a single section. The collapsed walls of asci from which the spores have been shed appear in the middle. $\times 1,350$.

Fig. 42. Two young asci. $\times 1,800$.

Fig. 43. A young ascus. The nuclei have not yet fused. $\times 2,700$.

Fig. 44. A young ascus, the nuclei fusing. $\times 2,700$.

Fig. 45. An ascus with young fusion nucleus. $\times 2,700$.

Fig. 46. Part of ascus, showing fusion nucleus in synapsis. $\times 2,700$.

Fig. 47. Fusion nucleus with what appear to be paired chromatin threads. $\times 2,700$.

Fig. 48. A similar, but somewhat later stage. $\times 2,700$.

Figs. 49 and 49a. The same nucleus from two sections, showing the secondarily contracted chromatin. $\times 2,700$.

Fig. 50. The fusion nucleus with its four chromosomes standing in relation to the central body, but as yet no spindle has been formed. $\times 2,700$.

Fig. 51. The first spindle with central and mantle fibres and three of the four chromosomes. $\times 1,800$.

Fig. 52. The first spindle with two chromosomes, the right of which at least appears to have broken into two parts. $\times 2,700$.

Fig. 53. The first spindle, anaphase stage. $\times 2,700$.

PLATE XL.

Fig. 54. The first spindle, a later stage. Only the central fibres have persisted. There are indications of vacuolar cavities marking the beginnings of the daughter nuclei. $\times 1,800$.

Fig. 55. One of the two daughter nuclei in division. $\times 2,700$.

Fig. 56. A rather earlier stage in mitosis of the nuclei shown in Fig. 55. $\times 2,700$.

Fig. 57. The four-nucleate stage of the ascus. The sister nuclei are paired. $\times 1,800$.

Fig. 58. A prophase stage of the third mitosis. $\times 2,700$.

Fig. 59. A later period in the prophase. $\times 2,700$.

Fig. 60. Equatorial plate stage in third mitosis. $\times 1,800$.

Fig. 61. A later period of same mitosis. $\times 2,700$.

Fig. 62. The daughter nuclei of the last mitosis about to form. Four of the eight shown—the two spindles have disappeared. Counting from the top the first and third are sisters. $\times 1,800$.

Fig. 63. The young spores with nuclei still attached to one pole. Two of the four non-functional nuclei in upper part of ascus. $\times 1,800$.

Fig. 64. Two young spores—a later stage than Fig. 63. The rays from the central body have floated in towards nucleus. $\times 1,800$.

Fig. 65. A later stage. The necks of nuclei have been retracted and nuclei are now spherical. $\times 1,350$.

Fig. 66. A still later stage, showing the elongating spores and the still persistent non-functional nuclei. $\times 1,350$.

Fig. 67. A single mature spore. $\times 900$.

Figs. 68 and 69. The resting primary nucleus of spore. $\times 2,700$.

Fig. 70. The primary spore nucleus in mitosis. $\times 2,700$.

The Cytology of *Primula kewensis* and of other related *Primula* Hybrids.

BY

L. DIGBY.

With Plates XLI-XLIV and two Figures in the Text.

AT no time has the great problem of heredity, which involves such far-reaching results, been more widely discussed or more diligently studied than at the present day. It is now realized that the possibility of an ultimate solution must entail the study of genetics combined with that of microscopical investigation, for it is within the cells that the factors reside which determine the morphological and physical character of the individual.

Much work has been done on the cytology of hybrids, both on the animal and on the vegetable side, and in many cases it has been possible to compare the nuclei of the parents with those of the offspring. The appearance and general character of the cytoplasm have been observed, the number and form of the chromosomes and their method of pairing in the bivalent combination have been described. After consideration of these cytological facts, conflicting hypotheses have been put forward in explanation of the causes of their frequently sterile condition. At present many of the detailed results remain as uncoordinated data, though it may be confidently anticipated that they will, in the future, be united into an intelligible scheme. It is in the hope of adding another item to these communications that this piece of work has been undertaken. Having regard to the curious horticultural history of the hybrid *Primula kewensis*, it seemed that a record of its cytology might be of interest. The attempt has been repaid, as the nuclear phases are wonderfully clear and the numbers of the chromosomes so low as practically to eliminate all chance of error. Moreover, the origin of the bivalent chromosome is suggestively easy of interpretation, and may throw some light on this much-vexed question.

METHODS.

The buds have been capricious as regards fixation, and unless it has been good, the nuclei take the stain diffusely. In those cases where fixing and staining have been successful, nothing can exceed the clear definition of the nuclear phases. Sharpness of detail is characteristic of this series of *Primulas*.

[*Annals of Botany*, Vol. XXVI. No. CII. April, 1912.]

The buds have been fixed in strong Flemming, Hermann, alcohol and acetic, strong and medium chromo-acetic, and Merkel. Fixations have been made between 11 a.m. and 12.30 p.m. on bright warm days. Under these conditions plentiful nuclear divisions have been obtained.

It is found that the nuclei of many of the buds are in the state of rest which intervenes between the last premeiotic and the first meiotic division. This stage must be one of long duration, for during its period the whole bud grows considerably. There is again a resting stage during synapsis, for it is not unusual to find all the five anthers of a bud with their pollen mother-nuclei in close synapsis. From the coming out of synapsis to the completion of the homotype division the sequence of the nuclear phases is extraordinarily rapid. Often, in the microscope field of a transverse section of a bud, the nuclei of the youngest loculus will be in 'hollow spireme', whilst those of the oldest loculus will have already passed through the two meiotic divisions and be in the tetrad stage. The two outer loculi of an anther are always in advance of the inner two, and one loculus in each respective pair is slightly ahead of the other in the progress of nuclear division. Moreover, there is a great difference in the stages between the pollen mother-nuclei near the top of a given anther and those near the base of the same anther, so that by following the sequence of the sections of an anther cut transversely a perfect gradation can be obtained.

A variety of stains has been used, including Heidenhain's iron-alum haematoxylin with a counter stain; Flemming's triple; Breinl; methylene blue and eosin; gentian violet and orange G, &c.

HORTICULTURAL HISTORY.

It is well known that certain *Primulas* are not difficult to cross artificially, and occasionally accidental hybrids have arisen, and to this class belongs *Primula kewensis* (13 and 14). *P. floribunda* and *P. verticillata* were grown in quantities at Kew, and when in flower were constantly placed near to one another. In 1899 Mr. F. Garrett, the foreman, noticed in a pan of presumably pure *P. floribunda* seedlings one which was stronger in growth and different in foliage to the others. When it flowered it was evident that it was a hybrid, for it possessed the combined characters of *P. floribunda* and *P. verticillata*. It inherited from *P. floribunda* its continuous flowering nature, the colour of its flowers, and the shape of its leaves, and from *P. verticillata* its size, the length of its leaf-stalks, its foliaceous bracts, the character of its flowers, and the traces of mealiness on the corolla tube, on the upper part of the calyx, and on the leaves. The feature of mealiness is a most pronounced characteristic of *P. verticillata*. This hybrid plant, *Primula kewensis* (type form), was exhibited at the Meeting of the Royal Horticultural Society on February 27, 1900, and was awarded a First Class Certificate.

During the summer of 1900, in order to verify the supposition that *P. floribunda* and *P. verticillata* were in fact the parents of *P. kewensis*, the cross was successfully achieved artificially, using *P. floribunda* as the seed parent and *P. verticillata* as the pollen parent. A proportion of the resulting plants were true *P. kewensis* (29). The hybrid was sterile; all its flowers were thrum-eyed, and hence the stock could only be increased by cuttings or division.

In 1901 most of the sterile stock of *P. kewensis* passed into the hands of Messrs. Veitch and Sons of Chelsea. There it continued to bear only thrum-eyed flowers, until, about 1905, a single pin-eyed flower was noticed. This flower was fertilized with the pollen of a thrum-eyed flower and good seeds were set. These germinated, and the resultant plants bore both pin-eyed and thrum-eyed flowers and were fertile. Thus the whole present-day stock of the seedling or fertile *P. kewensis* has originated from the single pin-eyed flower on the type or sterile *P. kewensis*. Messrs. Veitch have since produced by selection, not by cross-breeding, a varietal form, which they have named *P. kewensis farinosa*. This resembles the fertile *P. kewensis*, except that it possesses the pronounced mealiness of the leaves, calyx, and corolla so characteristic of *P. verticillata*.

The cross between *P. floribunda* and *P. verticillata* has again been repeated at Kew by Mr. J. Coutts, the foreman, in 1910 (29), but this time the offspring resembles the seed parent *P. floribunda*, and not a single plant of *P. kewensis* has appeared. On the other hand, *P. verticillata* crossed with *P. floribunda isabellina* has given rise to plants resembling *P. kewensis farinosa*, and, as will be observed, the interest is further enhanced by the fact that the number of chromosomes in this hybrid coincides with that of the plants of *P. kewensis farinosa* which were obtained by selection from *P. kewensis* (seedling form).

Such is the horticultural history of *P. kewensis*. It is now necessary to compare the chromosome numbers in the various generations.

CHROMOSOME NUMBERS IN THE PRIMULA GENERATIONS.

Both parents, *P. floribunda* and *P. verticillata*, have 18 for their diploid and 9 for their haploid number of chromosomes. These numbers, as might be expected, are repeated in the hybrid *P. kewensis* (type).

The fertile (seedling) *P. kewensis* has, however, by some means doubled the number of chromosomes, and possesses 36 for its diploid and 18 for its haploid number. These numbers are also retained in the varietal form *P. kewensis farinosa*, and again reappear in the *P. kewensis farinosa* which has arisen at Kew (29) as the result of crossing *P. verticillata* with *P. floribunda isabellina*, the pale form of *P. floribunda*.

Material of the fertile *P. kewensis* has been obtained from several

sources, and in every case the doubled number of chromosomes has been substantiated.

A similar example of the sudden duplication in the number of chromosomes has been found amongst the *Oenothera* mutants (31, 17, and 20). *O. gigas*, which is known to have originated from *O. Lamarckiana*, has 14 haploid chromosomes, whilst *O. Lamarckiana* has only 7 haploid chromosomes.

Another unlooked-for result has been obtained from crossing *P. floribunda isabellina* with *P. kewensis* (seedling form) (29). This cross resembles that of *P. floribunda isabellina* crossed with *P. kewensis* (type) in external characters as well as in the number of the chromosomes. Both hybrids have the typical *P. floribunda* number, 18 diploid and 9 haploid. In the case of *P. floribunda isabellina* \times *P. kewensis* (type) this result would be expected, but in the case of *P. floribunda isabellina* \times *P. kewensis* (seedling), where one parent has twice as many chromosomes as the other, there must have been some reducing process at work whereby the sum of $9x + 18x = 18 \cdot 2x$. An analogous reduction in the number of chromosomes in the hybrid, one of whose parents possesses a higher number than the other, occurs in the classical instance of *Drosera obovata* (33 and 34) and in a hybrid *Oenothera*.

According to Geerts (20), when *O. lata* with its 7 haploid chromosomes is crossed with *O. gigas* with its 14 haploid chromosomes, at the first meiotic division the 7 homologous chromosomes pair and the 7 superfluous chromosomes disintegrate. It may be that some such explanation may account for the elimination of the chromosomes in the *Primula* cross.

¹ The (x) number of chromosomes has not been counted, the most advanced pollen mother-nuclei being only in synapsis.

My thanks are due to the authorities at Kew, through whose courtesy it has been possible to obtain buds of the original type form of *P. kewensis*, and of all the crosses made by the foreman, Mr. Coutts, during the year 1910.

Messrs. Veitch have kindly supplied material from their stock of seedling *P. kewensis* and of *P. kewensis farinosa*.

It is proposed to begin the account of the cytology of this series of *Primulas* with a description of the premeiotic divisions. The seedling *P. kewensis* has been selected for this examination on account of the larger size of its nuclei as compared with those of the other forms. This will be followed by a review of the meiotic phase of the seed parent, *P. floribunda*. Subsequently that of the pollen parent, *P. verticillata*; of the sterile and of the fertile *P. kewensis*; of *P. kewensis farinosa*, and of the various crosses of 1910 will be dealt with in succession, but only the points of difference in the meiotic phase of these as compared with that of the selected type *P. floribunda* will be noticed. Then it is proposed to consider briefly the mode of union of homologous lengths of spireme in the bivalent combination as exhibited in these *Primulas*, with regard to the 'parasynaptic' and 'telosynaptic' views. Finally, to survey the cytological work that has been done on hybrids, with special reference to the *Oenotheras*, which have so many features in common with the *Primulas*.

PREMEIOTIC DIVISIONS.

It has already been stated that there is a long rest between the premeiotic and meiotic divisions of these *Primulas*. Hence, unlike *Galtonia* (9) and other forms, where the one series of divisions passes imperceptibly into the other, in *Primula* there is no possibility of tracing the transition between the two. *Primula* therefore is not illuminating as regards the origin of the parallel threads and paired chromatin masses in the heterotype prophase.

In a telophase of one of the premeiotic or of the somatic divisions, no diagrammatic alveolization of the chromosomes is to be found, resulting in the formation of two parallel threads (9 and 21), phenomena which are so beautifully displayed by the nuclei of some plants. In the *Primulas* the substance of each entire chromosome breaks up, for the most part transversely, into rounded granular-like portions (Pl. XLI, Fig. 1). Thus these granules are bits of whole somatic chromosomes, not bits of the longitudinal halves of somatic chromosomes. In *Primula* the granules may fragment into smaller and smaller particles, but in this fragmentation it would of course be impossible to say whether the division were longitudinal or transverse. In a late telophase the nucleus is traversed by a very fine arrangement of threads, and on these threads chromatin granules of various sizes are carried (Fig. 2).

When the nucleus enters upon the prophase, the granules trend

together like beads on a string (Fig. 3). At first they take the stain lightly, but as they increase in volume and in definiteness they become more and more chromatic. Gradually the limits of the beaded individual chromosomes become discernible, and fine threads are seen connecting the beads of one chromosome to those of another (Fig. 4). Then the beaded appearance becomes less and less marked, until finally it blends into the homogeneous chromosome with a smooth outline (Figs. 5 and 6). The chromosomes go on to the spindle, and the neat compact equatorial plates are most characteristic. It is only when on the equatorial plate that the longitudinal fission in the substance of each chromosome becomes discernible.

Thus the different manner in which the formation of the mature somatic chromosome is accomplished in the *Primulas* as compared with

TEXT-FIG. 1. Somatic division.

such forms as *Allium* (21), *Galtonia* (9), &c., is simply due to the fact that in the *Primulas* the longitudinal halves of the portions of segmenting chromosomes during telophase tend to remain together, whereas in *Allium*, &c., the longitudinal halves of the portions of segmenting chromosomes during telophase tend to separate (Text-fig. 1). In this latter case the separation of the two halves results in two parallel threads, each of which is a portion of the longitudinal half of a somatic chromosome. During the ensuing prophase these longitudinal halves come together again to form the whole somatic chromosome, but often this union is incomplete, leaving a space (longitudinal fission) between the halves which will take effect and separate the two daughter chromosomes when they are arranged on the equatorial plate. On the other hand, in the *Primulas*, the homogeneous, unsplit chromosome of the telophase breaks across transversely into portions, which therefore represent pieces of whole somatic chromosomes. During the ensuing prophase these whole pieces come together end to end,

remaining homogeneous, and do not display any inherent longitudinal fission until the chromosomes are about to proceed to the poles.

This tendency of the longitudinal halves of the univalent chromosomes to adhere to one another is also characteristic of the heterotype divisions, for in the early hollow spireme stage the univalent strands are homogeneous, and it is scarcely ever possible to detect any longitudinal fission in their substance.

During the somatic prophase the nucleolus buds constantly. This budding is carried on to a still greater extent during the heterotype prophase.

MEIOTIC PHASE OF *P. FLORIBUNDA*.

There is a long-drawn-out rest between the last premeiotic and the prophase of the first meiotic division. At the last premeiotic telophase the whole chromosome breaks up transversely into rounded portions (Fig. 1). During the rest, these granules for the most part disappear; perhaps they are absorbed by the large nucleolus. The nucleolus occupies the centre of the nucleus and usually stains very deeply, but sometimes appears as a plasmosome. The nucleolus, whether it be chromatic or not in staining reaction, buds freely (Figs. 7 and 8). Apparently it acts as the store-house for chromatin, which it deburses by exuding droplets of its substance into the nuclear cavity. The small buds whilst still attached to the nucleolus are more faintly staining, but as they separate they become chromatic and take a very bright stain, and pass to the periphery of the nucleus. Very delicate connexions join these round chromatic bodies to one another and individual bodies to the nucleolus. When the bodies arrive at the periphery they break up into smaller granules which as a rule stain less brightly. These bodies might be considered as representing prochromosomes, but without doubt they are derived from the nucleolus, and they are irregular in size, in number, and in shape. The cytoplasm round the nucleus, at this stage, is very dense.

A precisely similar resting stage has been described by Gates (15) and by Davis (5) in the *Oenotheras*.

As the nucleolus continues to bud, the chromatin in the nucleus shows a decided increase, and this is accompanied by growth of the nucleus (Fig. 9), which may be said now to have entered upon the prophase. At the same time the fine connexions form more definite strands (Fig. 10), and the rounded beads of chromatin arrange themselves on the threads (Fig. 11). Sometimes several beads amalgamate to form an irregular mass, the earliest indication of the preparation for the coming synapsis (Fig. 12). In places the linin threads, bearing the chromatin beads, are seen to run parallel to one another and sometimes to join (Figs. 10, 11, 12).

It is impossible to determine the significance of the parallel threads

present in the heterotype prophase, owing to the undecipherable character of the nuclear phases that immediately precede and succeed it. During the rest which intervenes between the telophase of the last archesporial division and the prophase of the heterotype, the chromosomes resolve themselves so completely that all trace of their identity is lost to view, and the arrangement of their units passes beyond the limit of interpretation. Again, during synapsis, the course of events is completely veiled by the dense tangle of the spireme. The parallel threads may either represent the pairing of whole univalent lengths of chromosome, according to Grégoire's view (22), and in that case each thread would be homologous with a length of univalent beaded spireme of the premeiotic prophases, or they may represent the coming together of the halves of univalent lengths of chromosomes preparatory to the condensation for the whole somatic (univalent) chromosome. In *Galtonia* the homology between the parallel threads of the last premeiotic division (the result of the alveolization of each chromosome) and the parallel threads of the heterotype prophase can be traced through a continuous and progressive series. In both nuclear phases the parallel threads represent the longitudinal halves of the univalent chromosomes. During the telophase the process of the breaking up of the chromosomes and the distribution of their substance throughout the nucleus entail a *separation* of the longitudinal halves, whilst during the prophase the gradual evolution of the chromosomes involves an *approach* and an increasingly closer association of the longitudinal halves. It is believed that the same interpretation of the parallelisms found in the heterotype prophases may hold good for *Primula*, but for the reasons already given the surmise cannot be directly verified. Moreover, in *Primula*, as in other forms, it seems probable that the considerable thickening of strands may be due to the premature pairing of whole univalent chromosomes, a pairing which, in *P. floribunda*, is most clearly shown in the post-synaptic stages. When it is remembered that the completion of a mature bivalent chromosome entails not only the condensation of the two split halves of each univalent chromosome, but also the union of the two univalent chromosomes to form one bivalent combination, it does not seem irrational to believe that preparations for both may be proceeding simultaneously in the presynaptic stages.

The chromatic contents of the nucleus increase and concentrate into groups (Fig. 13), and diffuse throughout the linin. Gradually the whole masses together at one side of the nucleus. Parallelisms in the escaping portions can often be seen; and faint strands of linin may extend to the periphery of the nucleus as loops, or apparently as free ends. At complete synapsis the chromatin mass has a very granular appearance, and is contracted into an extremely small space (Fig. 14). *Primula* does not conform to Lawson's view (30) that there is no chromatin contraction during synapsis. The nucleolus is generally to be seen projecting from the synaptic knot, and

is for the most part cytoplasmic in staining reaction, and once more buds freely. Droplets of nucleolar material may adhere to the chromatic knot (Fig. 14). Such droplets have been recently figured by Tischler (40) in *Musa sapientum*, var. *Kladi*, and he suggests that they may be of an excretory nature. They were also frequently seen in the synaptic figures of *Galtonia* (8 and 9).

As the synaptic knot unravels it loses its granular appearance and becomes more thread-like (Fig. 15). Occasional rounded chromatin masses are associated with the more definite lengths of spireme, and globules of faintly staining nucleolar material may be suspended with the chromatic substance (Fig. 15). The nucleolus is often pushed out first, and lies caught up by the loops in the clear space of the nuclear cavity. The appearances displayed by the loosening spireme are very various. For the most part it emerges in the form of loops, which stain homogeneously and show no longitudinal fission in their substance (Fig. 17). The looped spireme which comes out of synapsis and constitutes the familiar 'open spireme' stage is (for the most part) univalent in nature. It is, therefore, homologous with the univalent spireme of the somatic prophases. In the somatic prophases the univalent spireme segments directly into the independent univalent chromosomes; in the heterotype prophases, subsequent to the 'open spireme' stage, a pairing of univalent lengths of spireme takes place, resulting in a temporary association of two univalent chromosomes, forming the typical bivalent heterotype chromosome. Sometimes lengths of thick spireme, with bifurcating ends, emerge (Fig. 16). In some cases it seems obvious that the univalent lengths of spireme have already joined side by side—have, in fact, completed the approximation sometimes prepared for in the heterotype prophase. Especially in superficial sections of loosening knots, parallel threads arranged in a ladder-like way, united by bands of chromatin, are constantly to be found (Fig. 18). Notwithstanding the fact that some of the spireme, as it emerges from synapsis, may be bivalent in nature, yet the greater part is univalent, and it is only later that the definite arrangement of the individual univalent lengths into pairs to form the bivalent combinations takes place. Thus it seems probable that the rearrangement during synapsis has been chiefly concerned in the *formation* of the univalent lengths of spireme, and has not participated to any great extent in the *pairing* of the homologous univalent lengths of spireme. The looped nature of the spireme becomes more and more accentuated, and the already approximated portions tend to separate and to open out (Fig. 19). At the places of anastomosis there is always a chromatic swelling (Figs. 19 and 20).

During this time the nucleolus continues to bud freely. The buds become chromatic, and for a time remain tangled in the spireme. Sometimes more than one nucleolus is present.

At this and subsequent stages the nucleolus may stain either cyto-

plasmically or chromatically; its reaction does not depend on the fixative, for contrary results may be obtained in buds killed in the same manner.

When the coming out of synapsis is completed, and the nucleus has returned to the centre of the cytoplasm, the beautiful looping of the *continuous spireme* is most striking (Fig. 20); by this time the chromatic aggregations have been absorbed. Although there is always a certain amount of anastomosis, it is often possible to focus the loops passing freely and separately within and without one another. If the spireme be both *continuous* and *univalent*, then the future univalent chromosomes must necessarily be arranged *end to end* in the spireme. This supposition is supported by subsequent phenomena leading to the realization of the heterotype chromosomes. The loops show no longitudinal fission in their substance; they are homogeneous, smooth surfaced, and faintly staining. The earliest indication of the association in pairs of homologous lengths of univalent spireme is the withdrawal of the spireme from the periphery of the nucleus, which at the same time becomes arranged in fewer and more distinct loops (Fig. 21).

Univalent lengths of Spireme joining to form the bivalent combinations

TEXT-FIG. 2.

The sides of the loops tend to approach one another and finally to join in places (Fig. 22). At the points of union there is always a chromatic swelling (Figs. 22 and 23). Sometimes the two sides of the same loop approximate, sometimes it appears as if the side of one loop crossed over and associated itself with the side of another. The nipping in of the loops at the places of contact and the otherwise somewhat wide divergence of their sides produce a variety of figures as shown in the diagram (Text-fig. 2).

This is the beginning of the union of univalent strands to form bivalent combinations. As will be shown, each side of one of these loops becomes eventually a univalent chromosome. By degrees the sides of the loops come to lie closer together, and are concentrated into more definite figures (Fig. 24). Then each bivalent combination, the future heterotype chromosome, begins to dissociate itself from its fellows, and for the first time free ends are to be seen (Fig. 24). A still closer approximation of the univalent sides continues, forming thick bivalent strands (Fig. 25). Sometimes this approximation takes the form of a ladder-like union (Fig. 24), as was described in the loosening of the synaptic knot (Fig. 18). There is a great variety, even in a single nucleus (Fig. 26), in the appearance of the chromatic segments at

this stage, owing to the degree of progress exhibited in the process of the combination of the univalent strands. Some of the thick bivalent portions may open out into univalent loops; in others, the sides of the loops may be still apart and only united at intervals, whilst in others the loop may be curved like a ring, the future ring-shaped chromosome. Although, perhaps, in some cases the univalent homologous segments of a bivalent combination may never be intimately joined together, yet, as a rule, at this stage, most of the univalent segments are united side by side in pairs forming thick strands (Figs. 26 and 27), which always reveal their double character.

There is no definite second contraction in *P. floribunda*; it seems to be represented by the close approximation of univalent segments in each separate bivalent combination (Figs. 26 and 27). This fact materially simplifies the difficulties as regards the evolution of the bivalent chromosome, for so frequently the massing of the segments in the second contraction hides the sequence of events. In *P. floribunda* it is often possible to identify the limits of the nine bivalent chromosomes (Fig. 27) at this stage.

Having accomplished the necessary lateral approximation, the two univalent sides then proceed to split apart (Fig. 28). At first this splitting may be restricted to certain lengths, leaving places where the two are still in contact (Figs. 28, 29, and 30), thus repeating the figures of their first association, but very rapidly the splitting extends until the two univalent chromosomes are only attached at one end, or at both ends when a ring-shaped chromosome results (Fig. 31). At the place where the two chromosomes are in contact there is constantly a chromatic swelling (Fig. 31) like that which has been described at the points of union of the loops of the spireme. As the split separates the chromosomes, the chromatin of each becomes concentrated (Fig. 31).

The sides of the bivalent chromosomes thicken considerably and their staining power intensifies. They are typical and beautifully shaped heterotype chromosomes, and there are usually three or four rings amongst them. Radiations from four centres appear in the cytoplasm (Fig. 32), and these extend to the nucleus, which by this time has lost its limiting membrane. Sometimes the four apices of the spindle can be detected in the microscopic field. The quadri-polar spindle may persist for some time, but eventually it becomes bipolar. The chromosomes, which by this time have considerably contracted, attach themselves to the spindle. The spindle tapers to a point at either end and the fibres are coarse and distinct. Sometimes, in badly fixed material, where there has been much contraction, the spindle remains entire, showing that it is of so tough a consistency as to be untouched by violent chemical influences. The rigid character of the spindle radiations has been described by Farmer (10, p. 475) in *Fossombronia*. Often a laggard chromosome caps one of the spindle poles (Fig. 33), and then, belated, joins the other chromosomes on the plate. The equatorial

plate is very neat, the chromosomes, dumb-bell or kite shaped, being arranged in perfect symmetry. A transverse section of this stage shows the nine chromosomes (Fig. 34). Gregory (24) has found the reduced number of chromosomes in *P. sinensis* to be twelve.

The nucleolus disappears as the chromosomes go on to the spindle. The separation of the univalent chromosomes and their retreat to the poles, to which they are drawn by stout spindle fibres, is very clearly demonstrated. The chromosomes are round or oval in shape, they stain deeply, and show no sign of longitudinal fission (Pl. XLII, Fig. 35). Arrived at the poles, they at first, in the usual manner, mass together and lose their individuality. Then they separate, fine threads join the segments one to the other, a nucleolus makes its appearance, and the nucleus becomes bounded by a limiting membrane. Cytoplasmic connexions *passthrough the cell walls* and join diasters of adjacent cells to one another (Fig. 36). These connexions may be observed at earlier stages, but they are the more striking at the diaster, when the cytoplasm, contracted from the cell-walls, is mainly collected round the spindle. The fact that these cytoplasmic strands pierce the cell-walls gives a possible explanation for the transit of the chromatin bodies from one cell to another (8). Gates (15) has figured similar protoplasmic connexions between the pollen mother-cells of *Oenothera rubrinervis*.

To return to the telophase. The stages leading from the heterotype to the homotype division are extremely quickly passed through, in fact sometimes the chromosomes appear at once to reconstitute themselves. The more or less homogeneous masses of chromatin, representing the individual chromosomes, split longitudinally (Fig. 37), their sides become beaded (Fig. 38), and fine threads join the various portions to one another. The nearest approach to a resting stage that has been found is a nucleus containing the skeleton of each chromosome clearly outlined by granules, and amongst them some indeterminate groups of granules (Fig. 38).

The prophases of the homotype are indistinguishable from the telophases of the heterotype division, and the only means of recognizing the one from the other is that, by the time that the chromosomes are reconstituting themselves, there is no trace left of the spindle fibres of the heterotype division. The chromosomes are re-formed by the concentration of the granules. They show complete longitudinal fission, the two halves being in the same relative position to one another as the limbs of a V or of an X (Fig. 39). The figures are markedly tetrad-like in character (Fig. 40). Sometimes the fully formed chromosomes are composed of concentrated chromatin, sometimes they are beaded. Spindle fibres appear, and the chromosomes attach themselves irregularly (Fig. 40), but they finally collect at the equator, where they form a neat circle of dyads (Fig. 41). One spindle is generally at right angles to the other, but

occasionally they may both lie in the same plane. In a transverse section of an equatorial plate of the homotype division, the chromosomes are seen to be arranged in a square of three (Fig. 41). The spindles taper bluntly. As in the heterotype anaphase, the chromosomes, on arriving at the poles, form themselves into a compact mass, and then separate out once more, and a nuclear wall forms (Fig. 42). The chromosomes then proceed to break up into granules. In the resting tetrad nuclei these granules are scattered in the nucleus, and are joined together by fine connexions. The cytoplasm between the nuclei constricts, and each of the four nuclei, surrounded by its cytoplasm, becomes an independent cell. At the late telophase of the homotype division the protoplasmic threads perforating the cell-walls, and joining tetrad groups to one another may still persist. The pollen-grain is tetrahedral in shape.

P. VERTICILLATA.

P. verticillata is a stronger and larger form than *P. floribunda*; the pollen mother-nuclei in both plants are almost identical in size, but the pollen-grains of *P. verticillata* are considerably the larger of the two.

The resting, presynaptic, and synaptic stages are similar to those already described in *P. floribunda*. From the synaptic stages onward there is, however, a decided modification on the simple process adopted by *P. floribunda* in the formation of its bivalent chromosomes, a process which can be clearly followed throughout its course, and is not marked by the confusion of the second contraction. *P. verticillata*, on the other hand, has a well-marked second contraction from which the bivalent chromosomes emerge. This is but another example of a feature which these *Primulas* share with the *Oenotheras*. Gates found a well-marked second contraction in *Oenothera rubrinervis* (15), whilst Davis saw none in *O. biennis* (5).

During the early hollow spireme stage of the heterotype division, tracts of spireme trend together, forming a flat, deeply staining, band-like chromatic mass (Fig. 43). From this mass strands pass to the periphery of the nucleus. These strands are irregular in their distribution, vary in thickness, and anastomose freely with one another. The usual chromatic swellings are found at the places of anastomosis. At a slightly later stage the chromatic mass has further increased in bulk and is lumpy and thick in appearance, and from it radiate a few irregular loops of spireme (Fig. 44). Gradually, though the central chromatic concentration remains undecipherable, the escaping portions of spireme are seen to have a more definite arrangement and significance (Fig. 45). These may be in the form of loops, the univalent sides united at the apex, where there is the familiar chromatic swelling; or free bivalent ends may project showing the intimate side by side union of univalents; or loops of univalent spireme may be seen, anastomosing freely, but showing no approximation of homologous lengths. It is difficult to get a good fixation of this stage. In these

preparations there has always been a considerable amount of contraction which is displayed by the crinkled edges of the cytoplasm. Gradually, as the second contraction becomes sorted out, the protruding portions of spireme thicken considerably, and clearly show their bivalent nature. Sometimes in the same nucleus (Fig. 46) some of the chromosomes may be almost fully formed, whilst the outline of others may be but indicated by the union of univalent spireme lengths, recalling the figures in the realization of the bivalent segments in *P. floribunda*. As the bivalent chromosomes emerge from the second contraction, they are often in the shape of rings joined together like the links of a chain (Fig. 47). Several rings may go to form one bivalent chromosome, for a large loop of spireme may become constricted in one or more places, resulting in a spectacle-shaped or chain-like chromosome.

When the nine bivalent chromosomes have been evolved out of the confusion of the second contraction they tend to segregate into two groups, and often the chromosomes in these groups become so pressed together as to lose their visible individuality (Fig. 48). Sometimes the chromosomes split into their univalent halves after they have issued from the second contraction. In that case the usual deeply staining, unsplit portions can be sharply distinguished from the symmetrically arranged, lightly staining, newly split univalent halves (Fig. 50). Under favourable conditions, but very rarely, the longitudinal fission in the but lately split limb can be seen (Fig. 49). The univalent chromosomes remain attached at one end, condense, and thicken considerably, and adopt the typical heterotype form (Fig. 51). There are always several large ring chromosomes. A transverse section of an equatorial plate shows the nine diagrammatic chromosomes (Fig. 52). The spindle is at first quadripolar, then becomes bipolar, and the univalent chromosomes proceed to the poles in the normal way. At the late telophase of the first meiotic division, or the early prophase of the second meiotic division, the nine longitudinally split chromosomes are beautifully clear (Fig. 53).

There is nothing further to add about the homotype division. It has already been mentioned that the pollen-grains of *P. verticillata* are larger than those of *P. floribunda*.

P. KEWENSIS (type).

The stages prior to the coming out of synapsis are like those of *P. floribunda* and *P. verticillata*.

In the formation of the bivalent segments, *P. kewensis* (type) adopts a method intermediate between the simple pairing of univalent strands characteristic of *P. floribunda* and the well-marked second contraction of *P. verticillata*. Although *P. kewensis* has no definite second contraction, there are small, isolated, thickened, chromatic areas to be found, formed by the massing, in places, of several univalent segments.

P. kewensis (type) resembles *P. verticillata* in the tendency of the bivalent chromosomes, after their evolution, to segregate into two groups, and also in the formation of chains.

As the spireme comes out of synapsis, it is much looped, and these loops intersect one another; at the junction there is the usual chromatic swelling (Fig. 54). By the time that the nucleus has returned to the centre of the cell, portions of chromatin of one nucleus may be protruded into the adjoining cell, at the same time retaining a connexion with the mother nucleus (Fig. 55). This phenomenon has not been seen in the other species of *Primula* examined, and recalls a similar condition figured by Gregory (23) in the Sterile Pea. These chromatic protrusions when found in *Primula* are not nearly so striking as the 'bodies' which are thrown off in *Galtonia* (8), and moreover suggest possible nuclear degeneration.

After the univalent loops have arranged themselves throughout the nuclear cavity, the spireme is as a whole much more beaded in character than is that of either of the parents. The beaded lengths of spireme arrange themselves in squares and in parallel lines, and in some places they unite to form the bivalent combination (Fig. 56). A single nucleus may exhibit very varied contents, for the same nucleus may have portions of its spireme in the beaded condition, whilst other portions may be homogeneous and pair as in *P. floribunda* (Fig. 57). Where the rows of beads, or the lengths of strands come together, there is always a decided thickening. A ladder-like condensation of univalent spiremes is of very common occurrence (Fig. 58). Strands may coalesce in one or more places, and create an undecipherable mass which may be described as an attempt to form a second contraction (Fig. 58).

In *P. floribunda* there is a stage when all, or nearly all, of the univalent segments are joined in their homologous pairs prior to the final splitting apart. On the other hand, in *P. kewensis* (sterile), some of the univalent lengths may be in the act of pairing, whilst others may already be splitting apart, and it is possible that in some cases a close union of the univalent members of each pair may never be achieved. Gates (15) has described the attraction for pairing between homologous chromosomes as being very weak in the mutant *O. rubrinervis*.

All stages in the splitting apart of the joined univalent segments may be seen (Fig. 59). These then concentrate and thicken, until the forms of the future bivalent chromosomes are recognizable (Fig. 60). When the bivalent chromosomes are individualized they tend, as in *P. verticillata*, to mass together into two groups (Fig. 61). When they again distribute themselves throughout the nucleus chains of rings are constantly to be seen (Fig. 62), and, as in *P. verticillata*, it is evident that several rings go to form one bivalent chromosome.

Then the univalent limbs of each bivalent chromosome diverge widely, and together they fill up the greater part of the nuclear cavity (Fig. 63). This is followed by a shortening and thickening of the chromosomes (Fig. 64), the spindle makes its appearance and the chromosomes attach themselves to the fibres (Fig. 66). A transverse section of an equatorial plate shows the typical nine chromosomes (Fig. 65).

There is nothing further to add about the heterotype division; this is followed by the homotype resulting in the formation of tetrads (Pl. XLIII, Fig. 67). It is only when the tetrad nuclei begin to separate from one another that some of the cells atrophy. A relatively small proportion of the pollen-grains appear to be normal (Fig. 68), but there are always depauperate ones amongst them (Fig. 69). Some of the anthers have a far higher percentage of healthy pollen-grains than have others.

In order to ascertain that apogamy is not responsible for the unaccountable doubling in the numbers of the chromosomes the embryo-sacs of both *P. kewensis* (sterile) and *P. kewensis* (fertile) have been examined. In both cases everything is regular. In *P. kewensis* (sterile) 18 chromosomes (Fig. 70) are found in the nuclei of the nucellus, and 9 in the nuclei of the embryo-sac mother-cell (Fig. 71).

P. kewensis (seedling form).

The striking and all-prevailing difference between *P. kewensis* (fertile or seedling) and those *Primulas* to which it is related is the fact that it has doubled its chromosomes. By some means, probably at the act of fertilization of the single pin flower, by pollen of the thrum flower, borne on the sterile stock, the 4 (x) number of chromosomes has been obtained, and this 4 (x) number is characteristic of all its subsequent generations. Moreover, *P. kewensis* with the 4 (x) number is fertile, whilst *P. kewensis* with the 2 (x) number is sterile. *P. kewensis* (fertile) has therefore 36 diploid (Pl. XLI, Fig. 6) and 18 haploid chromosomes (Pl. XLIII, Fig. 96). This double number is continued in the variety *P. kewensis farinosa* (Pl. XLIV, Figs. 107 and 108).

A most interesting recurrence of the doubling of the chromosomes has reappeared in the *Primula* crosses made at Kew in 1910 (29). The result of *P. verticillata* crossed with *P. floribunda isabellina* is a hybrid, which not only resembles *P. kewensis farinosa* in its external characters, but also with regard to its nuclei, for it possesses the number of chromosomes characteristic of the fertile *P. kewensis*, namely 36 ($2x$) (Fig. 108) chromosomes, that is to say it has duplicated the parental number. Thus the variety *P. kewensis farinosa* has arisen as the direct result of a cross, and indirectly as the result of a cross which has passed through an intervening sterile period. In both cases the number of chromosomes has been doubled.

The phenomenon of the sudden duplication of a chromosome number

has its parallel in the *Oenotheras*. The parent type, *O. Lamarckiana*, possesses 14 ($2x$) and 7 (x) chromosomes; its mutant, *O. gigas*, possesses 28 ($2x$) and 14 (x) chromosomes. This fact was first observed by Lutz (31), who counted 28 or 29 chromosomes in the roots. The numbers 14 ($2x$) and 7 (x) seem to be characteristic of this series of *Oenothera*; they are found in *O. lata*, in *O. nanella*, in the mutant *O. rubrinervis*, and in the hybrid arising from the cross *O. lata* \times *O. Lamarckiana*.

O. gigas appeared first in de Vries's experimental garden in 1895 amongst a crop of *O. Lamarckiana* which was known to have bred true for three previous generations (7). It arose without any intermediate stage, and the plants, grown from self-fertilized seeds, were with one exception pure *gigas*. Thus a new elementary species can 'appear without any obvious cause in a single individual and be absolutely constant from the very first' (7). *O. gigas* reappeared in 1898 from the seeds of a plant of *O. sublinearis*, which had itself arisen from the *Lamarckiana* family; and again in 1899 from a cross between *O. lata* and *O. hirtella*. Thus, like *P. kewensis* (seedling form), *O. gigas* has originated from more than one source. Gates (17) has worked out the cytology of the pollen mother-cells of *O. gigas* in detail, and he believes that the doubling of the chromosome number is to be regarded merely as a duplication of the set of chromosomes present in *O. Lamarckiana*. 'There is no evidence that any new unit characters have been added, or that anything really new has come into the germ plasm.' Whereas in *P. kewensis* the acquirement of the double number of chromosomes is apparently associated with the change from a sterile to a fertile condition.

P. kewensis (fertile) makes no attempt to form a second contraction, and in that respect resembles its parent *P. floribunda*. Another cytological characteristic peculiar to *P. kewensis* (fertile) is the temporary joining together of two of the bivalent chromosomes in the first meiotic division, resulting in a large quadrivalent chromosome, an association which is maintained until the univalent chromosomes, after having collected at the equatorial plate, separate off to the poles of the spindle. Further, *P. kewensis* (fertile) has a remarkable diakinesis in which the chromosomes are much contracted, a stage which has never been seen in the other *Primulas*. Lastly, the nuclei of the pollen mother-cells of *P. kewensis* (seedling) are considerably larger than are those of its parents. Thus it affords another example of the size of the nucleus in relation to the number of its contained chromosomes.

A rest occurs between the last premeiotic and the first meiotic division as in the other *Primulas*. During this and the subsequent stages the nucleolus buds most vigorously (Pl. XLIII, Fig. 72). There is a close synaptic knot, which leaves a large nuclear space. The buds at first stain faintly, but they gradually become chromatic in their staining reaction.

As the spireme comes out of synapsis the nucleolus continues to bud, with the result that many large rounded chromatin masses are caught up in the loops of the spireme (Fig. 73). In course of time these seem to become absorbed (Fig. 74), for they disappear, leaving only a few isolated beads, which are generally situated at the points of intersection of the loops (Fig. 74). The somewhat beaded character of the spireme recalls that of the sterile *P. kewensis* (Fig. 75). The beads are joined together by fine threads, and these tend to run in pairs, and where they meet there is always a chromatic swelling (Fig. 75). Even at this early stage in the pairing of homologous univalent spireme lengths it is possible to distinguish the skeleton of the future bivalent chromosomes. Gradually the paired portions of univalent spireme severally dissociate themselves from the others. At first these parallel threads have paired chromatin masses arranged at intervals along their length (Fig. 75), but as concentration proceeds less and less of the thread is visible, the chromatin becoming more diffuse (Fig. 76); as the sides of the chromosomes concentrate they become beaded (Figs. 77 and 78).

When it is possible to identify the limits of the individual bivalent chromosomes, it is apparent that two are joined together end to end (Figs. 79 and 80), forming as a rule a large looped figure. The univalent sides of each bivalent chromosome thicken, and often one or two chromosomes remain attached to the nucleolus (Fig. 81). Gradually the chromosomes become typically heterotype in shape (Fig. 82), and the large quadrivalent chromosome is most striking (Fig. 83). Then the heterotype chromosomes separate from one another, they become increasingly beaded (Fig. 84), and the fine threads joining them are tightly stretched. They stain less deeply and contract considerably (Figs. 85 and 86); the large chromosome often takes the shape of a ring (Fig. 86). After passing through this extremely beaded phase the chromosomes gradually lose their granular appearance and become slightly more condensed (Fig. 87), more homogeneous, and rounded in outline (Fig. 88). There is still further contraction of the chromosomes, each univalent chromosome of the bivalent combination becoming oval or rounded in shape (Fig. 89), the large chromosome appearing as a tetrad (Figs. 89, 90, and 91). The tetrad may be in the form of a square, or of a closed or partially opened ring, but in every case its fourfold character is evident (Fig. 91). The bivalent chromosomes are placed widely apart, and they are still connected to one another by fine threads. The nucleolus has by this time fragmented, and rounded globules of faintly staining nucleolar material may be seen adhering to the chromosomes (Fig. 92). Such is the peculiar and characteristic diakinesis of *P. kewensis* (fertile), the preparation for which is so prolonged.

Several counts have been made of the chromosomes at this stage. Very rarely 18 bivalent chromosomes all of the same size are to be found ;

the greater number show 17 bivalent chromosomes together with 1 quadrivalent chromosome, a few show 16 bivalent and 1 quadrivalent, and one case was found of 15 bivalent and 2 quadrivalent. Some of the discrepancies may be accounted for by the fact that the nuclei appeared in two sections and had to be pieced together, but the trend of the results seem to prove conclusively that the large chromosome represents the joining together of two bivalent chromosomes, and this statement is further corroborated by the subsequent behaviour of the large chromosome on the equatorial plate.

It is interesting to note that Rosenberg (33) in the hybrid *Drosera obovata* found that the chromosomes in the homotype division sometimes appeared as tetrads, and remarks 'dass wir in dem Vorkommen der Vierergruppen im zweiten Teilungsschritt einen Ausdruck der Hybridität sehen können' (p. 116).

Strasburger (35) in *Melandrium rubrum* describes one chromosome in the heterotype division which is much larger than the others; it reappears in the homotype division, and is present also in the embryo-sac mother-cell.

Agar (1) noted a conspicuously larger pair of chromosomes in *Lepidosiren paradoxa*, which are seen in the spermatogonial divisions, and which can be identified throughout the two maturation divisions.

In both *Melandrium* and *Lepidosiren* the large bivalent chromosome results from the association of two proportionately larger univalent chromosomes, and not from the temporary union of two bivalent chromosomes as in *P. kewensis* (fertile).

The spindle of *P. kewensis* (fertile), like that of the other *Primulas*, is quadripolar at its origin (Fig. 93). When the chromosomes have completed their equatorial arrangement, the quadrivalent chromosome is easily recognized (Figs. 94 and 95). Sometimes before the other chromosomes have separated, the quadrivalent chromosome may have prematurely divided into its four univalent units, though the members of each pair may continue to be joined one to the other (Fig. 94); in other cases the quadrivalent chromosome may not divide until the other chromosomes are about to pass to the poles (Fig. 95). The chromosomes have been counted several times in the polar views of equatorial plates. In several cases the number has been found to be 18 (Fig. 96), but 17, 16, 15, and even 14 chromosomes have been counted. Possibly this inaccuracy may be due to the position and relative degree of separation of the quadrivalent chromosome. This suggestion is supported by the fact that polar views of anaphases and polar views of asters (Pl. XLIV, Fig. 99) almost invariably show 18 chromosomes.

As they proceed to the poles (Pl. XLIII, Fig. 97) the univalent chromosomes which composed the quadrivalent combination cannot be distinguished from the others (Pl. XLIV, Fig. 98). The anaphase and telophase have been studied in detail, and there is no reappearance of the large chromosome. The chromosomes of the late anaphase at first mass together (Fig. 100), then

as they protrude and stretch to the periphery of the nucleus a limiting nuclear membrane appears (Fig. 101); gradually each chromosome lies independently, as a rounded mass of homogeneous chromatin, in the nuclear cavity (Fig. 102). In a polar view of this stage 18 chromosomes have again been counted. A definite cloudy band, indicating the position of the future cell-wall, stretches across the equator of the fast disappearing spindle (Fig. 102). The next stage shows the longitudinal fission of the chromosomes preparatory for the homotype division (Fig. 103); again 18 chromosomes can be counted. There is nothing remarkable about the homotype division; it is normal in every way.

The pollen-grains are larger than those of *P. floribunda*, and approximate in size to those of *P. verticillata*.

The embryo-sac has been examined, and the embryo-sac mother-cell nuclei show 18 bivalent chromosomes (Fig. 106). There is no indication of the adherence of two bivalent chromosomes; apparently this peculiarity is only characteristic of the heterotype division of the pollen mother-nuclei. At diakinesis (Fig. 104), in the profile (Fig. 105), and in the polar (Fig. 106) views of equatorial plates all the bivalent chromosomes are of the same size and are independent of one another.

P. kewensis farinosa.

It has already been mentioned that *P. kewensis farinosa* has arisen from two sources: in the one case as a variety of the fertile *P. kewensis*, in the other as the direct result of a cross between *P. verticillata* and *P. floribunda isabellina* (29), and both have doubled the number of the parental chromosomes.

The meiotic phase of *P. kewensis farinosa* obtained by Messrs. Veitch from selection of *P. kewensis* (seedling) has only been studied with the view of ascertaining the number of the chromosomes, and these without any doubt are 36 and 18 (Fig. 107).

The buds procured from the *P. kewensis farinosa* hybrid at Kew were young and had not as yet entered upon meiosis, but the somatic and arche-sporial divisions showed clearly that their chromosomes numbered 36 (Fig. 108).

Therefore *O. gigas*, whether it arises as a mutant or as a hybrid, and *P. kewensis farinosa*, whether it arises indirectly or directly as a hybrid, have both in each case doubled the parental number of chromosomes.

P. verticillata × *P. floribunda*.

The result of the cross between *P. verticillata* and *P. floribunda* (29) is a hybrid which repeats the number of the parental chromosomes, 18 (2x) and 9 (x), and resembles the seed parent, *P. verticillata*.

***P. floribunda isabellina* × *P. kewensis* (type).**

The hybrid derived from this cross resembles the seed parent, *P. floribunda isabellina*, and possesses the 18 ($2x$) and 9 (x) chromosomes.

The reciprocal cross, *P. kewensis* (type) × *P. floribunda isabellina*, set no good seed.

***P. floribunda isabellina* × *P. kewensis* (seedling form).**

An unexpected result is obtained from this cross. The hybrid resembles that of the preceding cross, *P. floribunda isabellina* crossed with the sterile *P. kewensis*, in external features as well as in the number of chromosomes, which are accordingly 18 ($2x$) and 9 (x), notwithstanding the fact that one of the parents possesses the doubled number, 36 ($2x$) and 18 (x).

It is difficult to imagine by what regulating process this reduction in the number of chromosomes has been achieved; that is to say, how 18 (x) uniting with 9 (x) can give the result of 18 ($2x$). Once more the *Oenotheras* show an analogy, and offer a possible explanation for this phenomenon. *O. lata*, which has 14 ($2x$) and 7 (x) chromosomes, crossed with *O. gigas*, which has 28 ($2x$) and 14 (x) chromosomes, gives rise to a hybrid which has 21 ($2x$) chromosomes. In the heterotype prophase the chromosomes appear unpaired in their $2x$ numbers. Subsequently, as in the *Drosera* hybrid (34), Geerts (20) finds that the homologous chromosomes derived from either parent pair with one another and that the supernumerary chromosomes remain unpaired. In the *Oenothera* hybrid, therefore, 7 bivalent and 7 univalent chromosomes go on to the spindle. The 7 bivalent chromosomes separate normally, whilst the 7 univalent ones disintegrate. Some of the fragments may eventually reach the poles, but many may be left on the spindle and never enter the reconstructing nuclei. Geerts obtains the same results in the hybrid resulting from the cross between *O. gigas* and *O. Lamarckiana* and in the reciprocal cross of *O. Lamarckiana* × *O. gigas*. In the polar views of the asters of the heterotype and homotype divisions of both these hybrids there are 7 distinct and perfect chromosomes to be seen, and amongst them many fragments. In the second generation of the cross between *O. gigas* and *O. Lamarckiana* the number of $2x$ chromosomes has reverted to the original 14. Thus 'wenn die Chromosomen wirklich die Träger der erblichen Eigenschaften sind, genügen also 7 Chromosomen der *O. gigas* für die Vertretung aller erblichen *gigas*-Eigenschaften in diesen Hybriden' (p. 163).

It may be that the hybrid *Primula* makes use of some similar means, perhaps at the first segmentation division, whereby it eliminates its superfluous chromosomes.

Further interesting results have been recorded from crossing *O. gigas* with *O. lata* and *O. Lamarckiana*. De Vries (6) has found that when

O. lata is crossed with *O. gigas* the F. I. generation shows 50 per cent. of a type intermediate between *O. lata* and *O. gigas*, and 50 per cent. intermediate between *O. lamarckiana* and *O. gigas*. Lutz (32) experimented on crossing *O. lata* with *O. gigas*, and from a study of forty hybrid plants was able to divide them into three classes, both in respect to their external characters and to their number of chromosomes: (1) *lata* type with 15 ($2x$) chromosomes; (2) *gigas* type with 30 ($2x$) chromosomes; and (3) intermediate type with 22 or 23 ($2x$) chromosomes.

GENERAL COMPARISONS.

It is proposed to limit this brief discussion to the manner of union of the lengths of spireme in the formation of the bivalent chromosome; to the cytological detail of the nuclei of hybrids, especially with regard to the number of their chromosomes; and to the fertile or sterile character of those hybrids.

Firstly, as regards the origin of the bivalent chromosome. A mass of controversial literature has accumulated round certain disputed points, especially concerning the significance of the parallel threads in the presynaptic stages and whether the union of the univalent spiremes in the formation of the bivalent chromosome may be described as telosynaptic (11) or parasynaptic (22), and consequently whether the fission in the spireme separates two whole univalent chromosomes or whether it is the premature fission in the substance of the univalent chromosome which will take effect in the homo-type division.

This series of *Primula* does not throw any light on the meaning of the parallelisms in the heterotype prophase. During the long rest between the last premeiotic and first meiotic divisions all sequence of events is lost, so that it is impossible to trace any relationship between the parallel threads of the heterotype prophase and the chromosomes of the preceding mitosis. Neither can any relationship be established between the parallel threads of the heterotype prophase and the parallel lengths of post-synaptic spireme, for during synapsis all proceedings are hopelessly obscured. Therefore whether each thread represents the longitudinal half of a portion of a univalent chromosome, and the pairing is the preparation for the condensation to form the whole univalent chromosome, or whether, according to the view held by Grégoire (22), each thread represents a portion of a whole univalent chromosome, and the parallelism is the premature pairing of homologous chromosomes, is a problem which cannot be solved by the study of *Primula* alone. Perhaps both arrangements may be proceeding simultaneously in the presynaptic prophase. Moreover, the interpretation of the parallelisms does not materially affect the question as to the ultimate telosynaptic or parasynaptic origin of the bivalent chromosome, for it is the post-synaptic stages that elucidate this point.

As the spireme comes out of synopsis it exhibits a certain amount of approximation between its lengths, but by the time that the open spireme stage is reached the spireme is thrown into loops, the sides of which are widely separated, the only places of union between them being the points of intersection. Gradually the sides of portions of the looped spireme approach one another, and thus indicate, in the *still continuous spireme*, that association which will eventually result in the formation of the respective future bivalent chromosomes. The lateral association between the strands becomes increasingly more intimate. The spireme then segments. When the necessary blending of the two is accomplished, then the bivalent segment splits into its two univalent chromosomes. These retain their connexion during diakinesis and finally separate on the spindle of the first meiotic division.

Thus *Primula* clearly illustrates the views held by Farmer and Moore (11) regarding the telosynaptic arrangement of the univalent chromosomes in the spireme. It is evident that in the looping of the continuous spireme the future univalent chromosomes, which separate at the heterotype mitosis and are distributed between the two daughter nuclei, are arranged end to end, for each side of a loop becomes in process of time a univalent chromosome. As the loops fold over and the sides approximate there is secondarily a greater or a less degree of parasynapsis between them before their ultimate separation.

This telosynaptic origin of the bivalent chromosome is wonderfully clearly shown in *Primula*, both on account of the sharp definition of the spireme and also owing to the fact that in two of the *Primulas* examined there is no second contraction, so that the whole process of association, fusion, and splitting apart of the univalent spiremes can be traced in perfect sequence.

The univalent spireme of *Primula* is of even thickness and its outline so definite that the places where it forms a bivalent association are most obvious. This gives it a great advantage over some other forms in which the spireme is apparently very viscous, which makes it impossible to decide whether the strands are of the bivalent or of the univalent order, for they may be stretched into a fine thread or contracted into a broad ragged band.

Besides being regular in thickness, the spireme of *Primula* is almost invariably homogeneous. It has been shown that the spireme is univalent in nature, so that in the rare cases when fission in its substance has been seen it must be the premature appearance of the fission which will divide the univalent chromosomes at the homotype division.

Secondly, as regards the character of the nuclei of hybrids. As a rule hybrids are sterile, or partially so, but it is not a feature peculiar to them, as it has frequently been shown that pure races may be also largely sterile. Geerts (19) found that 50 per cent. of the pollen-grains of *O. Lamarckiana*

were abortive. In a hybrid cotton plant obtained by crossing *Gossypium Barbadosense* with *G. herbaceum* Cannon (2) observed that in the material collected in November and December most of the male cells were normal, whilst in the material collected in the spring amitosis occurred. Jenčič (26) has worked out the ratio of the sterile to the fertile pollen-grains in many hybrids. In the hybrid *Primula austriaca*, a cross between *P. pannonica* and *P. acaulis*, he found that between 50 and 60 per cent. of the pollen-grains were sterile, and in the hybrid *P. venusta*, a cross between *P. carniolica* and *P. Auricula*, that 42 per cent. were sterile.

It is generally accepted that the $2x$ number of chromosomes in the hybrid is equivalent to the sum of the x number of parental chromosomes, and in most cases this statement can be corroborated. One of the most convincing examples is to be found in the eggs of *Ascaris*. Herla (25) discovered that some *Ascaris* eggs possessed three chromosomes, of which two were larger than the third, and that the small chromosome was always isolated from the others. He concluded that it must have arisen from the *univalens* parent, but he was unable to verify the hybrid parentage. Zoja (41), later, definitely proved that the eggs with three chromosomes were the result of a cross between *Ascaris megaloccephala bivalens* and *A. megaloccephala univalens*. He confirmed Herla's supposition that the small chromosome was the paternal one, and hence concluded that 'la cromatina paterna e la materna restano indipendenti nel nucleo delle cellule embrionali'.

Again, the investigation of Rosenberg (33 and 34) on the hybrid *Drosera obovata* furnishes another convincing example of the fact that the hybrid possesses the sum of the x numbers of the parental chromosomes. In the hybrid the $10(x)$ chromosomes obtained from the parent *D. rotundifolia* pair with 10 of the (x) number of the chromosomes of the parent *D. longifolia*; the remaining 10 chromosomes of *D. longifolia* remain unpaired. The ten bivalent chromosomes behave normally, but it seems to be a matter of chance to which pole the unpaired chromosomes repair, both in the heterotype and in the homotype divisions. Consequently the resulting tetrads possess a variable number of chromosomes. The pollen, as might be expected, is usually sterile. After several attempts Rosenberg has successfully crossed *D. obovata* with *D. longifolia* (34), and the offspring has about 37 chromosomes.

The recent work of Geerts (20) on the hybrid resulting from the cross between *O. lata* and *O. gigas*, and his interpretation of the union and behaviour of the parental chromosomes, are in direct accordance with the phenomena exhibited by the *Drosera* hybrid. On the other hand, Gates (16) has come to different conclusions as regards the behaviour of the chromosomes in the hybrid *O. lata* \times *O. gigas*. He agrees with Geerts that, in the heterotype prophase of the hybrid, the chromosomes

appear in their $2x$ number, namely 21. No pairing of homologous chromosomes ensues, but 10 move off to one pole and 11 to the other. 'The 10-11 segregation of chromosomes in the formation of the germ cells of this hybrid shows that there is not here a pairing and separation of homologous chromosomes of maternal and paternal origin, but that the segregation tends to be into two numerically equal groups' (p. 195).

The hybrid fern *Polypodium Schneideri* (12) furnishes another example of an inequality in the number of the parental chromosomes, one parent having a far higher number than the other. The parent *P. aureum* has 35 (x) chromosomes, the other parent, *P. vulgare*, var. *elegantissimum*, has about 90 (x) chromosomes, and the number of chromosomes appearing at meiosis in the hybrid *P. Schneideri* varies from 95 to 125. This figure can only be considered as an approximate estimate, as the chromosomes are so irregular and numerous, whilst at diakinesis some are apparently bivalent, and others univalent, that it is impossible to make an accurate count. The peculiar amitosis which is of such common occurrence in hybrids, and which may occasionally be found in pure strains, is frequently met with in *P. Schneideri*, dividing the pollen mother-nuclei, first into two, and then into four. The spores of this hybrid fern are always abortive.

The above enumerated hybrids have parents possessing unequal numbers of chromosomes. There are other cases in which the parents possess the same number as in the case of *P. kewensis* (type). It has been shown that this hybrid, derived directly from *P. floribunda* crossed with *P. verticillata*, is sterile. On the other hand, Cannon (3) crossed two peas, both of which had 14 ($2x$) and 7 (x) chromosomes, and the hybrid which repeated the same number was fertile.

In certain 'race hybrids' of *Lathyrus odoratus*, Gregory (23) found that abortion took place at various stages in the course of the meiotic division. The chromosomes were more ragged than were those of the parents and showed a deficiency of chromatin. Sterility in this case is a recessive character and is generally confined to those plants which have light-coloured leaf axils, that being a recessive character.

Finally, there are those cases of hybrids in which the chromosomes of the parents are too numerous, and the spindles of the hybrids too irregular to afford accurate data as to the relative numbers of the chromosomes. Such is the case with the hybrid *Syringa rothomagensis*, a cross between *S. vulgaris* and *S. persica*. Juel (28) was unable to count the chromosomes, but he believes that there are more in the hybrid than in the parents. He finds very irregular spindles, and also the curious modification of amitosis. 'Bei so vielen Arten von Unregelmässigkeiten bei der Tetradentheilung kann es nicht Wunder nehmen, dass *S. rothomagensis* in Bezug auf den Blütenstaub fast steril ist' (p. 647). Tischler (39) has confirmed Juel's investigation

of this hybrid, which he calls *S. chinensis*. Tischler (36) found in the hybrid *Cytisus Adami*, a cross between *C. Laburnum* and *C. purpureus*, most irregular divisions resulting in an unequal distribution of chromosomes to the poles. Again, in the hybrid *Bryonia* (37), a cross between *B. alba* and *B. dioica*, he has shown that the presynaptic and synaptic stages are normal, but that the chromosomes go on to the spindle irregularly, while some remain behind in the cytoplasm. The hybrid is always sterile. In the hybrid *Ribes intermedium*, a cross between *R. sanguineum* and *R. nigrum* (38), the meiotic phase is normal and 10 to 15 per cent. of the pollen-grains are well developed.

The fact that a hybrid may be either sterile or fertile does not therefore appear to depend on the pairing of an equal number of parental homologous chromosomes, nor can the irregularity of the spindle figures be called a determinant of hybridity. It is true that irregular figures and the peculiar amitosis must entail an unequal partition of chromatin amongst the tetrads, and hence may render them functionless, but these abnormalities are not confined to hybrids, but may also occur in pure breeds. Juel (27) has emphasized this fact in the nuclei of *Hemerocallis fulva*.

Tischler and others believe that the arrangement of the chromosomes cannot be taken into account with regard to the cause of sterility, but that the sterile condition is more probably due to the poverty of the cytoplasm and to the alteration in the constitution of the idioplasm.

Most cytologists have arrived at the conclusion that, in the blending of the male and female germ cells, physiological and chemical changes are induced, which fundamentally disturb the metabolism of the cells of the resultant offspring. The abnormal nuclear phases, the anomalous behaviour of the chromosomes, and the feeble condition of the cytoplasm afford visible expressions of the influence of unrevealed agencies which effect these intrinsic changes.

In conclusion, it is of interest to emphasize the points of similarity between this series of *Primulas* and the varieties of *Oenothera*. Briefly the character of the heterotype prophase, the presence in some forms and the absence in others of the second contraction, the longitudinal fission in the chromosomes throughout the interkinesis of the two meiotic divisions, the cytoplasmic connexions between the pollen mother-cells, are all features which the *Primulas* possess in common with the *Oenotheras*.

Moreover, both in the *Oenotheras* and in the *Primulas* a form has arisen from different sources, which has suddenly doubled the number of the chromosomes characteristic of the type. From the *Oenothera* evidence it seems probable that this duplication has been brought about by longitudinal fission, creating what is believed to be a double set of homologous chromosomes, for the duplication of the chromosomes has not been accompanied by the acquirement of any new characters. On the other hand, in the case

of *P. kewensis*, the duplication is accompanied by the acquirement of the character of fertility.

Further, both in the *Oenotheras* and in the *Primulas*, an example of a decrease in the chromosomes is found, whereby the duplicated number is reduced to the typical number. In the *Oenotheras* this reduction has been shown to be achieved by the actual disintegration of the supernumary chromosomes. It may be that in the hybrid produced by crossing *P. floribunda isabellina* with *P. kewensis* (seedling form) a similar elimination of chromosomes has taken place in the first segmentation division after fertilization.

SUMMARY.

1. The parents, *P. floribunda* and *P. verticillata* of the sterile hybrid *P. kewensis* have both 18 ($2x$) and 9 (x) chromosomes.

This number is repeated in the sterile hybrid *P. kewensis*.

P. kewensis (seedling form), which originated from *P. kewensis* (sterile) by the fertilization of a pin flower with pollen of a thrum flower (both on the sterile stock), has doubled the typical number of chromosomes and possesses 36 ($2x$) and 18 (x).

This number is repeated in the variety of the seedling form, *P. kewensis farinosa*, and reappears in the *P. kewensis farinosa*, which resulted from crossing *P. verticillata* with *P. floribunda isabellina*.

P. floribunda isabellina crossed with *P. kewensis* (seedling form) results in a hybrid which has reduced its chromosomes to the typical number of 18 ($2x$) and 9 (x).

2. The prophases of the premeiotic divisions show a stringing together of homogeneous beads of chromatin, which gradually condense to form the chromosomes. Longitudinal fission in the substance of the chromosomes is seldom seen until the chromosomes are arranged on the spindle.

3. The long rest between the last premeiotic and the first meiotic division makes it impossible to trace the homology of the parallel threads of the heterotype prophases.

4. In *P. floribunda* and in *P. kewensis* (seedling), there is no second contraction. Hence the sequence of events leading to the formation of the bivalent chromosomes can be traced without intermittence, namely, the looping of the *continuous univalent spireme*; the approximation and association of the univalent sides of the loops; and the final splitting apart of the approximated sides to form the univalent chromosomes of the bivalent combination.

5. This series illustrates clearly the telosynaptic arrangement of the *univalent* chromosomes in the *continuous univalent spireme* of the hollow spireme stage of the heterotype division, and the secondary parasynaptic union of homologous univalent segments to form the future bivalent heterotype chromosomes.

6. In *P. verticillata* there is a typical second contraction.

In *P. kewensis* (type) the spireme segments tend to amalgamate in parts, but they never form a definite second contraction.

7. In *P. kewensis* (seedling form) two of the bivalent chromosomes join together in the heterotype prophase of the pollen mother-nuclei, forming a large quadrivalent chromosome. This union is maintained until its univalent portions separate on the spindle.

In the homotype division all the chromosomes behave normally. There is also no connexion between two of the chromosomes in the first meiotic division of the embryo-sac mother-cell.

8. *P. kewensis* (seedling form) has a most typical diakinesis. The chromosomes are extremely contracted and are widely separated from one another, but are connected together by fine tightly stretched threads. The ordinary bivalent chromosomes resemble dyads, the quadrivalent chromosome a tetrad.

9. Protrusions of chromatin from a nucleus into the adjacent cell are sometimes found in the 'open spireme' stage of *P. kewensis* (type).

In conclusion I wish to express my most grateful thanks to Professor J. Bretland Farmer, F.R.S., for the valuable help and advice that he has given me throughout the course of this work.

DIGBY — CYTOLOGY OF PRIMULA.

Some Points in the Morphology and Physiology of Fasciated Seedlings.

BY

T. REED, A.R.C.Sc.

Senior Demonstrator of Biology, Guy's Hospital Medical School (University of London).

With nine Figures in the Text.

A FASCIATION is a form of abnormality in which the organ concerned becomes flattened or banded. This may be brought about in two ways, (1) by the fusion of organs which are ordinarily distinct, or (2) by the lateral expansion of an organ at its growing point.

The study of abnormalities in general has always occupied a more or less prominent place in botanical science, but the point of view from which they have been regarded has largely been that of the 'curious'. The two following quotations show in a striking manner the attitude of the botanists in the middle of the nineteenth century and the beginning of the twentieth. M. T. Masters (18), in his 'Vegetable Teratology', is describing the attitude of the botanists of the day, and says of malformations, 'They have been too long looked upon as monsters to be shunned, lawless deviations from the ordinary rule and unworthy of the attention of botanists.' Hugo de Vries (21) in 1905 says, 'Monstrosities are often considered as accidents, and rightly so from the morphological point of view, but *physiology excludes all accidentality*. Some internal hereditary quality is present though often latent, and the observed abnormalities are to be regarded as responses of this innate tendency to external conditions. Monstrosities should always be studied by physiologists from this point of view.'

Looked at from this point of view abnormalities become invested with a much greater importance.

The normal development of an individual is the result of two factors, the inherent tendencies of the organism and the external influences to which it is subjected. An abnormal form is one which deviates to any considerable extent from the normal or 'usual' form, as a result of the disturbance of one or other of these factors. If, however, the organism

deviates from the 'usual' course of development because of its being subjected to *new* external influences, then the term abnormal should cease to have any meaning *so far as that individual* alone is concerned, for obviously if it has been caused to deviate from the usual path of development because of certain specific new conditions, then that altered form is merely a *new* form which fits in with new conditions; that is to say, it is *normal* in so far as it is an *individual* which has developed as a result of inherent tendencies and external conditions, but abnormal when considered in relation to the 'type form'.

Within recent years many experimental facts have been obtained which go to show the truth of de Vries's suggestion.

It has been shown by G. Klebs (10), amongst others, that an alteration in the nutrient medium of an organism may have an important effect upon the form or phase of life of the individual concerned, and A. F. Blakeslee (1) has shown that it is possible to cultivate distinct physiological races by varying the conditions of culture. Similarly with the variations in *Oenothera Lamarckiana*, which de Vries discovered near Amsterdam in 1886. In its native soil the form had proved fairly constant, but in the potato field at Hilversum, where it met with *new* conditions, it soon began to assert its power to vary by producing 'abnormal' forms in the shape of fasciations and pitcher leaves, annual and triennial forms in place of biennials, and numerous other forms.

While altered conditions of culture may only result in a temporary 'variation' of the organism, it is important to notice that the individual can apparently be made to change in some degree.

It does not seem to be a far cry from these altered forms to those recently obtained by D. T. MacDougal (12). This observer injected solutions of sugar, zinc sulphate, &c., into the ovaries of flowers of *Oenothera biennis* and *Raimannia odorata*, and from the ovules of these plants he obtained seeds which on germination gave rise to individuals which deviated to a considerable extent from the normal parental type. These observations are particularly interesting in that not only were the individuals very different from the parental type, but also in that the derived forms have bred true over a period of five years. In other words, it would appear that we have here an 'abnormality' induced by a specific alteration of conditions of growth, i.e. an induced mutation. The 'derivative' form also breeds true to type when placed in the habitat of its parental type.

In nature it is not always easy or possible to analyse all the factors which may be operating on the individual, but it seems probable that there must be factors the effects of which, either singly or collectively, may be to induce modifications in the organism. What the actual mechanism is would be difficult to determine. Is it a definite chemical action of the disturbing substance on the constitution of the plant body, or is it an alteration in the

physical environment which 'permits' the variability of the organism to assert itself anew?

Abnormalities in the form of fasciations are of fairly frequent occurrence, and many examples have been described. C. Linnaeus (11) speaks of fasciations in his 'Philosophia Botanica'. He discusses their nature, and concludes that fasciated stems are due to the formation of an unusual number of growing points which become coherent, so that a whole bundle of shoots emerge as one. He says, 'cum plures caules connascuntur, ut unus ex plurimis instar fasciae evadet et compressus.'

At the beginning of the nineteenth century A. P. de Candolle (2) began to study malformations, but principally from the morphological point of view.

T. A. Knight (8, 1822), in a letter to the Secretary of the Horticultural Society, gives us some interesting facts concerning the production of fasciation in the Cockscomb (*Celosia*), perhaps one of the most widely known fasciations. He found that by applying larger quantities of manure he could produce larger and flatter specimens of the flower stalk of *Celosia*. By manuring the soil with 'one part of unfermented horse-dung fresh from the stable and without litter, one part of burnt turf, one part of decayed leaves, and two parts of turf, the latter in lumps about half an inch in diameter', and by applying 'liquid manure of steeped pigeon-dung in water', he could produce fasciated flower stalks eighteen inches wide. This fasciation is interesting in that the fasciated stem has now become normal and its inheritance is absolute. It is further instructive in that it is a definite example of a fasciation that has been induced by altered external conditions, the external condition which promotes fasciation being the superabundant nourishment.

A. Moquin-Tandon (15) in 1841 published his 'Éléments de tératologie végétale', wherein he discusses the significance to be attached to malformations. In this work he makes the interesting observation that the seeds of a fasciated *Circium* reproduced the same condition in the seedlings.

W. Hinks (7) in 1853 described instances of fasciation in *Primula vulgaris*, *Hieracium aureum*, *Ranunculus bulbosus*, *Bunium flexuosum*, *Cotoneaster microphylla*, &c. He states 'that these malformations are due to the operation of causes or principles, the ordinary operation of which produces the normal structure of the species'. He evidently recognized that 'extraordinary structures' were the result of 'extraordinary influences'. He, however, goes on to say that 'fasciated stems seem to be best explained on the principle of adherence of a number of buds which have arisen in close proximity owing to the presence of *superabundant nourishment*, especially if accompanied by check or injury'. He also combats the argument that fasciated stems are due to the dilation of a single stem, as had been supposed by many people.

M. T. Masters (18) published his 'Vegetable Teratology' in 1869, and there gives a host of examples of plants showing various forms of malformation. He recognizes that malformations are to be regarded as irregularities differing from variations mainly in their wider deviation from the customary structure and in their more obvious dependence on external conditions, and by their smaller liability to be transmitted by inheritance. He further goes on to say 'that it is even possible that malformations, especially when they acquire a permanent nature and become capable of reproducing themselves by seed, may be the starting-point of new species, as they assuredly are of new races, and between races and species he would be a bold man who would undertake to draw a hard and fast line'. Thus even as early as 1869 Masters thought it not improbable that mutations, caused by external influences, might give rise to new species.

Coming to more recent times, A. Braun, Celakowsky, Worsdell (23), Goebel (4, 5), Vöchting (18), and de Vries (19, 20, 21, 22) have given us many interesting observations on malformations.

K. Goebel (4, 5) states that it was mainly owing to the study of malformations that the idea of the foliar nature of the stamen came to be recognized. 'It is rather to the causes which condition the deviation from the normal development that we ought to pay most attention.' If by altering the external conditions an alteration can be induced in the organism, then we are in a fair way towards throwing some light on the great question of organic form. He gives examples of fasciations in *Taraxacum officinale* and mentions that it is only well-nourished specimens which show this phenomenon.

H. de Vries (19, 20, 21, 22) describes several examples of fasciated stems in *Taraxacum officinale*, *Thrinia hirta*, *Picris hieracioides*, and *Crepis biennis*. The latter gives off about 30 per cent. to 40 per cent. of heritable forms. He states that weak seedlings are not favourable examples for obtaining malformations, but strongly nourished plants should be taken. In speaking of stems which show biastrepis and fasciation, de Vries (19) also states that 'most monstrous plants require much manure; manure can hardly be given in excess; the richer the soil the better the proportion of twisted stems'.

A. D. Knox (9) describes instances of fasciation in *Oenothera biennis* and *O. cruciata*. She describes the anatomy of the fasciated stems and gives an account of the degree of heritability of the malformation. The causes of fasciation in these cases are said to be two, (1) injury to the growing point by insects, and (2) superabundant nourishment. She concludes that 'given similar conditions of culture the factors involved in the production of fasciations are the specific mode of attack of insects, the character of the plant, and the rapidity of development. The second of the three

appears to be of most importance.' A point worthy of special notice is that the fasciations usually just precede the date of flowering, i. e. at a time when the carbohydrates of the plant will be very abundant.

Molliard (14) describes cases of fasciation in which he found the apices of the plant injured by insects.

J. Peyritsch (17) found fasciations which he thought were due to fungal attacks.

T. Petch (16) states that fasciations are frequently found in *Hevea Brasiliensis*. The trees affected are principally young trees. He thought that in some instances fasciation was due to attack of insects and Fungi, but in the majority of cases no definite cause could be stated.

R. H. Compton (3) describes the anatomy of a 'ring fasciation' in the Mummy Pea, *Pisum umbellatum* (Miller). This form also breeds true, its peculiar character behaving as a simple recessive in crosses with the normal type.

A review of the historical evidence leads us to conclude that fasciations are due to at least two causes. Firstly, the presence of superabundant nourishment and suitable conditions for rapid development; and, secondly, the sudden arrest of the activity of growing points due to insect and fungal attacks. It would appear, though, that a third factor ought to be added to account for the many cases of fasciation which appear for no apparent reason, but which might very easily be caused by mechanical injury to the growing point.

In any case, it now appears to be fairly certain that whatever the inducing factor may be there must be present within the plant a considerable quantity of elaborated sap to supply the demands of increased meristematic activity, and it may well be that this is the essentially determining cause in all.

In the present investigations seedling plants of Leguminosae were chiefly used, but others were introduced for purposes of comparison.

The seeds were germinated in various soils, and when the plumular shoots had developed a length of about an inch or so the apical bud was cut away and the seedling allowed to continue its growth.

Two types of seedling were used, the epigeal and the hypogeal types.

A. HYPOGEAL.

I. PHASEOLUS MULTIFLORUS.

The plants were grown in both soil and sawdust. In about two days the radicle had penetrated the testa and grown down into the substratum. Two or three days later the epicotyl and plumular leaves had appeared above the soil and attained a length of about an inch. The main portion of the epicotyl was removed and the seedlings allowed to continue

their growth. As a consequence of the arrested growth at the stem, apex shoots were developed in the cotyledonary axils (Fig. 1, *b*). The

FIG. 1.

buds from which these shoots are developed normally remain dormant. Many of these shoots, instead of following their normal course of development, were found to show very pronounced fasciations and biastrepis

(i. e. twisting). If the further development of these shoots is also inhibited by the removal of their apical buds, more fasciated and twisted shoots are produced at their bases until quite a tangle of such shoots is formed in the cotyledonary axil. Such seedlings are shown in Figs. 2 and 3, *b*. If the seedling is now permitted to continue its growth it does so for a short time only, and sooner or later all further growth ceases and the plant dies.

FIG. 5.

FIG. 6.

FIG. 7.

FIG. 8.

FIGS. 5-8. *xy*, secondary xylem. *Pxy*, protoxylem. *Plt.*, plumular stele. *Fst.*, *Fst.*², first and second fasciated shoot steles.

In addition to the development of the axillary fasciated shoots, the hypocotyl also develops enormously and presents a fasciated appearance (Fig. 2, *d*).

The leaves which are laid down on the fasciated shoots also remain small and in many cases do not even unfold from the bud (Fig. 4, *f*).

The development of the root system appears to be quite normal.

The power of the plant to respond to various stimuli also appears to be

interfered with. The shoots twist and curl in all directions, with an apparent disregard for all heliotropic and geotropic stimuli (Fig. 3, *k*).

Anatomy of fasciated shoots. As is well known, four bundles pass into the hypocotyl from each cotyledon. In passing down the hypocotyl these become orientated, so that a tetrarch stele is formed in the root.

Secondary thickening commences very early, so that in a young seedling an almost complete vascular ring is found near the top of the hypocotyl (Fig. 5). From this ring is given off the vascular supply to the fasciated shoots. To the right and left of this central stele lateral steles are given

off which pass out into the fasciated shoots. It has been pointed out above that the hypocotyl has also become fasciated, and this fasciation is also reflected in its anatomical structure. These lateral steles do not immediately become separated from the central stele, but they run parallel with it for some little distance, so that at this level one gets a polystelic structure consisting of three parallel steles (Figs. 6 and 7, *F.st.*). This condition of the stele has been frequently described by Worsdell and others for other plants.

Before these steles are separated from the parent stem they proceed to give off other lateral steles which pass out into the second fasciated shoots. These steles behave similarly to the first pair of laterals and remain attached to the parent stem, so that a polystelic structure consisting of five steles is shown (Fig. 8, *F.st.*²). Sooner or later, however, the fasciation breaks up and the steles pass out into the separate fasciated shoots.

The anatomical features of the individual fasciated shoots call for no detailed description.

The normally cylindrical stele becomes laterally attenuated and follows more or less completely the configuration of the malformed shoot. No pronounced abnormal structures were seen in the stele of these shoots, although it is not uncommon to find that the whole arrangement of the stele may be considerably interfered with. On the whole one finds perhaps fewer lignified elements in such vascular tissue, but this may be correlated with the comparatively rapid growth of the shoot and its generally etiolated appearance, and the fact that its subsequent development is also arrested, so that the elements remain in a more or less immature condition.

A case which calls for special mention is one in which the fasciation

FIG. 9. *Pl*, arrested main shoot. *F*₁, *F*₂, *F*₃, *F*₄, fasciated shoots. *L*, reduced leaves. *C*, cotyledons.

appeared 'spontaneously'; that is to say, the fasciation was not artificially induced by amputation of the growing point. Although I was not able to determine with absolute certainty the immediate factor which brought about the fasciation, a careful examination of the seedling showed that the development of the main shoot had been interfered with and its growth checked. This check may have been due to mechanical injury of the growing point, or the apical bud may have been attacked by a fungus or insects, &c. As a result of the check the axillary shoots developed and became strongly fasciated. This seedling is figured in Fig. 9.

VICIA FABA.

Seedlings of this plant were also grown and treated in a similar manner to those of *P. multiflorus*. Fasciations were obtained, but they were not nearly so pronounced or numerous as in the case of *P. multiflorus*.

The same general features were observed in the hypocotyledonary anatomy, but never more than three vascular rings were met with.

PISUM SATIVUM.

Seedlings of this plant were similarly treated, but here again, while fasciations were produced, they were few in number.

It will be noticed that the three types of seedling above studied are all of the hypogeal type and all show fasciations to a greater or lesser degree. It was therefore thought desirable to test the power for producing fasciation in epigeal seedlings.

B. EPIGEAL TYPES.

Phaseolus vulgaris (French Bean), *P. vulgaris* (var.?) (Butter Bean), *Lupinus Douglassii*, *Ricinus communis*, and *Cucurbita Pepo* were chosen because of the fleshy nature of their cotyledons or because of the large amount of reserve food available to the seedlings.

The seedlings were grown in pots along with the types already studied, and also grown separately in pots with the other types as controls grown near to them. They were subjected to treatment similar to that which the previously studied types had undergone. Although the cotyledonary shoots developed in many instances, in no case was a fasciation produced.

Is this power of the hypogeal type of seedling to produce fasciations an accidental quality which is not possessed by the epigeal type, or is it that the food reserves of the two types of seedling differ in quality or quantity?

It has frequently been stated by other observers that an abundant supply of food material is necessary for the production of fasciations.

Analyses were made of the seeds of *P. multiflorus*, *P. vulgaris*, and *Vicia Faba*. For these analyses I am greatly indebted to Mr. T. J. Ward, of the Chemical Department of St. Mary's Hospital Medical School, Paddington.

In each case the testa was removed from the seed before the analysis was made.

The results of the analyses were as follow:—

Constituents.	<i>P. multiflorus.</i>	<i>Vicia Faba.</i>	<i>P. vulgaris.</i>
Moisture	14.44	13.305	13.46
Benzine extract. (Oils, fats, resins, &c.) . . .	2.72	2.11	1.98
Alcohol extract. (Tannin, glucosides, and some sugars)	(11.04)	(4.51)	(29.99)
Soluble carbohydrates, as dextrose	10.155	16.004	9.81
Starch	46.35	37.296	43.01
Cellulose	2.31	2.09	2.15
Proteids	21.04	27.83	21.96
Diastatic value as wt. of starch converted by 100 grm. of bean	(3.5)	(1.85)	(3.33)
Calcium (as oxalate)	0.196	0.123	0.216
	<u>97.811</u>	<u>98.758</u>	<u>92.586</u>

Each sample contains dextrine, glucosides, albumins, globulins, albuminoses, and substances which on hydrolysis yield pentoses.

The total percentages are in all cases below one hundred, and this is due to the fact that the alcohol extracts are not included in the total percentages. The extracts contain a considerable quantity of a resinous substance which was not identified with certainty owing to the methods for the determination of glucosides and tannins being unsatisfactory. *P. vulgaris*, however, contains a larger quantity of this resinous substance than either of the other two. This result is important, for it is stated by Jost that tannin would inhibit the action of diastase. This point, however, will be referred to again later.

The differences in the amounts of carbohydrates are not considerable, but the epigeal type (*P. vulgaris*) contains the smaller quantity, the combined amounts of soluble carbohydrates, starch, and cellulose being:—

<i>P. multiflorus.</i>	<i>Vicia Faba.</i>	<i>P. vulgaris.</i>
58.815	55.390	54.97

In regard to their proteids *P. vulgaris* contains a smaller amount as compared with *V. Faba*, but a slightly larger quantity as compared with *P. multiflorus*.

The 'diastatic value' was estimated as follows: A cold-water extract was made from the bean and so it contained no starch, as was shown by testing before making an estimation. Definite amounts of the extract were added to a dilute solution of pure starch. The tubes were immersed in a water bath at 40° C. for one hour and then cooled and tested, after making sure no starch remained unconverted. The experiments were carried out by gaslight, but as the tubes were immersed from five to six inches in water they were removed from the influence of light.

The smallest value is given for *V. Faba* and the greatest for *P. multiflorus*.

P. vulgaris contains a greater quantity of calcium oxalate than either of the other two.

The analyses show that the epigeal type contains less carbohydrates, about the same amount of proteid, but more resinous matter. Apart from the resinous substances the three seeds do not differ to any considerable extent quantitatively. It does not follow, however, that this 'ready manure' is equally available for use by the two types of seedling respectively. In the one case the food reserves are not normally exposed to the action of light, whilst in the other they are carried up into the light. It is quite possible that this latter fact is of importance, for J. R. Green (6) states that light has an inhibitory effect upon the action of diastase and so the starch may not be as available to the seedlings of the epigeal type as to those of the hypogeal type. The presence of a greater quantity of glucosides in the epigeal type may also interfere with the conversion of starch into soluble carbohydrate, for according to Jost this also has an inhibitory effect upon diastatic activity.

That there is a difference between the two types of food reserve and general organization of the developmental cycle is shown by the degree of dependence which each type of plant has on its reserves.

Young seedlings of *P. multiflorus* and *V. faba* were allowed to grow until the first pair of plumular leaves was unfolded. The cotyledons were then completely severed from the seedling and the plant permitted to continue its development. Growth is continued for a very short period only; the leaves expanded a little more, but sooner or later the mutilated seedlings died. During the same interval (Oct. 11—Nov. 3) the normal control plants grew about four feet in height.

A second batch of seedlings was then taken and allowed to grow until the first pair of plumular leaves was fully expanded; their cotyledons were then removed. In this case growth in length of the stem continued for a little while, but no new leaves were unfolded, the plant on the whole showing an etiolated appearance. More advanced stages of germination were taken, and it was found by this series of experiments that these plants were dependent upon their cotyledonary food reserves until they had expanded their third or fourth pair of leaves.

A similar set of experiments was made with the French Bean and Butter-bean. In these cases the cutting away of the cotyledonary food supply appeared in no way to affect the subsequent growth of the plants, the mutilated ones being indistinguishable from the controls.

From this series of experiments it would appear that, although the reserve food materials of the cotyledons may be very similar in the first instance, their immediate and relative availability to the two types of seed-

ling is very different. The fact that the cotyledons are hypogeal in the one case suggests that the reserve food stored within them is sufficient to give the plant a good start in its development, such, at any rate, that it does not bring them above ground to assist in the processes of assimilation. On the other hand, the epigeal type brings its cotyledons into the service of the plant by enabling them to assist in assimilation. On the whole, then, it seems that the hypogeal type has an immediate and readily available stock of food, on which it draws largely when germination begins. In the case of the epigeal type of seedling it may well be that the cotyledonary food reserves are early used up in the growth of the cotyledons and the fairly long hypocotyl, and as a consequence the seedling has from the early stages acquired the habit of foraging for itself.

Then again, since the cotyledons of the epigeal type are carried into the light and become green, it is quite possible that the materials produced by photosynthesis become mixed up with the reserves, which in this way may be rendered less directly available for the plant.

With a view of testing this suggestion, seedlings were grown in the dark room and the plumular buds amputated as in previous experiments; controls were also kept under the same conditions. Fasciations were only obtained in those plants which show them under the other experimental condition. The seedlings of *P. multiflorus* produced good fasciations, but the epigeal types developed their cotyledonary shoots without showing any trace of fasciation. A second set of experiments was also made in which *P. multiflorus* seeds were germinated in the ordinary way and the plumules amputated as before. The cotyledons were then uncovered and the testa removed, so that the cotyledons were fully exposed to the light. The exposure of the cotyledons, however, had no apparent effect on the plants' power to fasciate, for fasciations appeared in considerable numbers.

It would appear, then, that light is not the only determining factor, for the epigeal type does not fasciate when its cotyledons are removed from the influence of light, nor does the hypogeal type cease to fasciate when its cotyledons are brought under the influence of light.

Further experiments were made in which seedlings of the epigeal type were given a plentiful supply of nitrogenous manures. Although the unutilized plants were very vigorous in their growth the mutilated plants did not produce any fasciated structures.

SUMMARY.

1. The plants used in these experiments may be grouped in two classes: (1) Hypogeal types—*Phaseolus multiflorus*, *Vicia Faba*, and *Pisum sativum*; (2) Epigeal types—*Phaseolus vulgaris*, *Phaseolus vulgaris*, var. ?, *Lupinus Douglassii*, *Ricinus communis*, and *Cucurbita Pepo*.

2. Fasciations were induced in the former class but not in the latter.
3. The hypocotyl of hypogeal seedlings may be fasciated as a result of the adherence of a number of fasciated shoots. The vascular anatomy of such a structure is polystelic.
4. The food reserves in the two types of seedling may be similar, chemically, but the availability of that food is different for the two types of plants.
5. Hypogeal seedlings are remarkably dependent on their cotyledonary food reserves for their early development as contrasted with seedlings of the epigeal type.

My thanks are due to Prof. J. B. Farmer for suggesting that the work should be undertaken and for much valuable help and criticism during the earlier stages of the investigations; to Mr. W. Hales, of the Chelsea Physic Garden, where most of the experimental work was done, and also for much valuable advice on the culture of seedlings; to Mr. T. J. Ward, of St. Mary's Hospital Medical School, for the analyses of some of the seeds; and to Mr. E. Lee for much friendly criticism during the preparation of the paper.

The Attaching Discs of the Ulvaceae.

BY

E. MARION DELF.

With Plate XLV and three Figures in the Text.

THE thallus in the Ulvaceae consists of a somewhat delicate green frond, terminating below in a narrow and very often short stalk or stipe, which is attached to stones, wood, or, less often, to other Algae by means of a tough disc-like expansion.

This attaching organ was described by Thuret¹ in 1878 as a small disc formed by the interwoven tubular prolongations of the cells of the thallus. Any cell of the thallus was said to have the power of forming the tubes, with the possible exception of those cells which become zoosporangia. Just above the disc the thallus is distinctly thicker than higher up, and Thuret noticed that in some cases the tubes were woven together in dense strands or bundles, several such strands occurring side by side in one disc.

Some material of *Ulva latissima* (Harvey), preserved in formalin, was accidentally obtained growing upon a fragment of the frond of some other seaweed of the *Furcellaria* type. Hand sections showed that the tubular prolongations of the cells (or disc filaments, as I shall call them) had in some places displaced the small peripheral cells of the supporting thallus, in a way which suggested either a parasitic or a saprophytic habit. Later on, in fresh material from Rottingdean, a frond of *Ulva* was found attached to part of a thallus of the *Polysiphonia* type of structure, and here the disc filaments had actually penetrated into the cells of the host, just as is done by the intracellular hyphae of some parasitic Fungi. Other *Ulva* plants were collected which were attached to small chalky stones, and the discs of these were detached, carefully scraped, and washed free from grit as far as possible; they were then fixed in weak Flemming solution and embedded in the usual way. The microtome sections obtained from this and also from the parasitic material were stained with Kleinenberg's haematoxylin and eosine. Hand sections and preparations of teased-out hyphae were also examined.

A vertical section through the disc of a thallus of *Ulva* at its point of attachment to the supporting seaweed showed the tubular prolongations of

¹ Thuret: *Études algologiques*, 1878.

the superficial cells passing obliquely down to the disc, where they spread out and appear to become closely interwoven with one another. When they reach the host, the tips of the filaments swell up and become closely appressed to the surface, often appearing to form a kind of pseudo-parenchymatous investment; this is shown diagrammatically in Text-fig. 1.

* TEXT-FIG. 1. Longitudinal section through attaching disc of *Ulva*: outline, and cells of host, drawn with camera lucida; filaments of the disc shown much simplified, and somewhat diagrammatically. $\times 100$.

Microtome sections through the discs of fronds which had been attached to stones showed that wherever the filaments had reached the exterior their tips had become swollen and multinucleate; often definite cell-divisions appeared to have taken place, two or three successive segments having been cut off from the swollen part of the filaments (Pl. XLV, Figs. 5, 6). These larger segments were often surrounded, especially on the outside, by the cut ends of many minute filaments. Some of these had their origin in peripheral cells of the thallus, as seen in Pl. XLV, Fig. 8, at *a*; others appeared to have reached the periphery from within, and to have found no room for expansion at the end of their course; it is possible that some may also have formed by the branching of larger filaments, such as that shown in Pl. XLV, Fig. 1. The longitudinal section of such a disc is seen in Text-fig. 2, and a small part taken from the region A is shown in detail in Pl. XLV, Fig. 7.

The region marked B is part of the disc of another frond, formed, as it appears, from an outgrowth of the disc filaments, but this capacity for forming new fronds from the tissue of the disc was seen better in a hand section, which is represented diagrammatically in Text-fig. 3.

On teasing out the filaments from thick sections, it was found that they pursue a somewhat sinuous course through the lower part of the thallus, often bending on themselves, and the pointed awl-shaped tip suggests an active boring movement, as though the penetration of the tangled filaments were against distinct resistance (Pl. XLV, Figs. 2, 3). In some cases the filaments appeared to have branched, as in Pl. XLV, Figs. 1, 4, but these were very difficult to isolate, owing to the delicate nature of the tubes. In one case, however, no fewer than ten branches had been given off (Pl. XLV,

Fig. 1). Thuret states that the tubular filaments may reach a length of 6-10 mm., but those measured by me were never more than 3 mm. in length.

The superficial cells of the thallus giving rise to the filaments seem to be always multinucleate. In their upper region from three to five nuclei have usually been observed (Pl. XLV, Fig. 8). The tubes are exceedingly narrow, and are smaller when running on the outside than when running in

TEXT-FIG. 2. Diagram of longitudinal section through disc of *Ulva latissima*. The oblique lines show the general direction in which the filaments run. The dotted regions show the false tissue formed by the large and small filaments at the periphery of the disc: the region around A is that from which Pl. XLV, Fig. 7 is drawn in detail. At B is the lower part of a frond formed from an outgrowth of the disc.

the interior of the thallus (Pl. XLV, Fig. 8, at a); in either case minute nuclei occur at intervals down these tubes, and from two to five nuclei are commonly found crowded together in the tips of the tubes. These apices vary very much in size; they are usually narrow and pointed, with small nuclei, until the periphery of some part of the disc is approached, when they increase greatly in size, the nuclei become larger and more numerous,

and two or three successive segments with usually more than one nucleus are cut off (Pl. XLV, Figs. 5, 6). It is probable that the small filaments bore their way into crevices and become firmly attached there, whilst the larger multinucleate segments give rise to the new thalli. All the filaments appeared to have been full of living contents at the time of fixing (early

TEXT-FIG. 3. Diagram of longitudinal section through disc of *Ulva latissima*, which has given rise to four fronds. The lines show the general direction of the filaments; the cross-hatched region is part of the periphery of the disc which has not been cut in the median plane.

spring), so that it is probable that, whilst the thallus of this species is annual, the discs are perennial.

The nuclei vary somewhat in size, but always appear as small refractive bodies, with a single nucleolus. Two nuclei may often be seen closely associated, but no case of an actually dividing nucleus has been observed.

Stained microtome sections through discs of *Ulva*, which were attached to a thallus of the *Polysiphonia* type, leave no doubt as to the parasitic or

saprophytic nature of the fronds. The host plant had been completely encircled by the developing disc, and the thick walls of the pericentral cells were pierced and riddled with the small pointed ends of the filaments, which usually contained more than one nucleus. In many of the cells the tips of the filaments had evidently expanded, forming a delicately vacuolated lining of cytoplasm almost filling the cell, and containing numerous and characteristic embedded nuclei (Pl. XLV, Figs. 9, 10). At the periphery of the host may be seen the appressed tips of large and small filaments, just as in the disc already described; both these kinds of filaments were found in the process of boring their way through the solid wall, and this is probably achieved, as in the Fungi, by the secretion of some cytohydrolithic ferment.

It is impossible for me to say whether the host plant was living at the time of fixing, but I have myself often observed both *Ulva latissima* and *Ulva lactuca* growing attached to the frond of some other living seaweed, and it seems probable, therefore, that this plant is at least a facultative parasite. Since, however, it is known that both species of *Ulva* grow luxuriantly in the presence of the nitrogenous products of decay, it is probable that the saprophytic habit could also be readily adopted.

THEORETICAL CONSIDERATIONS.

It is well known that the different species of *Ulva* which commonly occur on our coasts are especially abundant in the brackish water of estuarine localities, and also on the open shore in the neighbourhood of towns. In some cases the fronds grow so luxuriantly as to be cast up in masses by the tide, and the offensive smell of the sulphuretted hydrogen which is formed as these plants decay is sometimes a serious nuisance to the inhabitants. Before, however, this can be effectively remedied, much more must be known of the life-history and habits of the plant, as has already been shown in detail by Mr. A. D. Cotton in his suggestive paper on the subject.¹

From the above account it appears that there is probably a very effective means of reproduction in the formation of these adhesive discs, which are undoubtedly very tenacious of life, can probably live through the winter independently of the thallus (which is described by Harvey and others as annual), and can bear new fronds by the upgrowth of the filamentous tubes of the disc. It would therefore be necessary to adopt some measure to destroy the vitality of these in order to check their spread effectively.

From the point of view of affinity, the multinucleate character of the filaments of the disc in *Ulva* serves to emphasize the isolation of the whole group of Ulvales, and to remove it from any near relationship with the Ulothricales. On the other hand, the simple segmentation of the tips of the filaments has no resemblance to the method of wall formation in

¹ Cotton, A. D.: On the Growth of *Ulva latissima* in Water polluted by Sewage. Kew Bulletin, 1910.

a typically coenocytic group such as the Siphonales. The method of formation of the disc, indeed, resembles far more closely that found in the simplest red seaweeds, such as *Bangia* and *Porphyra*, but whether this is a case of true affinity, or of parallel development in widely different groups, must be decided only on the result of further research.

The apparently parasitic penetration of the disc filaments into the tissue of some other Algae, and the way in which they appear to entirely take possession of the cells of the host, are, as far as I know, unparalleled at present amongst the Chlorophyceae.

INTRODUCTION.

SUCCULENT plants are largely characteristic of dry, sandy, or rocky regions, where the physical conditions seem to favour rapid transpiration, whilst the water supply is limited, or in some way precarious. They are, however, also found in very different situations, as, for example, the epiphytes of a typical tropical forest where the atmosphere is warm and damp. Other succulent plants inhabit maritime districts, especially the neighbourhood of salt-marshes, and others, such as many of the Crassulaceae, though commonly found in stony or rocky places, thrive equally well in ordinary soil, and may then be freely associated with mesophytes. We may thus distinguish, according to their habitat, four main classes of succulent plants, which may be briefly designated as (1) *Desert Plants*, (2) *Rock Plants*, (3) *Epiphytes*, (4) *Halophytes*.

We are naturally led to ask how far the succulent habit is to be regarded as an adaptation to environment in all these cases; and in the

following pages this question will be discussed in its bearing on the problem of transpiration, firstly in relation to structural features, and secondly in relation to habitat.

I. TRANSPIRATION IN RELATION TO STRUCTURE.

Succulent plants have a number of anatomical features in common which are undoubtedly connected with the process of transpiration. We shall consider the character of (α) the transpiring surface, (β) the storage system, and (γ) the conducting system, from the physiological point of view.

(α) The Transpiring Surface.

In plants of extremely dry habitats there is often a notable reduction in leaf surface, the stem itself taking on the bulk of the work of assimilation and transpiration; there is therefore, presumably, a corresponding diminution in the total water loss, although not necessarily in the actual rate of transpiration, per unit area of surface. Examples of this are seen in the thorny almost leafless stems of desert species of *Euphorbia*, and the equally thorny swollen stems of *Opuntia*, *Echinocactus*, and some other genera of the Cactaceae. The same tendency to eliminate the leaf as a distinct organ is seen in the halophytic genera *Salicornia* and *Arthrocnemum*, where the leaves are reduced to mere fleshy lobes almost entirely adnate to the stem.

A large number of plants, however, have fleshy leaves or succulent stems without any such extreme reduction of surface, as, for example, the majority of epiphytic or halophytic plants; these are often termed semi-succulents.

It is commonly assumed that the percentage water content of a plant is in itself a criterion of its degree of succulence;¹ but I have reserved this phrase to indicate the water content per unit area of surface.² In this sense the degree of succulence of a plant is of some interest for problems of transpiration, and a number of determinations from my own experiments are given in Table I.

The method employed was that of finding the fresh weight of a leafy shoot, estimating the surface area, and drying at 100° C. until a constant weight is obtained. The greatest difficulty lay in the determination of the surface areas. For large-leaved forms the outline of the leaf was carefully traced on paper ruled in millimetre squares; when a number of leaves had to be traced in succession, they were kept in a damp chamber or floated on water until just before use, in order to minimize the shrinkage in surface due to loss of water in transpiration, which has been demonstrated to take place even before withering becomes perceptible.³ In the case of small-leaved forms the procedure was varied to suit the particular type of leaf.

¹ Cp. Aubert.

² Delf, E. M.: Transpiration and Behaviour of Stomata in Halophytes. *Annals of Botany*, 1911.

³ Cp. Thoday, D.: Experimental Researches on Vegetable Assimilation and Respiration, V. *Proc. Roy. Soc., B*, vol. lxxxii, 1909.

In the case of *Suaeda* and *Salsola* the method employed was that described in my paper on 'Transpiration and Behaviour of Stomata in Halophytes' ('Annals of Botany', xxv, p. 487); for *Salicornia* the micrometer screw method detailed in the same paper (p. 487); whilst the small leaves of *Mesembryanthemum crystallinum* were estimated both by the micrometer screw and celluloidin method,¹ and the mean between the two determinations (which usually differed by from 1-3 per cent.) taken as a fair approximation to the true surface area. In all cases the stem was included in the determinations both of areas and of dry weights.

The succulence of the leafy shoots of *Salsola Kali* and *Arenaria peploides* is probably somewhat underestimated, for the only material available had been sent by post from some distance, and although kept in water for some time before using were probably not fully turgid at the time of the experiment. The shoots of the remaining examples were obtained direct from healthy plants cultivated in the garden at the James Allen's Girls' School, Dulwich,² where there is an artificial salt-marsh, which is watered at intervals with a 1-2 per cent. solution of Tidman's sea-salt, and also an artificial sand-dune, and pebbly sea-shore, in a very flourishing condition. It was ascertained, by means of the thallium sulphate test, that the plants used had a very considerable salt content, but they probably show a somewhat less succulence than that of plants in their natural habitat, especially in the case of variable plants, such as *Aster Tripolium* and *Arenaria peploides*.³

³ Cp. Lesage, P. : Recherches expérimentales sur les modifications des feuilles chez les plantes maritimes. Revue Générale de Botanique, 1890.

The plants fall roughly into three groups which may be termed 'succulent', 'semi-succulent', and 'mesophytic', respectively. The plants belonging to the first group possess from 5 to 12 grm. water content to every square decimetre of surface; to this class belong, probably, the xerophytic succulent Cactaceae (*Opuntia*, &c.). The same degree of succulence may be attained by large and small leaved forms, such as *Mesembryanthemum edule* and *Suaeda maritima*; by adnation of the reduced leaf (as in *Salicornia*, and to a less extent in *Salsola*), or by the development of aqueous tissue in each separate leaf, as in *Arenaria peploides* or *Plantago maritima*. The plants belonging to the second group comprise most of our British halophytic plants, many rock plants, and would probably also include many sub-tropical or tropical epiphytes, and plants typical of the Mangrove swamps. These have from about 2 to 5 grm. water content per sq. dm. surface. The third group includes only typically mesophytic plants, such as *Saponaria* and *Mercurialis*, and perhaps also a few exceptionally thin-leaved halophytes like *Statice*, in which the aqueous tissue is limited to the region of the midrib, and in which the epidermis is provided with small excretory glands. *Frankenia* and *Tamarix*, two other somewhat thin-leaved halophytic genera, at least in some of their species, are also provided with epidermal glands, and it is possible that the excretion of salt which is said to take place through these glands may account for the absence of the succulent habit.

Whether reduced or not, the transpiring surface is protected by a definite tissue, the epidermis, which may be more or less cuticularized. Haberlandt¹ describes an experiment in which he demonstrates the protective power of the epidermis in succulent plants. Two pieces of an Aloe leaf were covered with wax, except for a definite area, equal in both cases. The epidermis was carefully stripped from the exposed surface of one piece, but was left intact on the other; both pieces were then exposed to the air for three hours. The pieces were then weighed and the stripped leaf was found to have lost 524 mg., whilst the uninjured piece had lost only 2 mg. In this case the epidermis has a well developed cuticle, but there is, no doubt, a considerable amount of protection derived from even a slightly cuticularized epidermis.

Many succulent xerophytes have a thick cuticle and relatively little water loss, as the work of both Schimper² and Volkens³ shows. Holtermann also found some Cactaceae with thickly cuticularized epidermis in which the transpiration was almost imperceptible. In alpine plants, according to Leist and Bonnier,⁴ the outer wall of the epidermis is more strongly

⁴ Leist and Bonnier: Quoted by Dr. A. Burgerstein, in 'Die Transpiration der Pflanzen', 1904.

cuticularized than that of the same species living on the plains; and here again the function of the cuticle appears to be primarily protective rather than mechanical, as Fleischer¹ believed. Wiegand² suggests that cuticularization is particularly characteristic of plants which are exposed at all times to the danger of too great transpiration; whereas a thinner cuticle with a covering of hairs is more often found in plants in which transpiration must be reduced at times, and yet must remain unhindered when the air is damp, and transpiration therefore rendered difficult.

Schimper claimed that a thickened cuticle, as well as other xerophilous adaptations, is to be found in most epiphytes,³ in Mangrove plants,⁴ and in the plants of the Solfataras,⁵ or regions bordering a fumarole. He stated that in the first case the precarious water supply rendered protection against too rapid evaporation necessary; in the second case the presence of chlorides, and in the third case of sulphates in the soil, renders the process of absorption so difficult that the transpiration also must be diminished by means of xerophilous adaptations. According to the more recent observations of Holtermann,⁶ however, this is by no means always the case. The epiphytic vegetation was found to occur, at least in Ceylon, mostly in damp tropical or subtropical forests; the plants found in such localities showed little or no cuticularization of the epidermis, and they were, as a matter of fact, found to be capable of very rapid transpiration; such are, for example, many species of *Ficus*, *Peperomia*, *Drymoglossum*, many Bromeliaceae, and some Orchidaceae. A few epiphytic orchids which were found growing in a dry atmosphere had a thickened cuticle, but these were distinctly exceptional. In *Sonneratia*, *Rhizophora*, and other plants of the Mangrove formations there was similarly but little development of cuticle, and, at times, a rapid rate of transpiration. In *Agapetes vulgaris* and *Rhododendron retusum*, the two most characteristic plants of the Solfataras of Ceylon, there was also absolutely no protection against excessive water loss.

Aubert⁷ measured the rate of transpiration of a number of succulent and mesophytic plants and came to the following general conclusions:

1. With equal surfaces, succulent plants, such as many Crassulaceae and species of *Mesembryanthemum* which have a thin cuticle, transpire more freely than many mesophytes with a thick cuticle (*Hedera Helix*, *Picea excelsa*); with equal fresh weights, however, the succulent types transpire less than these.

⁷ Aubert, E.: Turgescence et transpiration des plantes grasses. Ann. des Sci. Nat., Bot., 1892.

2. The Cactaceae transpire less than any plants examined, whether reckoned on equal surfaces or equal fresh weights.

The work of both Stahl¹ and Rosenberg² points to the fact that many European halophytes possess the power to transpire freely, as judged by the cobalt paper test. I have shown,³ and have often observed, that in many of our British salt-marsh plants the transpiration may be much greater for equal transpiring surfaces than in a typical mesophytic plant; in others the value approaches, but rarely falls below, that of the typical mesophyte under similar conditions at the time of the experiment. The figures in Table II give some of these results; but since the observations were made of necessity at different times,⁴ the transpiration is estimated per hour per square decimetre, relative to the loss of a water surface measured at the same time under the same experimental conditions, the latter value per hour per square decimetre being taken as 100 in each case; the variations in transpiration due to the purely physical effect of the environment are now eliminated, as Livingston⁵ pointed out. Throughout the experiments the transpiration observed is that of detached leafy shoots with no water supply; the cut end was sealed immediately after being severed from the plant, and the fresh weight at once obtained; the shoot was then allowed to transpire, hung up in the air of the laboratory, away from any draught or direct sunlight, and the water loss during the first hour or two hours of withering determined by means of an accurate balance. The values obtained will be somewhat below those of the normal plant, since, in all the plants examined, the stomata close within the first half-hour of experiment, and also because the transpiration falls off as the water content of the whole plant falls below the normal.

A large number of succulent plants, therefore, show but little development of cuticle, and can endure a rapid rate of transpiration per unit area of surface without harm.

Many succulent plants, however, in addition to the possession of a more or less developed cuticle, have a coating of wax which acts as a further protection against water loss. Garreau¹ offered experimental evidence as to the protecting power of wax coverings in the case of *Centranthus ruber*, *Syringa vulgaris*, *Sedum verticillatum*, and some others, where the rate of transpiration was increased from 1.5 to 3 times by removing the wax. Frequently the wax not only coats the free surface of the epidermal cells, but also blocks the apertures of the stomata more or less completely. Dr. F. Darwin² has shown that, generally speaking, the stomata of a plant tend to become aggregated in the areas covered by the wax or bloom. Thus, if bloom be only found on one side of a leaf, the stomata are often either less numerous or altogether lacking on the side which is not thus protected. The association of stomata with a wax covering may, however, also be connected with the prevention of the blocking of the stomata by rain or heavy dew, since the maintenance of gaseous exchange is of great importance in the economy of the plant.

A wax covering is chiefly characteristic of plants inhabiting dry regions, as the observations of Schimper, Volkens, and others show. Holtermann³ found that in Ceylon those epiphytes which lived in the warm damp air of the tropical forests were glabrous, whereas those which were found in exposed, sunny places were frequently coated with wax. Wiegand,⁴ from his experiments with artificial surfaces, concluded that a wax covering would form an equally effective protection whether in still air or in wind.

Most halophytes which live in damp or marshy situations are glabrous, as, for example, *Rhizophora*, *Salicornia*, and *Aster Tripolium*. *Suaeda maritima* is an exception, for the small leaves are covered with a fine bloom, and it is often found in marshy places. *Psammophilous* halophytes are frequently covered with wax if sclerophyllous, or very slightly succulent, as in *Elymus* and *Eryngium maritimum*; but if succulent the leaves are commonly glabrous, as in *Cakile maritima*, which also has only a very slight development of cuticle.

Hairs, whether glandular or protective, are not common in succulent plants; they are, indeed, much more characteristic of sclerophyllous vegetation. We may, however, instance *Sempervivum arachnoideum*, a succulent alpine plant, the rosettes of which are clothed, and perhaps also protected by long loose hairs. Some species of *Avicennia* are hairy, and *Evolvulus*

alsinoides is a littoral plant from the drier coastal regions of Ceylon, which is stated by Holtermann to have a number of small, succulent, and yet hairy leaves. According to Wiegand¹ a hairy covering is a relatively much more effective protection against transpiration in windy than in still weather; whilst in damp air it yet allows of a considerable amount of transpiration.

Many species of *Atriplex* are covered with short, closely set hairs, which form an almost continuous sheet of large thin-walled cells covering the much smaller cells of the epidermis, except for narrow chinks above the stomata. According to Volkens these hairs readily give up their water in time of need to the cells below, and then their walls collapse, and the empty cells thus form a very complete protection for the whole transpiring surface; the hairs can probably also absorb water from rain or dew, or they may be replenished from within when the roots are able to absorb freely. Some species of *Mesembryanthemum*, as *M. crystallinum*, *Forskali*, and *nodiflorum*, have a number of swollen papillae which, according to Hagen,² have a protective function. The papillae are thin walled and appear to be filled with a mucilaginous cell-sap, which does not easily allow of evaporation; we shall see that these papillae probably also function as absorbing hairs for rain and dew.

¹ Wiegand : Relations of Hairy and Cutinised Coverings to Transpiration. Bot. Gaz., 1910.

² Burgerstein : Die Transpiration der Pflanzen, p. 224.

It was established by Czech,¹ and has been confirmed by Volkens and other observers, that, in general, the stomata of plants growing in wet or even damp situations are more numerous per unit area than are those of dry places. Thus *Veronica Chamaedrys* was found to have 175 stomata per sq. mm., whilst *Veronica Beccabunga* had 248. So far as I have been able to observe, this holds true also for succulent plants, those from dry regions, such as some species of *Mesembryanthemum* and *Sedum*, having considerably fewer than have those, such as *Salicornia*, from marshy places. Table III gives the distribution of the stomata of such plants as I have observed, and also a few of Czech's figures for comparison.

According to Burgerstein² the degree of opening of the stomata affects the amount of transpiration far more than the actual number present. Leitgeb³ was the first to call attention to the power of the stomata to open and close, and regarded it as a means for regulating the amount of transpiration. This view has been widely accepted, but has been objected to recently by Lloyd,⁴ who found that in *Fouquiera splendens* and in *Verbena ciliata* the 'rate of transpiration may undergo sudden and wide changes, without the accompaniment of a sufficient change in the dimensions of the stomata to account for them on the theory of stomatal regulation of transpiration.'⁵ According to Lloyd the capacity for diffusion of the stomata of *Fouquiera* is well in excess of what would be required for the greatest observed transpiration rate, and he therefore concludes 'stomatal regulation of transpiration does not occur, though of course conservation of the contained water follows on complete closure of the stomata. It is open to doubt, however, if this condition ever obtains.' On the other hand, some experiments of Dr. F. Darwin, a preliminary account of which was given at the meeting of the British Association, 1910, and a further account of which is now in the press, lead to the conclusion that in many plants, if they can be observed by a sufficiently delicate method, stomatal movements are found to correspond closely with changes in the rate of transpiration caused by alteration in external conditions. It is clear, therefore, that the whole question of stomatal regulation requires further investigation.

So far as the power of movement of the guard cells in the stomata of succulent plants is concerned, we have but little direct evidence. In xerophytic succulents the stomata may be so much sunken or overlaid by cuticle that they seem to have little or no scope for movement. Stahl,⁶ however, states that the stomata of xerophytes all possess the power to close, and they are, therefore, presumably capable of the reverse action.

⁴ Lloyd, F. E. : The Physiology of Stomata.

⁵ Lloyd, F. E. : *ibid.*, p. 137.

⁶ Stahl : Einige Versuche über Transpiration und Assimilation, 1894.

In a paper recently published by Linsbauer¹ on the physiological anatomy of the epidermis of some Bromeliaceae, it is shown that the stomata are surrounded by at least two pairs of subsidiary cells, which are arranged as though to protect the guard cells from contraction when the neighbouring aqueous tissue collapses. In the case of *Quesnelia* the stomata were found to be completely closed, owing to the formation of a membrane across the outer respiratory cavity. In many of the Bromeliaceae the arrangements of the stomata and of the air passages in the leaf seemed to be such as to ensure the best ventilation with the minimum of transpiration.

In all the succulent plants which I have examined the stomata appear to be capable of movement, but I have frequently found the stomata of species of *Sedum* and of various fleshy halophytes in the closed condition, especially when the sun was on these plants and the weather dry. Stahl² asserted, chiefly from the results of experiments made on the transpiration of halophytes grown in an artificial salt-marsh, that the stomata of these plants are not capable of closing. Stahl used the cobalt paper test, relying chiefly on the time of coloration of the dried paper; but the careful observations of Rosenberg,³ using the same method and confirmed by means of direct microscopic examination, show conclusively that this is not the case, at least when the plants are growing in their natural habitat. Rosenberg suggested that the inactivity of the stomata observed by Stahl was due to the culture conditions. However, in the artificial salt-marsh at Dulwich I have frequently observed that the stomata of halophytes possess the power of closing, and they appear to me to be especially sensitive to air of low humidity. The stomata of *Salicornia annua* and of *Aster Tripolium* also close in darkness.⁴

So far as I have seen, the stomata of succulent plants close during the earliest stages of withering, and this appears to me to be an adaptation to conserve the water supply as far as possible during time of need. Lloyd⁵ states that in *Fouquieria splendens* and in *Verbena ciliata* 'the beginning of closure occurs somewhat later than initial wilting, and seems to be a result of water loss by the leaf as a whole. There is no adaptive closure, meaning by this a closure in anticipation of wilting.' On the other hand, Rosenberg⁶ found that when he observed the transpiration of the leaves of some halophytes (as *A. triplex*, *Cakile maritima*, *Plantago maritima*) immediately after detaching from the parent plant, a distinct drop in the rate of trans-

¹ Linsbauer: Zur physiologischen Anatomie der Epidermis und des Durchlüftungsgewebes der Bromeliaceae, 1911. Anz. Kais. Akad. Wiss. Wien, mathemat.-nat. Klasse, ix.

⁵ Lloyd: The Physiology of Stomata, 1907.

⁶ Rosenberg: Ueber die Transpiration der Halophyten, 1897.

piration was to be detected by means of the cobalt paper test ; this may be fairly interpreted as due to closure of the stomata prior to wilting. Other plants were brought into the laboratory and there the test was repeated. No such slowing down of the transpiration was then observed immediately after detaching ; and microscopic examination showed that the stomata on the whole plant had closed. I have myself ascertained by direct experiment that the stomata of *Mesembryanthemum edule* closed within fifteen minutes after detaching a healthy leaf on which the stomata were initially open ; and in the case of *Aster Tripolium* and *Plantago maritima* the stomata closed in five to seven minutes after detaching a leaf. In neither of these cases could any sign of withering be detected until some time after the stomata had been observed to close. Moreover, in the case of *Mesembryanthemum edule*, the leaf is well supplied with centrally placed aqueous tissue. When such a leaf withers the cells of the aqueous tissue gradually collapse, beginning from the innermost and slowly extending to the more peripheral cells. All the cells of the aqueous tissue show signs of collapse before the palisade tissue appears to suffer at all from want of water ; and the epidermis of a detached leaf only shows wrinkling after many hours' exposure to drought, because the actual volume of the leaf is slowly diminishing. It appears to me impossible, at least in this case, to regard the closure of the stomata within the first fifteen minutes after detaching as due to 'the loss of water in the leaf as a whole' ; on the other hand, it seems probable that the closing of the stomata so promptly is, in this and probably also in many other cases, an adaptation which reduces the transpiration of the leaf to the least possible under the particular physical conditions experienced at any time.

How far the stomata of succulent plants are able to regulate transpiration is, however, a very difficult question. I am inclined to think that the limiting power of the stomata may be much greater than has been supposed. Even in the apparently closed condition of the guard cells some regulation of the size of the outer respiratory cavity may be demonstrated, as the following experiment with *Salicornia* shows.

Two healthy similar shoots of *Salicornia annua* were chosen, and the cut ends sealed with a wax mixture. Both shoots were placed under the same conditions, one being used to determine loss of water during transpiration, and the other to determine the condition of the stomata during the course of the experiment. It was observed that the stomata appeared closed even before the shoots were cut ; the guard cells, however, showed a wide rift above the closed pore. The average dimensions of the stomata and the loss due to transpiration are shown in Table IV. At the end of the first hour the shoots were removed to a more shaded place, and this probably accounts mainly for the diminution in size of the rifts, since, owing to the abundant aqueous tissue, an exposure of three hours could hardly affect

seriously the water content of the epidermal and guard cells. It will be seen that a change in dimensions of the rift of 20 per cent. was accompanied by a change of 28 per cent. in the rate of transpiration; it is suggested that the two processes are therefore closely connected.

TABLE IV.

Transpiration and Behaviour of Stomata in Salicornia annua.

Loss in Weight due to Transpiration.			Average size of Stomata.			
Time.	Light.	Water Loss.	Guard Cells.		Rift.	
			Length.	Diameter.	Length.	Diameter.

Diminution in rate of Transpiration =			Diminution per cent. =			
		28 %	6	7.7	20	20

As has already been stated, the stomata of xerophytic succulent plants are commonly depressed below the level of the epidermal cells. In many cases they are further protected by wax, as in *Euphorbia Tirukalli*,¹ where a ring-like wall of wax surrounds each stoma; by cuticular projections overarching the guard cells, as in the case of *Aristida ciliata* described by Volkens; or by subsidiary cells, as in the stomata of some of the Bromeliaceae recently described by Linsbauer, to which reference has already been made.

The stomata of epiphytes are, however, often not at all sunken or protected, as in the epiphytes described by Holtermann² from damp, shaded spots in the Ceylon forests. The stomata of *Rhizophora*, *Bruguiera*, *Aegiciras*, and other Mangroves were stated by Schimper³ to be sunken, but in nearly every case examined by Holtermann this was not found to be the case. In many species of *Atriplex* the stomata lie below chinks in the parenchymatous covering of leaves, but are not at all depressed below the level of the epidermal cells. In all the species of *Sedum* and in all the succulent halophytes (excepting two species of *Suaeda*) which I have observed, the guard cells are not at all sunken.

In many cases, especially in the leaves of tropical epiphytes, the transpiring surface is supplied by aqueous tissue interposed between itself and the assimilating cells. The aqueous tissue consists of colourless, usually parenchymatous cells filled with a watery cell-sap, which is often readily given up, both in transpiration and in supplying the assimilating tissue. As the cells of the aqueous tissue are gradually depleted of their water, the thin walls collapse, and the collapsed cells form a more or less complete protection to the cells of the mesophyll. When a further water

¹ Haberlandt, Dr. G.: Physiologische Pflanzen-Anatomie, 1896, p. 397.

² Holtermann, Dr. C.: Der Einfluss des Klimas auf den Bau der Pflanzengewebe, 1907.

³ Schimper, A. F. W.: Die indomalayische Strandflora, 1891.

supply is available, whether from root absorption or from rain or dew, the cells expand again and become again water reservoirs. In the leaves of the epiphytic *Peperomia incana* the delicate cell-walls of the aqueous tissue are strengthened at the corners, where they abut on the palisade tissue, with a horn-like substance, so that a firm framework is interposed between the mesophyll cells and the aqueous tissue when the latter collapses in dearth of water.¹ Occasionally the aqueous tissue is formed of deep, narrow, palisade-like cells, as in *Carappa moluccensis* and *Rhizophora mucronata*. Very often the amount of aqueous tissue increases in volume as the leaf grows in age, and this is accomplished by an often considerable increase in the size of the individual cells. This increase in storage capacity as the leaf attains its full size is of obvious importance in the economy of the plant.

Peripheral aqueous tissue is very characteristic of the leaves of epiphytes and of Mangroves. According to Holtermann² many epiphytic species of *Ficus* and *Peperomia* show well-developed aqueous tissue, whereas terrestrial species of the same genera may be entirely lacking in this respect. If the plant is growing in a very exposed, sunny place, the aqueous tissue will be protected on the outside from excessive water loss, as in *Ficus tomentosa*, by the formation of cuticle and hairs; but in epiphytes of damp regions, and constantly in Mangroves and plants of the Solfataras, the aqueous tissue is little protected, and at certain times may show enormous loss of water in nature.

Volkens³ has described various species of *Atriplex* with water-storing hairs, and also some desert species of *Mesembryanthemum*; to these reference has already been made.⁴ There is no doubt, as Haberlandt insists,⁵ that the presence of mucilage in the cell-sap of the aqueous tissue greatly increases its power of resistance to desiccation, even in otherwise little protected leaves, such as those of *Mesembryanthemum crystallinum*. The mucilage may be distributed throughout the whole of the aqueous tissue, as in *Agave*, or localized in special cells, as in *Rhizophora mucronata*; or it may be associated with storage tracheides, as in the leaves of *Loranthus europaeus*.

Most European succulent plants have an internal but no peripheral aqueous tissue; however, the colourless cells of the epidermis may themselves function to some extent as water reservoirs, as may be observed by actual experiment. For example, in one case observed by me, a leaf of *Aster Tripolium* was picked and at once placed in water. Owing, perhaps, to the dry air of the laboratory, both upper and lower epidermis when

examined next day showed much wrinkling and folding on the outside walls of all the cells except the guard cells, which were perfectly turgid, although all were closed or only narrowly open; the leaf itself did not appear at all limp to the eye or to have suffered from want of water. The whole leaf was then immersed in water, and in less than three hours had increased in weight by 13.7 per cent. The epidermis was again examined, and the wrinkling of the epidermal cells was much less apparent; about half the cells showed no wrinkling at all, and in the remaining cells the folds were clearly less numerous. Here, then, we have a case in which the epidermal cells may be partly depleted and filled again, without apparent injury, as in true aqueous tissue.

Glands are not found as a rule on succulent or semi-succulent leaves and stems. Volkens,¹ however, records the presence of glands on the somewhat fleshy leaves of *Cressa cretica*, *Reaumuria hirtella*, *Tamarix manifera*, and *Frankenia pulverulenta*, which appear to excrete salts, chiefly sodium chloride; these salts seem to have the power of condensing moisture, even from an apparently dry atmosphere, so that the leaves sometimes appear to be covered with moisture when no rain has fallen and, all around, the vegetation is dry. There is some difficulty in supposing with Volkens that the glandular tissue can so far alter in permeability as to first excrete a highly concentrated salt solution, and then absorb only pure water back again; but there appears to be no doubt that the layer of salt may be of value in preventing water loss, for these plants are found in some of the driest regions of the Egyptian-Arabian desert, and can withstand long and severe drought. If, however, the layer of salt be removed from the leaves of a cut shoot, the power of resistance to desiccation is strikingly diminished.

According to Rohlf² the same function is subserved by the glands in the leaves of some desert species of *Statice*; and Holtermann observed in the leaves of *Laguncularia racemosa*, *Acanthus ilicifolia*, and *Aegeiras racemosa* (all Mangrove plants) superficial glands which, when tested with thallium sulphate, showed an abundant salt content, and which sometimes even showed minute crystals of salt visible to the naked eye. Holtermann interprets the function of these glands as excretory, the salt being washed away by the dew, which falls heavily in those regions at night. The excretion of salt by these glands is used as an argument against Schimper's theory that salt accumulates in the leaves of halophytes to a harmful extent. Similar glands are found on the leaves of some European species of *Statice*, *Glaux*, and other halophytes; but these are scarcely succulent in habit, and little is known of the true function of the glands in these plants.

It is well known that many plants are capable of absorbing water over

¹ Quoted by Dr. A. Burgerstein : *Die Transpiration der Pflanzen*, 1907.

² Quoted by Dr. A. Burgerstein : *ibid.*

their whole surface ; but it has long been a matter of dispute how far this power is of importance to the plant in nature. The work of Wille¹ and others shows that the proportion of water thus absorbed, relative to that taken up by the roots, is mostly so small that the surface absorption can be of but little meaning biologically.

However, there is no doubt that such surface absorption may be of the utmost value ; rootless epiphytes, indeed, depend wholly on this method for their water supply, and in such cases adaptive mechanisms for collection and storage of water are often found, as, for example, the spoon-shaped leaves of some Bromeliaceae and the absorbing hairs of *Usnea tillandsioides*.

Aerial roots form additional organs of absorption in many epiphytes, especially in the epiphytic Aroids and tropical orchids. These are fleshy, greenish roots which stand out from the surface of the plant and are covered with a parchment-like layer of aqueous tissue, several cells deep. The cells of the aqueous tissue are usually thin walled, isodiametric, and lined with a delicate spiral of cellulose ; often the walls are perforated, so that when water reaches the surface it is sucked in rapidly by capillary attraction. It has even been suggested by Schimper and Goebel² that the aqueous tissue, or velamen, as it is here frequently termed, has the power to absorb water vapour and nutritive gaseous compounds, such as ammonia, from the air ; a very probable suggestion, although not yet substantiated by actual facts.

A number of other plants, however, show a considerable power of surface absorption, the value of which has been perhaps under-estimated. The papillate hairs of certain species of *Mesembryanthemum*, to which reference has already been made, are of some interest in this connexion, for they appear to have a marked power of absorption in addition to their capacity for retaining and storing water. Some cuttings of *M. edule* and *M. crystallinum* had been received by me from Cornwall, where both plants grow freely in a semi-wild state. They had been packed loosely in a cardboard box and were obviously suffering from want of water when unpacked. *M. edule* is a glabrous species with somewhat thickened cuticle and slightly sunken stomata. *M. crystallinum* has papillate leaves with little or no cuticle, and small unprotected stomata, and it therefore seemed worth while to compare their power of surface absorption. A shoot of each was chosen with about the same number of healthy uninjured leaves ; they were detached and weighed accurately after the cut end of each had been sealed up with an adhesive wax mixture. The shoots were then immersed in water, and dried and weighed at intervals. The results given in Table V show that *M. crystallinum* has an absorption from three to seven times as great as *M. edule*. Both these species live in dry, rocky places where there is a limited

¹ Burgerstein, Dr. A. : Die Transpiration der Pflanzen, p. 232.

² Haberlandt, Dr. G. : Die physiologische Pflanzenanatomie, 1896, p. 201.

water supply, and *M. crystallinum* transpires, as I have observed, at about the same rate, relative to the amount of surface, as a typical mesophytic plant, such as *Saponaria*, so that there must often be a need of water. In the above experiment the shoot of *M. crystallinum* was flaccid at first, but appeared to be quite turgid after five hours in water, and therefore, since dew often falls heavily, and lasts for longer than five hours, this plant may well be benefited by the absorptive power of the hairs. In *M. edule*, however, the absorption is so slight that dew formation could hardly be of value except in checking transpiration for the time.

TABLE V.

Absorption of Water by Transpiring Surfaces in Mesembryanthemum.

Time.	<i>Mesembryanthemum edule.</i>		<i>Mesembryanthemum crystallinum.</i>	
	Absorption % of Initial Weight.	Absorption % per hr.	Absorption % of Initial Weight.	Absorption % per hr.
5 hrs.	0.47	0.09	1.7	0.34
23 hrs.	2.7	0.11	16	0.7
3 days	10.7	0.15	27	0.38

Holtermann¹ asserts that the Mangroves of Ceylon appear to have the power of absorbing rain and dew, since the leaves were always fresh and turgid in the early morning after a rainless but dewy night, following a hot day in which they had all perceptibly flagged. However, as Burgerstein² points out, this is not necessarily due to surface absorption of the dew; it may simply be that the presence of the dew checks transpiration and so allows the water absorbed by the roots to accumulate within the plant until the tissues are again turgid. In those Mangroves and desert plants provided with salt glands the superficial absorption appears to be of real biologic importance, and is regarded by some as an adaptive mechanism for increasing the resistance of the plant to drought.

Burgerstein,³ who has made an exhaustive study of the whole question of superficial absorption of water, came to the conclusion that any part of the plant, whether heavily or slightly cuticularized, and whether provided with stomata or not, was yet capable of water absorption to some extent. However that may be, the presence of cuticle is a distinctly retarding factor, and in the absence of hydathodes or glandular hairs the surface absorption of a much cuticularized surface is practically nil. The presence of wax or bloom which makes the leaf practically unwettable is also a character which prevents any appreciable surface absorption, and those succulent plants which have bloom are not those which can absorb freely. The hairs

which clothe the surface of many Chenopodiaceous plants may be absorbing, but this has not yet been experimentally demonstrated.

I¹ have suggested that species of *Salicornia* and *Aster Tripolium*, which are very sensitive to dry air and which are subject to a variety of conditions physically, may derive real benefit from their well-marked power of surface absorption. The same suggestion was made independently by Miss A. C. Halkett,² whose experiments bear this out to some extent.

(β) The Water-storing System.

We come now to the question of the system of water-storing tissues which are essentially characteristic of succulent plants. We have already seen that many epiphytes and mangroves have a superficial storage tissue, which perhaps also affords protection to the chloroplasts from the intense sunlight; many of these also have internal water-storing tissue, so that the assimilating cells are covered both above and below by aqueous tissue, as in many species of *Peperomia*. In fleshy leaves the water-storing tissue often gradates insensibly into spongy mesophyll cells with very scattered and pale chloroplasts; it is, however, sometimes localized in thick fleshy petioles. In stems the aqueous tissue is often located in the cortex, either completely encircled by the chlorophyll-containing cells, as in *Salicornia*, or interrupting the assimilating tissue in places, as in *Salsola*, where the stem shows streaks of transparent tissue between the chlorophyllous tissue; the epidermis above the transparent streaks has no stomata. Water is also stored in tubers or corms, as in epiphytic orchids, and in the species of *Sauromatum* popularly known as 'Monarch of the East'. In these cases the plant can live for long simply on this reserve, and in the last case the whole flowering spadix and the single large leaf are produced at the expense of the corm, which shrinks greatly as development proceeds.

In many cases the aqueous tissue contains a highly acid or highly saline cell-sap, which produces a high osmotic pressure internally. This may serve to facilitate surface absorption in plants, such as *Mesembryanthemum crystallinum* and *Salicornia*, but it certainly tends to retard evaporation, for water evaporates less readily from stronger than from weaker solutions; thus Aubert³ found that in *Sedum dendroideum* the acid content increases as the young leaf becomes adult, and those leaves which had the maximum acid content had also the least transpiration. In many cases, in addition to the acid cell-sap, mucilage passages or cells occur, as in the Cactaceae, which are even more retentive of water; for example, with *Opuntia*, Aubert

¹ Delf, E. M.: Transpiration and Stomatal Behaviour in Halophytes. *New Phytologist*, 1911.

² Halkett, A. C.: Some Experiments on Absorption by the Aerial Parts of Certain Salt-marsh Plants. *New Phytologist*, 1911.

³ Aubert, E.: Turgescence et transpiration des plantes grasses. *Annales des Sciences Nat., Bot.*, 1892.

found that the rate of transpiration increased steadily from the young shoot to the old, until the quantity of mucilage and gums began to become important. From that time the transpiration steadily fell off, until in the adult segments it was almost negligible.

Aubert's work further shows that the presence of organic acids is intimately connected with the succulence of the plant; thus a number of different species of *Sedum* arranged in order of their acid content per gramme fresh weight were found also to be arranged roughly in order of their fleshiness. This is intelligible when we remember that both organic acids and the sugars which are derived from them in metabolism are osmotically active substances, and would exert a high attraction for water.

In the Cactaceae the organic acid is mostly present as salts of malic acid; in the Crassulaceae mostly as free or combined isomalic acid, together with traces of tartaric acid, whilst the species of *Mesembryanthemum* examined gave abundant oxalates together with traces of mineral acids. The observations of Wolff¹ and others show that in halophytes malic acid is present in small amount, in addition to chlorides.

It has been suggested by Diels² that it is the presence of organic acids in halophytes which prevents the harmful accumulation of salts in the aqueous tissue of those types which do not possess secretory glands. The succulent habit is then regarded as connected with the formation of organic acids in restricted respiration, rather than with the biologic necessity of reducing transpiration, in order to avoid harmful accumulation of salts brought up by the ascending sap.

This theory was based upon a series of experiments, in which it was found that if a normal halophytic plant, such as *Cakile maritima* or *Salicornia*, was kept for some time in distilled water, or in a very dilute solution of chlorides, a gradual diminution in the percentage chloride content of the plant took place. Since the plants were, as far as possible, uninjured, the whole root system having been transferred to the solution, the inference was that the chlorides had in some way interacted with the organic acids and passed out from the plant in a form not thus far detected experimentally.

Unfortunately, all the calculations made were reckoned on equal initial fresh weights, no allowance having been made for changes in water content during the course of the experiment, owing to the effect of the transference to water or salts, or owing to changes in the physical conditions affecting the rate of transpiration. In a critical account of Diels's theory, Benecke³ drew attention to these omissions, and further recorded some experiments made by himself, following Diels's method as nearly as possible, but ob-

¹ Wolff: Quoted by Burgerstein, loc. cit.

² Diels: Die Entchlörung und der Stoffwechsel der Halophyten. Pringsheim's Jahrbücher, 1906.

³ Benecke, W.: Ueber die Dielsche Lehre von der Entchlörung der Halophyten. Pringsheim's Jahrbücher, 1901.

serving the chloride content relative to the total ash content, as well as relative to the fresh weight. Benecke's figures show clearly that, although there is an apparent diminution of chloride content owing to the changes in water content of the plant, there is no change in the actual proportion of chloride present in the ash. The whole theory of diminution and disappearance of the chlorides, through the intervention of organic acids, thus stands at present unsubstantiated by facts.

Lesage¹ was the first to show clearly that it is the saline character of the habitat which appears to chiefly cause the succulent character of the leaves of halophytes. No less than ninety species found near the coast were examined, representing thirty-two families. Of these fifty-four had leaves thicker by the sea than when inland, twenty-seven were indifferent, and four were thicker inland than by the sea. Of the fifty-four which showed increase in fleshiness from the more saline position, some were oftener found inland than by the sea (and may be termed 'facultative' halophytes), such as *Solanum Dulcamara*, *Plantago Coronopus*, and *Ranunculus sceleratus*, and some were typical littoral forms, as *Beta maritima*, *Cakile maritima*, *Glau-cium luteum*, and *Arenaria peploides*; a few species, although littoral, were indifferent, as *Psamma arenaria*, *Suaeda maritima*, and *Triglochin maritimum*. With the exception of the few species mentioned, there was a distinctly greater fleshiness in the littoral than in the inland forms.

Most of these plants have no definite aqueous tissue, and their succulence is brought about by an increase in the number or size of the mesophyll cells. Thus the mesophyll cells of *Parietaria* appeared to increase in size, those of *Ranunculus sceleratus* increased in the number of layers, whilst *Beta maritima*, *Atriplex portulacoides*, and *Cakile maritima* showed increase in both number and size of the cells. Unfortunately, no mention is made of aqueous tissue as such, although the observation is made that in some cases the chloroplasts become paler and fewer in the plants grown in salty substrate. However, there is little doubt that some of these interior cells with little chlorophyll function as water-storing tissue, especially in plants with fleshy leaves, susceptible to salt content, such as *Salicornia*, *Cakile maritima*, and *Arenaria peploides*; there is little doubt, also, that this colourless water-storing tissue tends to increase in saline situations. Observations were supplemented by culture experiments with *Lepidium sativum* and other plants which could endure saline solutions, when it was found that, in general, the more concentrated the solution the more fleshy were the leaves produced.

Some experiments of Holtermann throw further light on the question of the effect of the salt content of the habitat in the Mangrove vegetation of Ceylon. A number of Mangroves (*Lumnitzera*, *Avicennia*, *Rhizophora*,

¹ Lesage, P.: Recherches expérimentales sur les modifications des feuilles chez les plantes maritimes. Rev. Gén. de Botanique, 1890.

and others) were grown in ordinary soil in the Botanic Gardens at Peradenya, but were watered with salt solutions of varying strength. After a time the culture plants were compared with the same plants growing in their natural habitat. In nearly every case the aqueous tissue was found to be less developed than the normal in those plants which had been watered with dilute solutions, and it was more strongly developed in those which had been watered with more concentrated solutions of salts. In one instance the leaves of a swamp plant of *Avicennia officinalis* had from four to five layers of aqueous tissue, whereas leaves from a plant cultivated at Peradenya and watered with a 5 per cent. solution of potassium chloride showed from seven to eight layers. In the case of the flora of the Solfataras, observed by both Schimper and Holtermann, the excessive amount of sulphates in the soil appears to have the same effect in favouring the formation of aqueous tissue as the chlorides in the case of the Mangrove vegetation.

Not only are succulent plants provided with a reserve of water, but very often there is a marked conservation of the water supply, the younger leaves in time of drought being kept continually turgid at the expense of the older; this is probably true of all succulents with the exception of those which, like *Salicornia*, live in very moist habitats. It is also true, although to a much less extent, of a large number of mesophytic plants.

Meschayeff, in 1882, appears to have been the first to call attention to the oecological importance of this movement of water in plants; and subsequently numerous other observations of the same kind were made. Haberlandt hung up cut shoots of *Rhizophora mucronata* without any water supply. After one day the older and yellower leaves became withered, while the remaining leaves, except the youngest, were scarcely withered.

A more careful experiment is that of Burgerstein, who chose a pot plant of *Gasteria vittata*, a plant which has opposite pairs of fleshy leaves. The pot was allowed to stand with no water in a sunny place for six weeks, at the end of which time the earth was quite dry. Six leaves on one side were now cut off and weighed, the water content of each being found separately. The plant was now well watered, so that at the end of a month all the leaves seemed to have recovered their turgidity. The six remaining leaves were then detached and weighed, their water content being calculated as before. In comparing the water content of the full and the nearly depleted leaves, the amount of depletion was greatest at the lowest leaf and fell off regularly to the uppermost, as may be seen from the figures in Table VI.

The same gradual depletion of the old leaves at the expense of the young may be demonstrated more simply by observing the shrinkage in the dimensions of the different leaves on a shoot when allowed to wither. I have made such observations with species of *Mesembryanthemum* and of *Sedum*.

TABLE VI.

Water Content in successive pairs of Leaves of Gasteria vittata.

	Water Content % of turgid leaves.	Water Content % of withering leaves.	Loss during drought.
First Pair (lowest)	86.3	78.6	7.7
Second Pair	90.3	82.8	7.5
Third "	90.8	83.7	7.1
Fourth "	91.1	84.9	6.2
Fifth "	91.3	86.0	5.3
Sixth " (youngest)	93.4	91.8	1.6

In the case of *Mesembryanthemum edule* a shoot was chosen which had three pairs of expanded leaves and one very small pair, the leaves of which were closely appressed to each other. One leaf of each of the three pairs of expanded leaves was marked with Indian ink along the length and breadth of both upper and lower surfaces. The cross-section of one of these leaves forms an isosceles triangle, so that the marks on the lower surface were made on one flank only. The measurements were made with an accurately divided rule and a lens magnifying ten times. The shrinkage observed calculated as percentages is recorded in Table VII.

TABLE VII.

Shrinkage in Surface of Mesembryanthemum edule when withering.

		1st day. %	2nd day. %	3rd day. %	6th day. %	7th day. %
Lowest Leaf.	Length	4.6	0.3	2.4	(Shrinkage had obliterated marks.)	
	Upper Surface					
	Breadth	3.4	3.6	1.9		
	Length	7.4	0	0		
Second Leaf.	Lower Surface					
	Breadth	3.3	0	0		
	Length	0	1.1	0	5.6	2.7
	Upper Surface					
Third Leaf.	Breadth	1.9	0.9	0	1.2	2.2
	Length	1.8	0.7	0.3	4.6	1.6
	Lower Surface					
	Breadth	0	0	0	0	5
	Length	0	0	0	4.0	1.3
	Upper Surface					
	Breadth	0	0	0	1.0	0
	Length	0	0	0	(marks illegible)	
	Lower Surface					
	Breadth	0	0	0		

It may be seen that the upper leaves were entirely, and the middle pair almost entirely, protected from loss in water content during three days' exposure to warm, dry air. After the third day the lowest leaves shrivelled rapidly, turning yellow, and finally becoming mere empty shrivelled bags; during this time the second pair of leaves first began to suffer seriously,

and the third pair to a less extent. The innermost pairs of leaves grew to double their original size and remained perfectly turgid, as far as could be seen, throughout the experiment; they were, however, too inaccessible for accurate measurement.

Detached shoot of *Salicornia*
(probably *S. ramosissima*).

Very similar results were obtained with different species of *Sedum*, but with *Salicornia* the behaviour is quite different. A shoot of *Salicornia* was marked as shown in the figure, and the distance between the marks observed as before with a lens magnifying ten times. Only the lengths were observed, for it is almost impossible to obtain an accurate estimate of the diameter of anything as soft as a flaccid *Salicornia* stem. In this plant, as will be seen from the figures in Table VIII, the younger parts suffered first from the

loss in water, and later the older internodes also showed collapse, the whole plant having much less endurance in conditions of drought than *Mesembryanthemum*.

TABLE VIII.

Shrinkage in length of Shoots of Salicornia (probably S. ramosissima) during withering.

		Region.		Loss % per 24 hours.	
				1st day	2nd day
Main Shoot	(1)	Lowest internode		0	0
	(2)	Next above		10	0
Branch	(3)	Lowest internode		0	10.2
	(4)	Next above		3.6	6.7
	(5)	" "		11.9	3.2
	(6)	" "		11.9	3.2

Pringsheim,¹ in a paper dealing with this subject, records some experiments in which the attempt is made to analyse the water output of adult leaves which are both transpiring and supplying water to the growing parts.

¹ Pringsheim, E.: Turgorregulation und Wasserbewegung in welkenden Pflanzen. Pringsheim's Jahrbücher für wiss. Bot., 1906.

In a typical experiment with *Sedum spectabile* six similar shoots were chosen, with as nearly as possible the same number of leaves. On June 20 the ten oldest leaves of three shoots were detached and weighed; no account was taken of the cut surface where the leaf had been attached, since this is unusually small in species of *Sedum*. The detached leaves were left to dry on blotting-paper, together with the remaining three shoots, the fresh weight of which was also found. On July 10 the six lowest leaves of the shoot were quite dry; the detached leaves were withered, but less so than those on the plant. The weight of each set of leaves was again taken, and the initial weight of the cut leaves was calculated in terms of an equal weight of the shoots with attached leaves. The results are shown in the following table, taken from Pringsheim's paper:

TABLE IX.

Leaves of Sedum spectabile, withering.

I. Detached Leaves.	All 10 leaves.	Lowest 6 leaves.	Upper 4 leaves.
a. Initial wt. June 20	7.92 grm.	4.29 grm.	3.71 grm.
b. Wt. July 10	5.23 "	2.74 "	2.49 "
c. Loss % fresh wt.	33.9 "	36.1 "	32.9 "
II. Attached Leaves.			
d. Wt. July 10	1.64 "	0.165 "	1.45 "
e. Loss % fresh wt.	79.5 "	96.3 "	60.9 "
f. Transport of water % fresh wt.	45.6 "	60.2 "	27 "
g. Transport % of Total Loss	57.1 "	62.5 "	46 "

From these figures Pringsheim concludes that the water loss of individual leaves on the plant is greater than when detached, and that the greater part of this water loss is due to displacement within the plant. Very similar results were obtained from experiments with the most varied type of plant, such as *Bryophyllum*, *Cotyledon*, *Mesembryanthemum*, *Tradescantia*, *Rhipsalis*, *Sambucus*, and *Vicia*.

Not less interesting are the observations made by Pringsheim on the osmotic conditions within the same plants, both normally and when withering. It was found that, with very few exceptions, the older leaves had a lower osmotic pressure than the upper; for example, in leaves of *Sedum spectabile*, the osmotic equivalent expressed in terms of a standard 10 per cent. solution of potassium nitrate was found to be—for leaves

5-5½ cm. long (oldest)	18-20 per cent.
3 " " (younger)	24-26 " "
2-2½ " " "	30 " "
1-1½ " " "	38 " "

The osmotic equivalent was thus greatest at the growing point, falling off quickly and remaining fairly constant for the adult leaves.

In a few plants no difference could be detected, as in *Rochea falcata*, where all the leaves are fleshy, and in *Phaseolus*, where the leaves are mesophytic, the youngest leaves had a lower osmotic equivalent than the older ones. In these exceptional cases, however, there appeared to be no water transport from the older leaves to the younger during withering.

Wiesner suggested that the water transport was due to the correlation between the young growing parts and the older leaves, the need of the actively growing parts forming a kind of mechanical check on the water loss of the older leaves by evaporation. Pringsheim remarks that this theory would not account for the fact that adult attached leaves transpire from the same fresh weight more strongly than similar detached leaves under the same conditions, and suggests that there is an internal regulating mechanism which adjusts the osmotic condition of the cell-sap throughout the plant, according to circumstances. In support of this theory, Pringsheim describes a number of experiments on the osmotic conditions of withering plants. Not only is there found to be what may be termed an 'osmotic gradient' in the normal plant, but this gradient is, in many cases, more or less maintained during withering; a few of Pringsheim's results are quoted in Table X.

TABLE X.

Osmotic Conditions in Withering Plants.

		Fresh. %	After one week's withering. %
<i>Tradescantia fluminensis</i>	Young parts	22-24	30-32
	Adult "	10-12	20
<i>Sempervivum tectorum</i>	Young "	28-30	34
	Adult "	20-22	30

However, the most striking example of turgor-regulation was seen in the case of storage organs for food reserves, such as tubers. In the potato the osmotic pressure of the growing shoot was always greater than that of the tuber itself, but fell off from day to day as the reserve was gradually depleted, and in this way only as much starch would be utilized as would be needed for growth. The mechanism of turgor-regulation as conceived by Pringsheim consists in the manufacture of osmotically active substances in the actively growing regions, thus setting up a diffusion stream upwards which, however, can last only as long as the turgidity of the cells concerned is not wholly lost.

It is probable that there may be some such regulatory mechanism within the plant, but this difficult question can hardly be regarded as wholly solved. As regards the question of the rate of transpiration of attached and detached leaves, whilst Pringsheim's figures seem indisputable for transpiration measurements reckoned on fresh weight, yet, in experiments

which I have made, the loss per unit area of the detached leaves was undoubtedly greater than that of attached similar leaves taken at the same time, under the same conditions. My experiments, however, were generally for much shorter periods of time, lasting from one to eight hours instead of several days, as did Pringsheim's. In the case of *Mesembryanthemum edule* a shoot and an adult detached leaf, both sealed at the cut end, were weighed at intervals for three weeks. Throughout that time the loss in water per unit area of the detached adult leaf was much greater than that of the shoot with which it was compared. In the other cases examined by me, where the same is true, pairs of similar shoots were chosen and the transpiration per sq. dm. of a whole shoot compared with that of the lowest leaf of the control shoot detached from its stem. In every case loss from evaporation at the cut surface was prevented by sealing over with an adhesive wax mixture. In every case the transpiration of the detached leaf per unit area was greater than that of the attached ones.

Whatever be the explanation, however, of this conservation of water in the plant, there is no doubt that it may be of great oecological value, as Pringsheim points out, not only in enabling the plant to withstand long periods of drought without injury to the growing point, but also in providing a means of vegetative reproduction; for in many cases the exhaustion of the water supply of older parts causes the death of the lower parts; the apex then continues its growth, and often roots freely, and becomes independent in some more favourable spot. This is seen in many species of *Sedum*, *Mesembryanthemum*, *Crassula*, *Rhipsalis*, *Cassytha*, and many others. The ease with which adventitious roots form in these examples, however, varies greatly. In *Sedum* one or more adventitious rootlets regularly form, even in very dry air, just above the axil of the leaf, when each leaf is about half depleted. In *M. edule* roots are formed, but much less readily, and in *M. crystallinum* often not until many weeks have passed. In mesophytic plants the advantage is less obvious, for they have less power of storing water and often none of rooting from the apex; but the greater transpiration of the younger, less protected leaves may be, at least in part, compensated by the water supply from the older ones.

(γ) The Conducting System.

There is no doubt that the means of water conduction in a plant stands in close relation to the rate of transpiration. In general, the greater the amount of transpiration the larger will be the number and size of the conducting elements in the stem and root. Jost found that by cutting off the leaves and buds of seedlings of *Phaseolus multiflorus* and other plants, the vascular bundles, and especially the water-conducting elements, remained in a rudimentary condition. He interpreted this as

a kind of self-regulation, keeping the nature of the conducting tract in relation to the particular need of the plant.¹

In the case of succulent plants we have little information as to the conducting tissue. Volkens, in his observations on plants of the Egyptian-Arabian desert, found that the conducting tissue of the shrubs and trees there was but poorly developed, and many of these would be succulent or semi-succulent plants either in stem or leaf.

The experimental observations of Cannon,² however, at the desert laboratory at Tucson, do not bear out Volkens's statement. A number of plants, including *Fouquieria splendens*, *Covillea*, and *Zizyphus*, were grown in the desert region, but were kept constantly irrigated with water for from two to four years. At the end of that time a careful comparison was made between the structure of the wood in irrigated and non-irrigated plants. It was found that in every case the irrigated plants grew much more luxuriantly and organized more woody tissue than the non-irrigated; but they formed a relatively large number of non-conducting parenchymatous elements; whereas in branches of the same diameter of the unwatered plants larger and more numerous tracheal elements were found. Cannon concluded that the desert flora in these cases is a reaction to a minimum water supply, the relative transpiration being greater in the non-irrigated plants, although the total water loss would be less.

In some epiphytes and many halophytes the aqueous tissue is provided with storage tracheides. These may be developed in connexion with the bundle system, and these usually occur as a group of isodiametric elements at the ends of the finest veins of the leaf. Often, however, storage tracheides are developed from the parenchymatous cells of the ground tissue, either singly as idioblasts, or as small groups of cells; but in each case independent of the bundle system. These storage tracheides seem to play an important part in the distribution of the water in fleshy stems and leaves. They occur always near a source of water, and are usually also in connexion with the assimilating cells, which they probably keep supplied with water. There appears to be no direct evidence that these tracheides can exercise a distributive function, but in the case of many species of *Salicornia*, Dr. E. de Fraine³ tells me that their disposition in the stem would lend support to this view. They appear to be most numerous near the periphery of the fleshiest region of each internode, and they are more numerous in the flowering than in the vegetative shoot. In *Salicornia* the storage tracheides are unligified, but they are spirally thickened with cellulose, and, according to this observer, retain their shape even when empty of water;

¹ Haberlandt, Dr. G.: *Physiologische Pflanzenanatomie*, 1896, p. 296.

² Cannon: *Water-conducting Systems of Desert Plants*. *Bot. Gaz.*, 1905.

³ Moss, de Fraine, and Salisbury: *On the genus Salicornia* (anatomical section). *Linn. Soc. Trans.* (in the press).

moreover, in some species of *Salicornia* there appears to be every transition between lignified stereides and spirally thickened unligified storage tracheides.

II. TRANSPIRATION IN RELATION TO HABITAT.

Probably the factors in the environment which most affect the transpiration of a plant are the water supply and the atmospheric conditions, although undoubtedly other climatic and edaphic influences are also concerned. We have now to consider the effect of the chief physical factors on the principal types of succulent plants.

In the truly xerophilous succulents of desert regions we have a reaction to extreme scarcity of water, to strong illumination, and to the desiccating effects of warm, dry air; adaptations are, therefore, found connected with both absorption and retention of water. The former process is facilitated by the development of deeply penetrating and often much branched root systems, and in many cases there is little doubt that the plants are for this reason almost independent of rainfall. Volkens, indeed, describes shrubs in the deserts of Northern Africa which seem to thrive where there is absolutely no rainfall for eight months of the year. In some cases the root absorption seems to be supplemented in an important way by absorption of dew by means of glands on the leaves, as in the Tamaricineae, also described by this author for the same region.

It is, perhaps, on account of the efficiency of the extensive root systems, that in spite of the very limited water supply the desert plants examined by Cannon developed more conducting tissue when grown in a dry than in an irrigated place. The same explanation may apply to the statements of Prof. F. E. Lloyd that *Fouquieria splendens* and *Verbena ciliata* are characteristic of truly desert regions and yet form leaves which in structure resemble those of a slightly succulent mesophyte; here, however, there is the additional explanation that the leaves are annual and are shed just before the hottest season.

The retention of water within the plant is accomplished partly by the formation of protective structures in the epidermis, and partly by the accumulation of mucilaginous substances and salts of organic acids within the aqueous tissue.

The most frequent protective adaptations are the development of a thick cuticle, which is often covered with a coating of wax, or with finely divided wax particles, the formation of relatively few stomata, which may also be sunken below the level of the neighbouring epidermal cells, protected with depositions of wax particles or surrounded by a raised wax collar as in *Euphorbia Tirukalli*.¹ Less often the stomata are protected by hairs. In all these cases there is a certain amount of reduction of

¹ Figured in Haberlandt's *Physiologische Pflanzenanatomie*, 1896, p. 397.

transpiring surface, consequent on the adoption of the succulent habit; and in the epiphytic Bromeliaceae Linsbauer has recently found that the protective means and surface reduction seem to ensure the minimum of transpiration which could be consistent with sufficient aeration.

The experimental work of Aubert shows clearly how important is the presence of organic acids and of mucilaginous substances in the aqueous tissue of all succulent plants. There is little doubt that, owing to the high osmotic activity of these substances, the retention of water in the aqueous tissue is greatly facilitated.

The storage of water which is thus rendered possible may be of the greatest importance to desert plants, enabling them to endure long periods of drought without any evil consequences to the assimilating cells. In extreme cases, like that of *Sauromatum*, the so-called 'Monarch of the East', so much water is stored in a fleshy corm until the beginning of the dry season that the whole inflorescence and, later, the single leaf, are produced entirely at its expense. In the majority of succulent plants there is a definite displacement of water, in time of need, from the older to younger parts, and Pringsheim has shown that this is of value not only in prolonging the life of the more important tissues, but in providing a means of vegetative reproduction. In this way new shoots and buds are for long supplied with sufficient water for growth even when detached from the parent plant; and, in habitats in which germination is attended by great danger from drought, the reproduction is commonly effected by the rooting of such buds and shoots.

Much discussion has been raised over the question of the transpiration of plants of the warm, damp forest regions of the tropics, many of which are either epiphytic, as in the case of the Orchidaceae, or halophytic, as in the case of the genera collectively known as 'Mangroves'.¹

The experiments of Haberlandt² led to the conclusion that transpiration of plants in these regions is less active than in most mesophytes of middle Europe, both in rate and in total amount. The observations of Stahl, Wiesner, Burgerstein, and Giltay, however, pointed to an exactly opposite state of affairs. The explanation of these conflicting results was finally given by Holtermann, who proved that although for hours together the transpiration of these plants may be wholly suspended owing to heavy dews at night and nearly saturated misty air by day, yet for a few hours near midday, under the influence of a tropical sun, the rate of transpiration might become enormous. The plants which are exposed to these alternating extremes are provided with aqueous tissue, although to a less extent than

¹ Schimper noted the similarity in habit between epiphytes and Mangroves; in the case of *Ficus diversifolia* the same species is found growing equally well as either an epiphyte or halophyte. Holtermann: *Der Einfluss des Klimas*, &c., p. 125.

² Quoted by Burgerstein in *Die Transpiration der Pflanzen*, 1904.

in many succulent desert types, and during the periods of rapid transpiration the aqueous tissue may become so depleted of its water that the leaf becomes perceptibly flaccid. This, indeed, frequently happens after a hot day, according to Holtermann, in the plants of the Mangrove swamps. The following morning, however, the leaves may be found erect and turgid again after a night of heavy dew, so that Holtermann suggests that an appreciable surface absorption of the dew must have taken place. On the other hand, it is possible, in the light of the experimental researches of Wille¹ and others, that root absorption persisting all through the hours of suspended transpiration would alone account for the change. A similar phenomenon may easily be seen in our British halophytes, and probably the same explanation may be found true.

The experiments of Haberlandt and Holtermann on Mangrove plants indicate that here, as in true xerophytes, there is some power of water displacement, but to a somewhat less extent than in typical desert and rock plants. I have noticed a distinct power of water displacement from old to young leaves during withering, in shoots of *Salsola Kali* and in *Mesembryanthemum edule*, and to a less extent in *Suaeda maritima*; the same power may exist in *Salicornia*, but if so it is not sufficient to prevent the young parts from withering in drought, before the older internodes appear to suffer. The displacement of water from old to younger parts in time of need is by no means limited to succulent plants; it is often to be seen in mesophytes, although here it is less obvious, and probably of little biological importance.

In the majority of halophilous and in many epiphytic plants, the transpiring surface is little protected from water loss, being usually glabrous, with little cuticle or none, and with often numerous unsunken active stomata; relative to the surface area the transpiration may often be far greater than obtains in the majority of mesophytes under the same conditions.

The question of the relation of the halophytic plant to its environment is one of much difficulty. There is no doubt, as Schimper, Lesage, Holtermann, and others have shown, that it is intimately related to the presence of chlorides in the habitat. Probably the conclusion of Warming comes nearest the truth: that, whereas some maritime plants are true halophytes and cannot thrive in the absence of chlorides, others are only halophilous and, whilst showing greater succulence in the presence of chlorides, can thrive almost equally well in their absence; such are *Aster Tripolium* and *Plantago maritima*, and numerous other examples might be given. Moreover, owing to concentration by atmospheric evaporation and to dilution by rainfall, the salt content of the soil water must always be a very variable factor, and the halophyte must, therefore, possess in an unusual degree the power of accommodation to such changes. Further evidence on this

¹ Quoted by Burgerstein, loc. cit.

point is given by some experiments of Mr. T. G. Hill.¹ Observations of the concentration of the soil water of the salt-marsh at Erquy, before and after heavy rain, showed a concentration of mixed chlorides varying from 3.3 per cent. to 0.7 per cent.; there is thus a definite dilution or 'washing out' of the salts present in the soil. Measurements of the osmotic equivalent of the root-hairs of young plants of *Salicornia* gave an average value equivalent to a 5 per cent. or 6 per cent. solution of sodium chloride when these plants had been growing in soil of which the soil water contained about 3 per cent. of chlorides. After bathing such a sod containing *Salicornia* seedlings with weaker solutions of chloride or with water, the root-hairs were found to have a correspondingly lower osmotic pressure; and, conversely, when seedlings which had acquired a lower osmotic pressure were transferred to successively stronger solutions and re-examined, the root-hairs were found to have regained a higher osmotic equivalent. There is, therefore, a definite accommodation in the cell-sap of these root-hairs to solutions of gradually increasing or gradually decreasing concentration. It would be of great interest to know how far the same property is possessed by 'halophilous' or facultative halophytes like *Aster Tripolium* or *Plantago maritima*, and by mesophytes.

It has long been known that there are some striking parallelisms between the adaptations of some halophytic and alpine plants, especially in the more succulent types. Occasionally exactly the same species are found on mountain-tops and in maritime districts far from each other, as in the case of *Dodonea viscosa*, which, according to Schimper, occurs in Java only in these two positions, and in *Plantago maritima*, which occurs in Europe, either as an alpine or littoral form.

Bonnier² has made a careful physiological analysis of the conditions affecting alpine plants. He found that the strong unshaded light in high altitudes was largely responsible for the modifications in structure found; whilst the intense cold and dry or rocky soil produced the well-known dwarf habit with long, deeply penetrating root system. The typical alpine plant, as well as the typical halophyte, shows much greater fleshiness in the assimilating organs, largely due to an increase in the depth of a palisade parenchyma; but in alpine plants this is accompanied by an actual intensification of pigmentation, so that there is a more rapid assimilation in alpine than in lowland forms, whereas in halophytes the thickening of the leaf is connected with feebler development of chlorophyll and less active assimilation, many of the internal cells of the mesophyll being probably almost entirely given up to the storage of water. In the case of alpine plants Bonnier regards the more intense pigmentation as a direct adaptation

¹ Hill, T. G.: Observations on the Osmotic Properties of the Root-hairs of Certain Salt-marsh Plants. *New Phytologist*, 1908.

² Bonnier, Gaston: Adaptation des plantes au climat alpin. *Ann. des Sc. Nat., Bot.*, 1894.

which enables the whole plant to achieve its period of growth in the shortest time, the rapid assimilation compensating to some extent for the short summer. A somewhat greater transpiration value was found for alpine than for corresponding lowland forms, both relative to surface and to fresh weight ; and this in spite of the fact that on the whole there was more cuticular and hairy protection afforded to the alpine types. The greater transpiration, however, is probably due to the relatively greater number of stomata which was found to be a characteristic feature of alpine plants, and to the direct effects of increased assimilation and respiration.

Observations of Holtermann¹ on the vegetation of mountain peaks in Ceylon indicate that here also something more than mere altitude must be responsible for the characteristic modifications which were found. According to Holtermann the peculiarities associated with alpine plants only appear in Ceylon on mountain peaks over 5,000 ft. in height, but not at all in the vegetation of plateaus of an even greater altitude. The most obvious source of explanation was stated to be the absence of humus in the rocky districts of the mountain summits, although possibly other climatic factors might be concerned. If this explanation be true for the alpine vegetation of Ceylon, it is, however, scarcely applicable to that of Switzerland, and it is not borne out by the experience of horticulturalists who now succeed in growing even exclusively alpine plants in suitably prepared rockeries, the interstices of which contain usually a rich humic soil.

Aubert² attempted to compare by direct measurement the rate of transpiration relative to both the transpiring area, and to the fresh weight in succulent and mesophytic plants. The method employed was, admittedly, rough, and is open to criticism, but the general conclusion is probably trustworthy, that the Cactaceae transpire the least of any succulent plants as yet tested, and that next in order of magnitude come succulent plants of the type of the Crassulaceae and the Mesembryanthaeae, which have, themselves, a greater rate of transpiration than many sclerophytes, such as *Picea* and *Nerium*. In these latter types, however, there may be a very large collective leaf surface, so that the total water loss may be very much greater than in more succulent plants. We have seen that in halophytic, epiphytic, and alpine plants the rate of transpiration may be distinctly greater than in the average mesophyte. Such observations as I have made indicate that in our British Crassulaceae, and in those Mesembryanthaeae which have become acclimatized, the transpiration is greater relative to the surface area than in ordinary mesophytes, although the latter usually possess more numerous stomata. The transpiration relative to the initial fresh weight is, naturally, less in succulent than in mesophytic plants. The explanation of the

¹ Holtermann, Dr. C.: *Der Einfluss des Klimas auf den Bau der Pflanzengewebe*, 1907.

² Aubert, E.: *Turgescence et transpiration des plantes grasses*. *Ann. des Sci. Nat., Bot.*, 1892.

greater transpiration in succulents is not altogether clear, but is probably connected with the need for uninterrupted gaseous exchange, by means of the stomata, to compensate for the reduced surface area.

SUMMARY.

In the course of this paper it has been shown that the chief structural peculiarities of succulent plants are connected with (1) the transpiring surface, and (2) the storage of water.

Summing up for the characteristics of the transpiring surface, we see that succulent plants show a varying amount of reduction in leaf surface, and this may or may not be accompanied by arrangements which tend to diminish transpiration. Succulent plants of dry habitat have often either much cuticle or a waxy covering; less frequently protective hairs are found. In many cases water-storing tissue is found, and often the transpiration is considerable relative to the transpiring surface; the stomata are often specially protected in plants of very dry habitats; but in many Crassulaceae, succulent Chenopodiaceae, and halophytes, as well as many epiphytes, the guard cells are unprotected, and lie on a level with the epidermal cells. Many epiphytes absorb water over their whole surface, some also obtain water by means of aerial roots, which are provided with porous water-storing peripheral tissue, forming the so-called velamen. It seems probable that halophytes and desert plants with salt glands absorb water through the hygroscopic nature of the salts excreted; and that other halophytes with a thin cuticle absorb water to a less extent by means of their leaves.

Most succulent plants are characterized by the possession of definite aqueous tissue; others have a great development of mesophyll in the leaves, and then the innermost layers tend to function as storage cells for water. The water stored may be required for long periods of drought as in all truly xerophytic succulent plants. In extreme cases, the whole plant may develop at the expense of the water stored, as in the corms of *Sauromatum*. On the other hand, the water stored may be of value in avoiding the evils of a fluctuating water supply, as in many rock plants; or it may be a provision against temporary rapid transpiration, as in the Mangrove swamps of Ceylon, and perhaps, also, our ordinary British swamp halophytes. How far the aqueous tissue can be replenished from external sources, e. g. rain or dew or standing water, must be regarded at present as an open question; but it is probable that this may at times take place. The formation of aqueous tissue seems intimately related, on the one hand, to the production of organic acids, owing to the influence of limited gaseous exchange on metabolism, and, on the other hand, to the presence of chlorides or sulphates in excess in the soil water. According to Holtermann, however, these influences alone are not sufficient to account for all the peculiari-

ties observed ; for, although many plants, such as *Salicornia*, are modified so far as to be obligate halophytes, and others, such as *Aster Tripolium*, are plastic or facultative, yet there are some plants which can endure a saline or non-saline habitat with little or no change of structure, such as *Suaeda fruticosa* and several species of *Atriplex*. In every case, however, the aqueous tissue appears to be mainly of value as a water-storage tissue, the cells of which are always depleted in time of drought before the assimilating cells lose in turgidity, and filled again when a renewed water supply is available.

Finally, we see that many of the peculiarities of succulent plants must be regarded as adaptations to environment of real importance to the plant. They may be produced during the lifetime of the individual, as in the development of additional mesophyll or storage tissue in a facultative halophyte, or they may appear as permanent characteristics, as in the case of plants which are found exclusively in saline situations. In all cases, however, the presence of aqueous tissue and the power of water storage are probably of the first importance in the economy of the individual, and enable it to support a rate of water loss which is very considerable, relative to the transpiring surface.

i. INTRODUCTION.

THE need for comparative researches on the Coniferae cannot be expressed better than in the words of Dr. Scott, who in his Presidential Address to the Linnean Society of London for the year 1910 remarked with regard to this group of plants, 'I am convinced that a thorough comparative re-investigation of the whole family will be needed before the question of their affinities can be cleared up. . . . A broad synthesis is urgently needed.'² The investigation described in the following pages is an attempt to treat of the structures met with in one of the less known orders of the Coniferae in a comparative manner. On the other hand, the investigation can by no means be described as thorough, for the difficulties of obtaining material of critical stages of some species and of obtaining material at all of others, have proved in many cases insurmountable. This is especially so in the case of gametophytic structures, where series of stages carefully fixed are essential. Owing to the kindness of Mr. W. T. Saxton it has been possible for me to examine the earlier stages of the gametophytes

¹ A Walsingham Medal Essay for 1911.

² Scott ('10), p. 77.

of *Podocarpus latifolius* in material collected by him in two gorges near Cape Town on Table Mountain (Stangoolie and Orange Kloof). This material was mostly collected between October 18 and December 17. On the latter date Mr. Saxton found that the ovules in these localities had all aborted, so that a sequence of the later stages has not been available. Dr. Marie C. Stopes has also most kindly provided material of *Podocarpus macrophyllus* and *P. nagi* collected by her in Tokyo. This material consisted chiefly of older ovules, which provided a sequence of later stages than those given by the material of *P. latifolius*.

I have also been enabled to examine material of *Dacrydium cupressinum* sent by Mr. Phillips Turner from Wellington, New Zealand, and material of *Microcachrys tetragona* collected in Tasmania and sent to Professor Seward by Mr. Maiden from Sydney, New South Wales. I would here record my hearty thanks to the botanists mentioned for their kindness in providing me with material, as well as to Mr. T. G. B. Osborn and Miss E. J. Welsford, from whom were obtained roots of *Dacrydium* and *Podocarpus*. I am also much indebted to the Director of the Royal Botanic Gardens, Kew, and to Mr. Boodle for facilities in collecting and fixing material. Most of the material of leaves and stems was collected at Kew, as well as male cones of *Podocarpus andinus* and female 'cones' of *Dacrydium Franklini*. It is a pleasure to me to acknowledge my indebtedness to Professor V. H. Blackman for help in various ways, especially in matters of technique, and to Professor Seward for the trouble he has taken in helping to obtain material for this investigation, and for his putting at my disposal much literature which would otherwise have been unavailable. To my colleague, Mr. J. M. Hector, I am indebted for many kindnesses.

ii. METHODS.

The methods used in this investigation require no very special comment. The material collected by Mr. Turner in New Zealand was preserved in methylated spirit; that of *Podocarpus nagi* and *P. macrophyllus*, collected by Dr. Stopes at Tokyo, was preserved in dilute spirit. The material collected near Cape Town by Mr. Saxton was fixed in the mixture of mercuric chloride, picric acid, and acetic acid, as used by him in his work on the Callitricheae. The vegetative material collected at Kew was mostly fixed in methylated spirit, although some was killed in cytological fixatives. The young female fructifications of *Dacrydium Franklini* were fixed in the mercuric-picric-acetic mixture mentioned above, while the most suitable fixative for the male cones of *Podocarpus andinus* was found to be Flemming's strong fluid.

In the anatomical part of the work microtome series were used wherever possible, as well as hand sections. In a few cases it was found necessary to use the celloidin method. Safranin and anilin blue was found

a most useful combination of stains for anatomical work, but several other combinations were also employed. For gametophytic and embryological work Benda's iron-alum haematoxylin was largely used. For thicker sections of 8μ and upwards combinations of anilin safranin with either Delafield's haematoxylin or light green were found extremely useful, owing to the transparency of the stain. For gametophytes not cytologically fixed these stains gave results equal to those obtained with iron-alum haematoxylin, and so were largely used.

iii. NOTES ON GENERA AND SPECIES: EXTERNAL FEATURES.

The division of the Coniferae into the two primary groups of Pinaceae and Taxaceae appears to date from the work of Lindley in 1836,¹ and has been followed by almost every writer on the Coniferae. A threefold division into Abietinae, Cupressinae, and Taxinae was earlier suggested by L. C. and A. Richard.² The main distinction between the two divisions is in the female fructification, this being a well-defined cone in the Pinaceae, whereas cone formation tends to be imperfect in the Taxaceae. This rule is not without exception, but in the case of female cone-bearing Taxaceae there is no doubt of their affinity with other members of the group.

The later grouping of the Taxaceae into Taxeae (Taxoideae, Taxineae) and Podocarpeae (Podocarpoideae, Podocarpineae) first appears in the work of Endlicher in 1847.³ The differences between the Taxeae and Podocarpeae extend to the male cones as well as the female fructifications. In the first-named group the microsporophylls are peltate or sub-peltate and bear several microsporangia, whereas in the Podocarpeae they are simpler structures bearing constantly two microsporangia on their under surface. As regards their female fructifications, the Taxean ovule is erect and surrounded by two symmetrical integuments; in the Podocarpeae the ovules are generally more or less inverted, and surrounded by a symmetrical inner integument, and an outer integument which only partially surrounds the inner. Here again the distinction is not absolute, for in the genus *Phyllocladus* the male cone is Podocarpean, while the megasporophyll bears a single *erect* ovule, with two symmetrical integuments, a Taxean character. This genus has therefore caused systematists a good deal of trouble. Thus we find it placed among the Taxeae by Endlicher⁴ and others, removed to the Podocarpeae by Strasburger,⁵ and placed in a sub-family by itself by Pilger.⁶ Later work has tended to show more and more that its proper place is among the Podocarpeae,⁷ so it is considered with them in this account. The remaining genera are *Podocarpus* with 62 species, *Dacrydium*

⁷ Pilger ('08), p. 38.

with 16, *Saxegothaea* and *Microcachrys* each monotypic, and *Pherosphaera* with 2 species.¹ In all genera and species a single ovule is borne in a median position on the megasporophyll. The megasporophylls may be closely aggregated in well-defined cones as in *Saxegothaea* and *Microcachrys*, the cone may be a reduced one as in *Pherosphaera*, a still more reduced one as in *Phyllocladus*, or the sporophylls may be several in number as in some species of *Dacrydium* and *Podocarpus*; lastly, they may occur singly or in pairs as in other species of these two genera. Again, the ovules may be pedicillate as in *Podocarpus*, or sessile on the sporophyll as in the other genera. In this case, they may be completely reversed as in *Saxegothaea* and *Microcachrys*, only partially reversed as in some species of *Dacrydium*, or erect as in *Phyllocladus* and *Pherosphaera*. Finally, they may have only one integument (*Pherosphaera*), two integuments with the outer only partially surrounding the inner, or the outer integument may be symmetrical (*Phyllocladus*). In spite of these differences there can now be no doubt that the forms here included form a natural family. Other evidence supporting this conclusion will be given in the course of the paper, and indeed such a view is now almost universally adopted.

The following genera and species have been examined:²

1. *Saxegothaea*, Lindl.

The single species *S. conspicua*, Lindl., has been described as *Squamotaxus Albertiana*, Senilis, but it would appear that no one but the author of the name has ever employed it. The plant is a small tree of Yew-like habit, native of the Chilian Andes, and is monoecious. A case has, however, been recorded in which some of the branches on a tree were mostly microsporangiate and others ovulate.³

2. *Microcachrys*, Hook. f.

The only species, *M. tetragona*, Hook. f., was for long confused with *Athrotaxis*, *Dacrydium*, and *Pherosphaera*. The male cones were first described by Sir W. J. Hooker in 1843 as *A. tetragona*,⁴ and again in 1845 by Sir J. D. Hooker as *Microcachrys tetragona*,⁵ the female cones then described under that name being those of *Pherosphaera*. Both male and female cones were described by Archer in 1850 as *Pherosphaera*.⁶

¹ The New Caledonian genus *Acropyle* (Pilger, '03, p. 117), with its single species *A. Pancheri*, probably belongs to this order, but so little is known of it that it seemed doubtful whether any useful purpose would be served by introducing it into this paper.

² The nomenclature of Pilger's monograph ('03) has been followed throughout as the most recent and most complete systematic account of the Podocarpeae. Further information on external features of the species is to be found in that work. Photographs showing the habit of some species of *Podocarpus* and *Dacrydium* are given by Laing and Blackwell ('08). For photographs of *Dacrydium Franklini*, *Pherosphaera Fitzgeraldii*, *Phyllocladus rhomboidalis*, *Podocarpus elatus*, and *P. spinulosus*, see Baker and Smith ('10).

³ Norén ('08), p. 102.

⁴ Hooker, Sir J. D. ('45), p. 149.

⁵ Hooker, Sir W. J. ('43), Tab. 560.

⁶ Archer ('50), p. 52.

The confusion in nomenclature between the four genera mentioned above was ultimately cleared away by Sir J. D. Hooker in 1860.¹

This plant in habit is not much more than a straggling shrub found on some of the mountains of Tasmania. As regards reproductive shoots the plant is dioecious. As well as in this it differs from *Saxegothaea*, as far as external characters are concerned, in the form and arrangement of the leaves and in the nature of the fruit.

3. *Dacrydium*, Soland.

The first description of a plant under the generic name *Dacrydium* in 1786² contains practically no mention of its structure, but is chiefly concerned with the use to which the plant is put in the making of a kind of Spruce-beer. Lambert³ appears to be the first writer to append a botanical description to the name.

This genus differs from *Saxegothaea* and *Microcachrys* in the reduction of the number of megasporophylls in the strobilus, and from *Podocarpus* in the absence of a stalk to the ovule, and in the freedom of the inner integument from the nucellus, and of the outer from the inner.

There is some range of habit among the sixteen species of this genus. Some, such as *D. Kirkii*, are trees reaching a height of 100 feet, the majority are small trees about 20 or 30 feet high, while others are low shrubs. The species are generally dioecious, but Kirk⁴ describes *D. laxifolium* as monoecious or dioecious.

Two species of the genus have been examined in the course of this work, *D. Franklini*, Hook. f., and *D. cupressinum*, Soland. Both are forest trees, the former being the Huon Pine of Tasmania, the latter the Red Pine of New Zealand.

4. *Podocarpus*, L'Hérit.

The first plant of this genus to be given a botanical name was *P. nagi*, (Thunb.) Pilger, which was described by Thunberg⁵ under the name of *Myrica Nagi*. Gärtner in 1778 realized that the plant belonged to a previously undescribed genus, and gave it the name of *Nageia Japonica*.⁶ Two species are confused in this description,⁷ so the generic name *Nageia* has been replaced by the later name of *Podocarpus*, which was first used by Labillardière⁸ in 1806 for the species now known as *Phyllocladus aspleniifolius*. In the next year L'Héritier's name *Podocarpus elongatus* appeared.⁹ L. C. and A. Richard in 1826 first gave the name *Phyllocladus* to what had previously been known as *Podocarpus aspleniifolius*.¹⁰ The Vienna Rules regarding botanical nomenclature reject the earlier name *Nageia* in favour

of *Podocarpus*, and similarly the name *Podocarpus* as it was first used in 1806 is replaced by the later name *Phyllocladus*.

The chief character distinguishing *Podocarpus* from other genera is to be found in the greater extent to which fusion of parts has taken place in the female reproductive structures. Whereas in the genera already noticed the outer integument is to a great extent separate from the inner, which is itself separate from the nucellus, in *Podocarpus* the fusion of these parts is always more or less complete. In all the species of this genus also the ovule is not sessile on the megasporophyll, but is borne in an inverted position at the end of a short stalk, so that the micropyle faces towards the base of the stalk. For the upper part of its length the stalk is fused with the integuments, so that it is impossible to define the limits of the stalk and of the outer integument.

Pilger¹ divides the genus into five sections:

1. **Dacrycarpus**, in which the fusion of parts has included the megasporophyll, which is connate with the ovulate structure. This has taken place in none of the following sections.

2. **Microcarpus**, in which the leaves are squamiform.

3. **Nageia**, where the leaves are plurinerved.

4. **Stachycarpus**, with linear or lanceolate leaves, but when in fruit without a fleshy receptacle formed by the fusion and swelling up of the sporophylls. In two species, *P. andinus* and *P. spicatus*, the megasporangiate strobilus consists of a branch bearing about eight megasporophylls separated by appreciable internodes. The other species of the section, however, are reduced in this respect like the species of other sections.

5. **Eupodocarpus**, with linear or lanceolate leaves and with a receptacle.

Species have been examined representative of the last three sections mentioned above; it was not found possible to obtain for examination any but herbarium material of the three species of *Dacrycarpus*, or of the single species of *Microcarpus*. One species, *P. nagi*, (Thunb.) Pilger, was examined of the section *Nageia*; two species, *P. andinus*, Poeppig, and *P. amarus*, Blume, of the section *Stachycarpus*; and eleven species of the section *Eupodocarpus*: *P. elatus*, R. Br., *P. spinulosus*, (Smith) R. Br., *P. polystachyus*, R. Br., *P. macrophyllus*, (Thunb.) Don, *P. neriifolius*, Don, *P. salignus*, D. Don, *P. Totara*, A. Cunn, *P. alpinus*, R. Br., *P. elongatus*, (Ait) L'Hér., *P. latifolius*, (Thunb.) R. Br., and an unknown species. It is unnecessary to indicate the external features of each of these species, which are treated of at length by Pilger.

There is a wide range of habitat from tall trees like *P. elatus* reaching a height of 100 feet, through smaller trees such as *P. andinus*, about 20 feet high, to low shrubs like *P. alpinus* and *P. nivalis*, found on the mountains of Tasmania and New Zealand respectively.

¹ Pilger ('03), p. 55.

Most species of *Podocarpus* are dioecious, though there are cases of monoecism in the genus. Mr. Saxton has made some interesting records when collecting material for this investigation. He found that *P. latifolius* was normally dioecious, but a single case was found of a female plant which bore a single male cone. In the locality in which this record was made male trees were found to be much more numerous than female ones.

It should be noted that *P. neriifolius*, Don, is perhaps more usually called *P. bracteata*, Blume; similarly *P. salignus*, D. Don, is possibly better known as *P. chilinus*, L. C. Rich., while *P. Thunbergii*, Hook., is the more familiar name of *P. latifolius*, (Thunb.) R. Br. The plant which figures most in past investigations of the genus is *Podocarpus chinensis*, Wall. (or *P. sinensis*). Following Pilger this is *P. macrophyllus*, subsp. *maki*, Sieb.

Of the 63 species enumerated by Pilger, 3 are placed by that writer in *Dacrycarpus*, 1 in *Microcarpus*, 4 in *Nageia*, 10 in *Stachycarpus*, and 34 in *Eupodocarpus*. The remaining 11 species are 'species incertae sedis', 3 of them possibly belonging to *Nageia* and 8 to *Eupodocarpus*. This fact alone shows the imperfect state of our knowledge of the genus at the present time, and it is possible that future systematic study may considerably alter the number of species.

iv. STEMS.

A. Primary Structure.

The primary structure of the stem has been examined in the following species: *Dacrydium Franklini*, *D. cupressinum*, *Podocarpus nagi*, *P. elongatus*, *P. amarus*, and *P. andinus*.

A transverse section through the young stem of *Podocarpus andinus* is roughly circular, and shows generally about four of the decurrent leaf-bases (Pl. XLVI, Fig. 1). There is in the stem a ring of seven or eight endarch collateral bundles. The centre is occupied by a parenchymatous pith; in the cortex is a ring of resin canals just outside the ring of bundles, one resin canal appearing just outside the phloem of each vascular bundle. In this species the resin canals of the stem are fairly large structures with a well-marked epithelial layer, and the canals are no doubt functional. The protoxylem, as usual, consists of spirally thickened elements, while the cells of the metaxylem have uniseriate bordered pits. The cortex is composed of parenchymatous cells; stone cells were not observed.

A leaf-trace arises by the division of one of the bundles, so that the two resulting bundles lie side by side in the ring. This is followed by the division of the resin canal in a similar manner. The leaf-trace and its accompanying resin canal then pass upwards and outwards into the leaf base.

Podocarpus elongatus is on the whole similar. A transverse section of the stem of this species is roughly square (Pl. XLVI, Fig. 2, and Text-fig. 1, *δ*).

The leaf-insertion in this species is decussate, and the leaf-traces pass rather quickly out of the cortex. Each bundle, as in *P. andinus*, is furnished with a single resin canal.

In *Podocarpus nagi* the stem is usually oblong in transverse section owing to the decussate arrangement of the leaves and to the fusion of the leaf-bases with the stem (Pl. XLVI, Fig. 3, and Text-fig. 1, *d*). As in *P. andinus* there is a ring of endarch collateral vascular bundles surrounding the pith. How small these primary bundles are and how little xylem beyond protoxylem occurs in them is shown in Pl. XLVII, Fig. 18. In the pith, as well as in the cortex, stone cells are of fairly frequent occurrence. In this species they

TEXT-FIG. 1. Diagrams of transverse sections through primary stems. $\times 30$. *a*, *Podocarpus andinus*; *b*, *P. elongatus*; *c*, *P. amarus*; *d*, *P. nagi*; *e*, *Dacrydium Franklini*.

appear to occur singly and frequently near the xylem. The resin canals are distributed as in *P. andinus* and *P. elongatus*, but are relatively much smaller. The great peculiarity in the stem of *Podocarpus nagi* is in the insertion of the leaf-trace. Here one of the stem bundles divides into three, the resulting bundles of the division consisting of two larger lateral ones and one smaller median one (Pl. XLVI, Figs. 3 and 4). Each bundle is accompanied by a single resin canal. These three bundles then pass upwards and outwards, as in the case of *Podocarpus andinus*. As far as the writer is aware, this is the only recorded case among Conifers of a leaf-trace consisting of more than two bundles, and even in *Podocarpus nagi* the three bundles forming the leaf-trace result from a single bundle dividing when about to pass out from

the ring of bundles comprising the stele. Probably the condition of affairs is essentially the same as in some of the Araucarieae.¹

Podocarpus amarus is essentially the same as *P. andinus* as regards the structure of the young stem. This is, as usual, a ring of bundles with a single resin canal outside each bundle. The case is, however, a little complicated as each leaf bundle is accompanied by three resin canals (Text-fig. 1, c). These three canals run down into the stem with their corresponding bundle, but the two lateral ones ultimately fuse with neighbouring canals, so that the bundle is left with a solitary canal. In this stem stone cells are extremely abundant in the pith, though before secondary growth had commenced only a few solitary ones were observed in the cortex. As in *P. nagi*, the primary xylem is practically limited to the protoxylem; Pl. XLVII, Fig. 17, shows a primary bundle in the stem just as the interfascicular cambium is forming.

In the stem of *Dacrydium cupressinum* there is a layer of sclerenchyma outside and in contact with the phloem. In the stems examined in the course of this work the sclerenchyma was two or three layers thick. The primary medullary rays in this stem are narrow, in some cases being only two cells wide. A ring of resin canals occurs in the cortex, as in the species of *Podocarpus* examined.

Dacrydium Franklini is the only other species of the genus examined. There is the usual ring of vascular bundles, but unlike *D. cupressinum*, and although resin ducts are present in the leaves, canals are absent from the stem (Text-fig. 1, e). The same is apparently the case in *Microcachrys*.

B. Secondary Xylem.

The accounts we possess of the structure of the stem in the Podocarpeae are mostly confined to accounts of the secondary wood. They are those of Bertrand² on *Podocarpus* and *Dacrydium* (treated as a section of *Podocarpus*), and of Penhallow³ on *Podocarpus macrophyllus*. Beust⁴ examined *Saxegothaea*, and Gothan⁵ *Saxegothaea*, *Dacrydium* spp., and *Podocarpus* spp. Baker and Smith have recently published photographs of the wood of *Dacrydium*, *Phyllocladus*, and *Podocarpus*.⁶ The writer has previously examined the stem of *Saxegothaea*,⁷ and in conjunction with Mr. Brooks that of *Podocarpus spinulosus*.⁸ Miss Gerry⁹ has recorded some observations on the occurrence of 'bars of Sanio' in these plants.

Bertrand's observations are largely in terms of *Taxus*. He found that in *Podocarpus* wood parenchyma was often present in greater quantity than

⁸ Brooks and Stiles ('10), p. 306.

⁹ Gerry ('10), p. 119.

in *Taxus*, that the phloem fibres early show thick walls, and that resin canals are absent from the wood or phloem.¹ Bertrand's observations were limited to *Dacrydium* and *Podocarpus*, but in *Saxegothaea* and *Microcachrys* his statement with regard to the absence of resin canals in the wood and phloem holds equally well.

On the nature of the pitting, Bertrand only remarks that all the tracheides do not have spiral thickenings as in *Taxus*.² Lately considerable attention has been directed to the nature and distribution of bordered pits on the walls of the tracheides. Beust³ and Gothan⁴ find that the pits in *Saxegothaea* are uniseriate, the pits being frequently in close contact and flattened above and below along the line of junction. This observation the writer was able to confirm.⁵ Very occasionally the pitting is for a short distance biseriate, when the pits are close together and alternate. As a result of flattening along the line of contact they have a partially hexagonal shape.

Gothan⁶ has observed this biseriate arrangement of the pits in the stem of *Dacrydium cupressinum* and two other species of the genus. I have examined the stem of *Dacrydium cupressinum*, but have not been able to confirm this statement. No doubt, as in *Saxegothaea*, the occurrence of the biseriate arrangement, at any rate in stems not many years old, is rather rare.

The writer has examined the wood of the fairly young stems of several species of *Podocarpus*. The pitting on the radial walls is uniseriate, and although the pits are sometimes in contact, this is not always the case, as variations in this respect may occur in the tracheides of the same section.⁷ That such a variation should occur is of importance when it is considered that the distribution of pitting is one of the characters used in the determination of fossil woods. On the tangential walls of the tracheides of the summer wood conspicuous and numerous large simple pits ('Eiporen') occur.⁸

The medullary rays throughout the order consist of parenchymatous cells only. They are only one cell wide, and in the young stems, at any rate, are not often more than five cells deep.

Gothan⁹ has made observations on the medullary ray pitting, a character on which he lays much stress in the determination of Coniferous woods. He finds four types of medullary ray pitting in the Podocarpeae.

1. *Saxegothaea* has the tangential walls of the medullary ray cells smooth, but the horizontal walls have numerous small simple pits.

⁹ Gothan ('05).

2. Typical 'Podocarpoid' pitting, consisting of smallish oval pits with a somewhat slit-like opening, occurs in *Podocarpus neriifolius*, *P. salicifolius*, and *Dacrydium laxifolium*.

3. A type characterized by large simple pits ('Eiporen') occurs in *Podocarpus andinus*, *P. spicatus*, *Phyllocladus*, *Dacrydium Franklini*, *Microcachrys*, and *Pherosphaera*.

4. A 'mixed type', with both the (2) and (3) kinds of pitting, is found in *Podocarpus Sellowi*, *P. falcatus*, *Dacrydium cupressinum*, and *D. elatum*.

v. LEAVES.

The leaves of the Podocarpeae show the usual xerophytic structure characteristic of Conifer leaves,¹ but, nevertheless, the range in structure, at least as far as external characters are concerned, is probably as great as that found in any order of the Coniferae.

A. External Features.²

The leaves of *Saxegothaea* and of many species of *Podocarpus*—for example, *P. andinus*, *P. spicatus*, and *P. ferrugineus*—are in external aspect very similar to those of *Taxus*. They generally end in a more or less acute tip, and are narrowed at the base. From this type of leaf there can be arranged a series of leaves of various species of *Podocarpus*, similar in shape, but increasing in size, such as *P. Totara*, *P. elongatus*, *P. macrophyllus*, and *P. polystachyus*, culminating in the large leaves of *P. amarus* and *P. elatus*, the leaves of the last-named plant being often 12 to 15 centimetres long and a centimetre wide.

Another kind of leaf is found in the familiar type of small appressed, more or less triangular leaf, which is found in *Pherosphaera*, *Microcachrys*, many species of *Dacrydium* (for example, *D. Franklini*), and in some species of *Podocarpus*. In more than half of the species of *Dacrydium* 'juvenile' forms of leaf occur which differ from those of the adult plant in being needle-like in shape. Such 'juvenile' forms are found in *D. cupressinum*, *D. biforme*, *D. Kirkii*, *D. Bidwillii*, &c. In *D. cupressinum* the leaves of the adult plant are shorter and flatter than those of the juvenile state, but yet are not triangular nor appressed to the stem, being rather intermediate in shape between the juvenile state and the more general adult state.

The most distinct type of leaf is found in the *Nageia* section of the genus *Podocarpus* (Pl. XLVII, Fig. 24). As is well known, the leaves in this section are comparatively wide and are traversed by a number of parallel veins; in this respect they are sharply marked off from all other species in

¹ See for example Warming and Vahl ('09), p. 310.

² A full account of the external characters of the leaves of the Podocarpeae is given by Pilger ('08), p. 3. See also the specific descriptions in that work.

this order. The leaf of *Podocarpus nagi* is about 6 centimetres long by 2 centimetres wide, and often has as many as 40 veins. The superficial resemblance of the leaves of *Nageia* to those of species of *Agathis* has been frequently commented on, as well as the resemblance of both these types to the leaves of *Cordaites*.

In *Phyllocladus* the true leaves are reduced to scales, being replaced functionally by phylloclades.

In most of the species the leaves are arranged spirally on the axis, but in the *Nageia* section of *Podocarpus*, as well as in *Microcachrys*, *Podocarpus vitiensis*, and *P. elongatus*, a decussate or sub-decussate arrangement prevails.

B. Internal Structure.

The internal structure of the leaves of the following species has been examined: *Saxegothaea conspicua*, *Microcachrys tetragona*, *Dacrydium cupressinum*, *D. Franklini*, *Podocarpus nagi*, *P. andinus*, *P. amarus*, *P. macrophyllus*, *P. elatus*, *P. polystachyus*, *P. salignus*, *P. Totara*, *P. elongatus*. In addition accounts of the structure of the following species have already been published: *Podocarpus chilinus*¹ (= *P. salignus*, D. Don), *P. nagi*,² *P. nerifolius* and *P. falcatus*,³ and *P. spinulosus*.⁴ The leaf of *Microcachrys* has been described by Thomson,⁵ and its structure compared with that of the megasporophyll, a comparison which has brought out some interesting points. Observations on the leaves of *Phyllocladus* have been made by Mrs. Arber.⁶ As well, there is the comparative account of the structure of the leaves of *Saxegothaea* and *Podocarpus* (in which the genus *Dacrydium* is included) by Bertrand.⁷ A brief general account of the anatomy of the leaves in the Taxaceae is given by Pilger.⁸

From these accounts, and from investigations on the species mentioned above, it is evident that several types of leaf occur in the Podocarpeae.

1. Perhaps the commonest type of leaf is that of *Podocarpus macrophyllus* (Text-Fig. 2, a). In this species the leaf is 5 or 6 centimetres long and about 7 millimetres broad. On each side of the xylem of the median vascular strand is found well-developed transfusion tissue (reticulate cells of Bertrand). From either side of this stretches to the margin of the leaf the accessory transfusion tissue of Worsdell (transfusion tissue of Bertrand and hydrostereome transversal of Bernard). Descriptions and figures of both transfusion tissue and accessory transfusion tissue are given by Worsdell⁹ and Bernard.¹⁰ On the lower or phloem side of the vascular bundle occur three resin canals, one median with regard to the bundle, the other two, one

⁸ Pilger ('08), p. 7.

¹⁰ Bernard ('04).

on each side of the median one, but yet distinctly underneath the phloem. These canals are small, but the epithelial cells seem to be of the normal type.¹

A sclerenchymatous hypodermal layer is developed beneath the epidermis on the upper side. On the lower side this layer is only developed below the midrib, and even on the upper surface it is discontinuous. At the base of the leaf, however, hypoderm is developed all round. Stomata seem almost entirely limited to the under side of the leaf. They are sunk below the surface, as is usual in Coniferae, and are of the usual Coniferous type. There is a well-marked palisade layer below the upper epidermis and hypoderm; the remaining mesophyll of the leaf is well provided with intercellular spaces. It is in this 'spongy' tissue that the accessory transfusion tissue is found.

The structure of the leaves of *Podocarpus elatus* and *P. polystachyus* seems to be essentially similar. In these species three resin canals beneath the phloem appear to be the rule. There are slight differences in the quantity of transfusion tissue, accessory transfusion tissue, and sclerenchyma, but no doubt the quantity of these is to some extent determined by external conditions. It is interesting to note that the leaves in which this type of structure has been observed are amongst the largest of the uninerved ones in the genus.

In leaves referred to *Podocarpus amarus*, obtained from the Royal Gardens, Kew, there are three resin canals, as in *P. macrophyllus*, but they are smaller than usual in this type, and are easily overlooked.

2. *Podocarpus vitiensis*, comprising Bertrand's monotypic subgenus *Polypodiopsis*,² according to that author has leaves characterized by a structure different from that found in other species in the genus. The chief difference consists in the distribution of the resin canals, one under the nerve and one in the parenchyma on each side of the leaf and near the margin. The decussate arrangement of the leaves and other characteristics given by Bertrand are also found in other species.

3. In the third type of leaf there is normally a single resin duct under the vascular bundle, as, for example, in *P. salignus* (Text-fig. 2, *b*). There is also a tendency towards reduction of accessory transfusion tissue and sclerenchyma as compared with the *P. macrophyllus* type. In *P. Totara* the accessory transfusion tissue is not very typical, the cells being rather short, and not much lignified, intermediate in character between the mesophyll cells and typical accessory transfusion tissue. Stomata were observed on the lower surface only, while a sclerenchymatous hypoderm was observed on both sides. *Podocarpus elongatus* appears to have leaves with a similar internal structure, but here, as Bertrand³ correctly observed, stomata are

¹ Pilger ('03, p. 8) records the frequent presence of three resin canals under the bundle in *Podocarpus*, but does not give the names of any species.

² Bertrand ('74), p. 66.

³ l. c., p. 60.

found on the upper as well as on the under surface. Pilger¹ would correlate this with the presence of palisade on both sides of the leaf, but in the leaves examined by the writer palisade was very feebly developed. The development of palisade on one side or on both sides of the leaf, as well as the extent of its development, probably, as in Angiosperms, depends mostly on external conditions. Bertrand's statement that, except in *P. elongatus*, *P. vitiensis*, the *Nageia* section of *Podocarpus*, and *Dacrydium*, the upper face of the leaves is without stomata,² can be accepted no more than his statement that there is *constantly* under each bundle a single resin canal.³ In *Podocarpus andinus*, for example, stomata occur on the upper as well as

TEXT-FIG. 2. Diagrams of transverse sections of leaves of the Podocarpeae. Xylem is shown in black and transfusion-tissue is cross-hatched. In *a* and *b* the distribution of accessory transfusion tissue is indicated, and in *c* the distribution of epidermis, palisade, 'spongy' tissue, and stone-cells. *a*, *Podocarpus macrophyllus*, $\times 19$; *b*, *P. salignus*, $\times 19$; *c*, *P. nagi*, $\times 36$; *d*, *P. andinus*, $\times 19$; *e*, *Dacrydium cupressinum*, $\times 36$; *f*, *D. cupressinum* (juvenile condition), $\times 36$.

on the under surface.⁴ This last species may be regarded as the extreme type of this group as regards leaf structure (Text-fig. 2, *d*), for in its leaves there is no trace of accessory transfusion tissue, nor is a sclerenchymatous hypoderm developed. Together with *P. ferrugineus* this species is classed by Bertrand in his section *Prumnopitys*, the chief characters of the section being want of both hypoderm and accessory transfusion tissue.⁵

4. Bertrand's characteristics of the leaf of *Dacrydium* are absence of accessory transfusion tissue and of differentiation of the fundamental tissue; the constant presence of stomata on the upper surface and of hypoderm below the epidermis.⁶ The writer's observations on *D. cupressinum* and

¹ Pilger ('08), p. 7.

² Bertrand, l. c.

³ l. c., cf. *P. macrophyllus* and *P. amarus*.

⁴ The case of *Microcachrys* was unknown to Bertrand.

⁵ Bertrand ('74), p. 65.

⁶ l. c., p. 67.

D. Franklini quite confirm these statements. The juvenile form of leaf of *D. cupressinum* is tetragonal in transverse section, with a sclerenchymatous hypoderm continuous round the leaf, except in the region of the stomata. These occur in two bands towards those corners of the tetragonal leaf which are morphologically the margins. Palisade tissue is continuous all round the leaf, there being perhaps a slight development of spongy tissue in the corners corresponding to the margins.

There is a single vascular bundle with a well-marked resin canal. A well-marked sheath of parenchymatous cells surrounds the bundle and resin canals, a single layer of similar cells separating the phloem and the canal. Well-marked transfusion tissue is absent, but some lignified parenchymatous cells about the xylem probably represent it. These cells, although in the position of centripetal xylem, have exactly the appearance of parenchymatous cells, except for their lignified walls, and in this case certainly do not appear to be modified xylem-elements (Pl. XLVII, Fig. 19). The leaf of the adult form is more flattened than the juvenile form, and is not markedly tetragonal in section (Text-fig. 2, e). The structure, otherwise, is almost identical with that of the juvenile form. The stomata are in a similar position, but more numerous, while the lignified cells probably equivalent to transfusion cells occur in two rather lateral groups (Pl. XLVII, Fig. 20).

5. The leaf of *Microcachrys tetragona* has been described by Thomson,¹ with whose account my own observations agree. There is a distinct palisade with sclerotic hypoderm on the lower surface, while hypoderm on the upper surface is wanting. The stomata, as in *Dacrydium*, occur on the upper surface only. The single resin canal is wholly foliar, not being carried down into the stem.

6. *Phyllocladus*. The writer has not had an opportunity of examining leaves of this genus. Mrs. Arber² has described those of *Ph. alpinus*, *Ph. trichomanoides*, and *Ph. rhomboidalis*. They are, as would be expected in such a reduced leaf, of very simple type. On the whole they most nearly recall those of *Microcachrys*, except that no hypoderm or palisade is present. A single resin canal is present under each bundle. There is no differentiation of tissues in the mesophyll of the leaf. Mrs. Arber did not observe stomata in *Ph. alpinus* and *Ph. trichomanoides*, but a few were present in *Ph. rhomboidalis*.

7. *Nageia*. Of the species of the *Nageia* section the only one whose leaves have been examined in the course of this investigation is *Podocarpus nagi*. In this species no stomata were observed on the upper surface of the leaf, a character in which, according to Bertrand, it differs from other species of the section. In the leaves from Tokyo examined there is a scleren-

¹ Thomson ('09²), p. 349.

² Robertson ('06), p. 260.

chymatous hypodermal layer on both sides of the leaf. It is occasionally interrupted, and always so at the stomata.

The palisade layer under the upper hypoderm is well marked; it consists of a single layer of cells occasionally doubled. The rather compact 'spongy' tissue is about eight layers of cells thick; solitary stone cells are scattered in it. A small resin canal is present under each bundle. Accessory transfusion tissue is absent (Text-fig. 2, c).

A remarkable character presents itself at the base of the leaf in this species. It has already been stated that the leaf-trace consists of three bundles. Shortly after leaving the central cylinder of the stem a cambium forms, not only between the xylem and phloem, but also on the upper side (as regards the leaf) of the bundle as well. In this way concentric bundles are produced which consist on one side of secondary tissue only (Pl. XLVII, Fig. 21). This state of affairs recalls that found in some of the vascular bundles of the axes of the inflorescences of *Welwitschia*, except that, whereas in *P. nagi* the xylem surrounds a parenchymatous area and is surrounded by phloem, in *Welwitschia* the concentric bundles have an amphivasal structure, with xylem surrounding the phloem.¹

vi. ROOTS.

An exhaustive account of the structure of the roots of the Coniferales is in process of publication by Noelle; of this account at the time of writing only the first part dealing with the Pinaceae had appeared.² In the description of Podocarpean roots to be given here it is not intended to describe these structures in any great detail, but merely briefly to indicate the more important characteristics of the roots of the few species available to the writer.

Perhaps the most conspicuous external character of the roots of *Podocarpus* and *Dacrydium* is the presence of numerous tubercles, which are said to be caused by an ectotropic mycorrhiza. These tubercles have been mentioned by Van Tieghem³ and described by Shibata.⁴

In all the species examined, *Dacrydium Franklini*, *Podocarpus macrophyllus*, *P. cupressinus*, and *P. alpinus*, the primary xylem forms a rather narrow diarch plate. In this respect it agrees with the roots of the Araucarieae,⁵ and most of the Abietineae.⁶ In some of the latter, namely,

¹ See, for example, Sykes ('10), pp. 192, 202. It is perhaps worthy of note in this connexion that Seward and Ford ('06, p. 338) record the presence of such a concentric leaf-trace bundle as I have described, in the cortex of a young stem of *Araucaria imbricata*. Seward and Ford, however, 'prefer to regard this concentric strand as a leaf-trace of unusual structure rather than attribute to what is undoubtedly an exceptional occurrence any morphological significance.'

⁶ Noelle ('10), p. 178.

Pseudotsuga,¹ *Pseudolarix*, and *Abies*,² the roots are diarch or triarch, while in *Pinus*, as well as in the Taxodiaceae and Cupressineae, the roots are polyarch.

The secondary wood is composed mostly of tracheides, but wood-parenchyma cells are fairly numerous. The annual rings are not always well marked, as was the case in my roots of *Podocarpus cupressinus*, whereas in *P. alpinus* the rings were very well marked. These differences are possibly individual rather than specific. The medullary rays are like those of the stem; they are one cell wide and wholly parenchymatous. The bordered pits on the walls of the tracheides are often contiguous; they are usually uniseriate, but a case was observed in *P. alpinus* in which there was a biseriate arrangement. Miss Gerry has recorded the presence of 'bars of Sanio' in the tracheides of the root in *Dacrydium cupressinum* and *Saxegothaea*.³ She also records the crowding of the pits in many cases.

Considerable emphasis has been laid on the value for phylogenetic and classificatory purposes of the distribution of resin canals in the root.⁴ In the roots of the Podocarpeae I have examined these structures were entirely absent.

vii. 'MALE' CONES.

In contrast to the megasporangiate structures, the microsporophylls of the Podocarpeae are always aggregated into cones. These are remarkably uniform structures throughout the whole of the order, but among the different species a fairly wide variation in size is exhibited.

In *Microcachrys* the mature cones are only about 4 mm. long and about 2 mm. broad; those of *Saxegothaea* are about twice this length,⁵ while in *Podocarpus andinus* and *P. spinulosus*⁶ they may be as long as 1 to 1.5 cm. The cones of *Podocarpus Totara Hallii* vary from 3 to 20 mm. in length.⁷ A larger type of cone is found in *Podocarpus latifolius*, while the strobili of *Podocarpus polystachyus* may reach a length of 10 cm.

In *Saxegothaea* and *Podocarpus* the male cones are borne at the apices of short pedicels, which occur either singly or two or three together in the axils of foliage leaves. In *Saxegothaea* one cone is usually found in the axil of a foliage leaf, though there may be two or three.⁸ In *Podocarpus andinus* the same appears to be the case. One cone in the axil is the rule in *Podocarpus nivalis*.⁹ In *Podocarpus Totara Hallii*, on the contrary, Burlingame reports that the cones are usually in pairs of one large and one small one.¹⁰ In *Podocarpus spinulosus* the number of strobili in the axil

¹⁰ l. c.

of one leaf may vary from one to four.¹ The strobili of *Phyllocladus* are borne in clusters of 2 to 8 in the axils of scales at the tips of the lateral branches.² In *Microcachrys*, on the other hand, the male cones are terminal on an ordinary leafy shoot.³

Coulter and Chamberlain⁴ have remarked on the relation of leaves and strobili in the Taxaceae as being such, that if the axis were shortened, a compound strobilus would result. Although this statement does not hold generally for the Podocarpeae (as witness the case of *Microcachrys*), yet it is nevertheless true for *Saxegothaea* and all the species of *Podocarpus* examined by the writer. The resemblance to a raceme of the cone-bearing branch previously noticed in the case of *Saxegothaea*⁵ is even still more noticeable in the case of *Podocarpus andinus* (Pl. XLVI, Fig. 5).

In *Microcachrys*, where the foliage leaves are arranged decussately, the sporophylls are arranged in alternating whorls of four. In all other genera, as far as they have been examined, the sporophylls are spirally disposed on the cone axis. At the base of the cone occur a few small spirally arranged bracts.

The writer has only had an opportunity of examining the male cones of *Saxegothaea*, *Microcachrys*, *Podocarpus andinus*, *P. polystachyus*, *P. spinulosus*, and *P. latifolius*, but descriptions are also available of a few other species. These cases are, however, sufficient to show that a good deal of variation in shape and mode of attachment of sporangia exists in the order (Text-fig. 3).

In *P. andinus* each sporophyll is attached to the axis of the cone by a short narrow stalk, which terminates in the relatively large triangular upward-projecting portion ending in a broad point. The two sporangia are inserted on this on the side near the cone axis, one on each side of the stalk and partly attached to it, and are not in contact with one another (Pl. XLVI, Fig. 6, and Text-fig. 3, *a*). In *Podocarpus latifolius* the extent of fusion is greater and the sporangia are radially elongated; a tangential section of the cone shows that they are fused together for the upper half of their vertical width (Text-fig. 3, *b*). In *Saxegothaea*, and presumably also in *Podocarpus Totara Hallii*,⁶ the two sporangia are fused together for the greater part of their vertical width (Text-fig. 3, *c*). The same is the case in *Microcachrys*, but here a large cavity is present between the two sporangia and below the phloem of the vascular bundle (Text-fig. 3, *d*). In *Saxegothaea* the line of dehiscence of the sporangium is transverse,⁷ and transverse dehiscence of the sporangium of *Dacrydium cupressinum* is figured by Richard and by Lambert,⁸ and described for *D. elatum* and

D. Colensoi by Thibout, while the same is said to be the case in *Podocarpus andinus*, *P. dactyloides*, and *P. Totara*.¹ In *P. spinulosus*² and some other species described by Thibout³ the dehiscence is oblique. Thibout also records oblique dehiscence in *Phyllocladus*.

The vascular structure of the cone axis is very similar to the primary vascular structure of the stem; that is, there is a ring of vascular bundles surrounded by a ring of resin canals, one canal outside the phloem of each bundle. *Saxegothaea* has traces of centripetal xylem in these bundles,⁴ but no such thing was found in *Microcachrys* or any of the species of *Podocarpus* examined, nor is any recorded in the case of *Phyllocladus*.⁵ No canals are present in the cone axis of *Microcachrys*.

The sporophyll trace originates in the same way as the leaf-trace;

TEXT-FIG. 3. Transverse sections through microsporophylls. *a*, *Podocarpus andinus*, $\times 32$; *b*, *P. latifolius*, $\times 32$; *c*, *P. Totara Hallii* (after Burlingame); *d*, *Microcachrys*, $\times 32$.

that is, by the division of a single bundle into two which lie side by side in the ring of bundles, above which point one of them passes out into the sporophyll. The resin canal divides similarly, and in *Saxegothaea*,⁶ *Podocarpus spinulosus*,⁷ and *P. latifolius* a canal passes into the sporophyll; in *Podocarpus andinus*, however, the canal does not enter the sporophyll.

The single vascular bundle in the sporophyll consists of a few xylem and phloem elements which require no special comment; in the terminal lamina the bundle ends in a development of transfusion tissue.

The development of the sporangium has not been traced in detail in any species of the order, but no doubt follows that of other Conifers. In the youngest material examined of *Podocarpus andinus* five layers of cells were visible outside the megaspore-mother-cells; in the mature sporangium only the remains of two layers were visible inside the sporangium wall. The latter in *Saxegothaea* and *Podocarpus latifolius* has conspicuous thickening bands on the vertical walls, but in *P. andinus* the walls are not very conspicuously thickened. In *Saxegothaea*¹ and *Podocarpus* spp. the sporophyll contains cells of presumably a secretory nature with deeply staining contents which are very like those figured by Seward and Ford² for *Araucaria Rulei*. In *Podocarpus latifolius* and *P. andinus* the terminal lamina contains a large air-space on the side below the vascular bundle.

viii. 'FEMALE' FRUCTIFICATIONS.

The features distinguishing the various genera of the Podocarpeae have been touched upon in a previous section of this paper, and for this purpose it was necessary briefly to indicate the chief differences between the female fructifications of the various genera. A more detailed account of these organs will now be given.

I. *Pherosphaera*. The sporophylls of this genus, according to Pilger,³ form small cones with 2 to 5 fertile sporophylls and several sterile ones. Each fertile sporophyll bears a single erect ovule surrounded by a single integument (Text-fig. 8, *a*); in the young condition it is stated by Pilger that the ovule is in the axil of the cone scale.

II. *Phyllocladus*. The female fructifications of this genus consist of small cones, solitary or several together in the axils of scale-leaves, which may be borne either on the branches of unlimited growth or on the phylloclades.⁴ The sporophylls may be either spirally or decussately arranged, and this is not even a specific difference, for in *Ph. alpinus*, although the usual arrangement of the sporophylls is a decussate one, yet a spiral arrangement sometimes obtains.⁵ In this species there may be one pair or two pairs of fertile sporophylls at the base of the cone, and several upper pairs of sterile cone scales.⁶

Each fertile sporophyll bears a single erect ovule, which appears from one of Mrs. Arber's figures to be borne in the axil of the sporophyll.⁷ When young the ovule is surrounded by a single integument, and the resemblance to *Pherosphaera* is thus striking (Text-fig. 8, *b*). Later a symmetrical outer integument (the aril) arises round the inner, and in the older seed forms a papery cup. The inner integument appears to differentiate into

⁶ l. c., p. 94.

⁷ l. c.

three layers: ¹ an outer 'fleshy' layer which does not thicken up, ² a middle hard sclerenchymatous layer, and an inner soft-celled tissue.

It would appear from Van Tieghem ³ that the sporophyll and ovular vascular supplies are connected independently to the cone axis. The ovular supply terminates below the base of the nucellus in a 'tracheal platform', no strands entering the integuments. ⁴

III. *Saxegothaea*. The structure of the cone of this species has already been described by several writers. ⁵ The cones, which are borne terminally on somewhat elongated branches, are somewhat spherical in shape, and consist of about twenty cone scales. Above the foliage leaves on the cone-bearing shoot, and below the cone, are a number of bracts intermediate in character between the foliage leaves and the lowest of the cone scales. These latter are sterile, and are themselves intermediate between the bracts and fertile cone scales. ⁶ Foliage leaves and megasporophylls are thus bridged over by numerous intermediate gradations. All these are spirally arranged on the shoot.

The cone scales are ovate-lanceolate or lanceolate structures, imbricate, and becoming fused together later, first at the base. Each fertile megasporophyll bears a single ovule medianly placed on the upper surface of the scale. ⁷ At the time of pollination the ovule is sunk in a cavity at the base of the scale, and is completely reversed, ⁸ that is, the micropyle faces towards the axis of the cone. The nucellus of the ovule is surrounded by two integuments; the outer is now generally known as the epimatium. The inner integument completely surrounds the nucellus, the epimatium only partly surrounds the ovule, being present indeed on its upper surface only (Pl. XLVI, Fig. 8).

The youngest condition of the cone has been described by Norén. ⁹ He finds the young ovule borne near the base of the scale and at right angles to it (Text-fig. 8, c), so that the micropyle faces towards the under side of the scale above. He finds the epimatium in this young state to be in close connexion with the integument; only through the subsequent growth do the outer parts of the epimatium and integument come to be free from one another. This does not support Pilger's statement ¹⁰ that the

¹ Robertson ('06), Pl. XVII, Fig. 11.

⁶ The application of the term 'bract' has been limited to the reduced leaves below the cone; the 'pièces du cône' are always referred to as 'megasporophylls' or 'cone scales'. It seems best not to use the term 'bract' in regard to the latter.

⁷ In several cones Thomson ('09²) has observed ovules borne on the lower surface of the sporophylls at the base of the cone.

⁸ See Norén ('08), Taf. 8, Figs. 19 and 20; the former of these figures is reproduced in Coulter and Chamberlain ('10), p. 327.

⁹ Norén ('08), p. 109.

¹⁰ Pilger ('03), p. 16.

epimatium is an outgrowth of the cone scale and has no nearer connexion with the integument of the ovule, but Norén refrains from disputing it, simply stating that he does not regard the question as settled.¹ In material a little older, Tison² confirms Norén's observations on this point. Tison's observations were made on cones about three weeks before pollination. By this time the ovule is lodged in a cavity at the base of the bract. Tison states that the ovule and epimatium are borne on the upper extremity, and appear to be the prolongation and termination of a mass of tissue differentiated from that of the cone scale. This may be so, but Tison's figures, cited to support this statement, do not in my opinion confirm it. This tissue is that undergoing rapid intercalary growth, as a result of which the ovule is carried further away from the axis, and becomes completely reversed, with the micropyle facing the axis (Text-fig. 8, *d*). As Tison remarks, the ovule in the very young cone is probably borne erect at the base of the scale, and it is by the continued intercalary growth at the base of the scale that the ovule comes to occupy a position some distance from the axis. Thus in the stage described and figured by Norén, the ovule is about one-eighth the length of the scale from the axis; in that described by Tison it is not less than one-fifth the length of the scale away, while at the time of pollination it may be as much as, or more than, one-third of the length of the cone scale from the axis. The later appearance of the cone has been described by Lindley³ and Pilger.⁴ The cone scales appear to fuse into an irregularly globose fleshy mass about a centimetre long; the scales are fused together at their base, but the acute tips remain free. In this fleshy mass are included the seeds, to about the number of six, so that a large number of ovules evidently fail to develop.

The structure of the ovule itself has been most minutely described by Norén. Tison's later description is almost identical with Norén's. The nucellus for the great part of its length is free from the integument. It is not circular in transverse section, but elliptical, the longer diameter being the one transverse to the cone scale.

Before the time of pollination the nucellus grows at a greater rate than the integument and epimatium, so that by the time pollination takes place it not only completely fills the micropyle, but projects beyond it so as to form a large stigmatic surface.⁵ Norén has described the peculiar mode of pollination in this species. Pollen, besides falling on the nucellus itself, may get lodged in the cavity round the ovule, in which case the pollen-tube may grow over the tissues of the integument and epimatium into the micropyle. Besides the interest attaching to such a peculiar mode of pollination,

¹ Norén ('08), p. 109.

² Tison ('09), p. 143.

³ Lindley ('51).

⁴ Pilger ('03), p. 42.

⁵ Tison ('08), p. 137; Norén ('08), p. 110, Figs. 19 and 20; Stiles ('08), p. 214, Fig. 31; Tison ('09), p. 143, Figs. 8 and 9.

is the greater one of its being essentially similar to the condition found by Thomson¹ in *Agathis*. As pointed out by the writer² and by Tison,³ this nucellar expansion is similar to that occurring in *Araucaria*, but is much more prominent. Tison⁴ reports that the nucellus is covered with a sticky secretion which no doubt keeps the pollen-grains attached to the nucellus during their germination. He finds that when the pollen is shed the sporophylls of the female cones on the same plant have already closed up.

A rather remarkable phenomenon is the occurrence of cells towards the apex of the nucellus which have thickening bands on their walls and a somewhat tracheidal appearance.⁵ Their function is obscure, but they may serve as water-storage reservoirs.

After pollination the stigmatic expansion continues to grow for about two months.⁶ Norén figures an ovule a year after pollination. The extruded part of the nucellus is still conspicuous at this late stage; fertilization had not taken place in the ovule.

The megaspore-mother-cell arises deep in the nucellus, at the level at which the nucellus and integument become free from one another. It is surrounded by 'spongy' tissue.⁷

Accounts of the vascular anatomy of the female fructification have been published by Thomson, Tison, and the writer.⁸ The accounts agree in the main, but those of Tison and the writer differ in details.

The axis of the cone contains a ring of endarch collateral vascular bundles with a resin canal outside each in the cortex (Pl. XLVI, Fig. 7). Thomson found near the base of the cone 'a few centripetal elements associated with the bundles at the sides of the gap left by the exit of the megasporophyll trace'. Similar elements were found, but rarely, in the upper part of the peduncle.⁹

A single bundle leaves the axis of the cone to supply the sporophyll. This bundle arises by the division of one of the bundles of the cone axis, so that the two bundles lie side by side in the ring. A little higher up the resin canal divides similarly. The sporophyll trace and its accompanying resin canal then bend upwards and outwards into the sporophyll. In the young condition observed by Thomson, the ovular supply is given off from the upper surface of the sporophyll bundle at the level of insertion of the integument. After the separation of the ovular supply from the sporophyll bundle, centripetal xylem-elements appear in connexion with the latter.

⁹ Thomson ('09²), p. 348.

Later, a more complicated, and, in the lower part of the cone scale, a very variable, vascular structure occurs. Generally, the ovular supply given off from the upper surface of the sporophyll consists of about two bundles, although the number is not constant,¹ with inverse orientation of xylem and phloem as compared with the sporophyll. At the same time the sporophyll bundle divides into a row consisting of a variable number of bundles; sometimes there are three, in other cases as many as five. The central bundle often divides partially, inasmuch as although the xylem separates into several groups, the phloems of the corresponding xylem groups remain joined laterally. This state of affairs was described formerly as the sporophyll bundle dividing *more or less* into a row of bundles,² a description which M. Tison has evidently misunderstood.³ The bundles on each side of the central one now bend round through two right angles so as to lie in the same line with the ovular supply given off from the upper surface of the sporophyll bundle; the end bundles of the row, however, gradually die out, often moving further away from the central bundles; these latter, generally to the number of three or four, bend round to the ovule, and fusing into two bundles just below it, enter the base of the nucellus and there terminate.⁴ The xylem of these bundles is almost all centripetal in its development. No resin canals accompany the ovular supply. Higher up the scale the sporophyll bundle appears more compact, the xylem masses having reunited. Centripetal xylem makes its appearance in the upper part of the scale in great quantity. The elements are short and wide and of irregular shapes, and have the appearance of transfusion tracheides.⁵ Near the tip of one cone scale the single resin canal accompanying the sporophyll bundle had divided into three bundles lying side by side. This is interesting when it is remembered that one type of leaf in the genus *Podocarpus* contains three resin canals underneath the vascular bundle.

IV. *Microcachrys*. The ovoid-globose cones of this genus are terminal on the branches and consist of about twenty sporophylls which are borne in alternating whorls of four; the uppermost are always sterile. These sporophylls are tetragonal in shape, and each fertile scale bears a single ovule in a median position on the upper surface. As in *Saxegothaea*, the ovule is completely surrounded by an integument, partially surrounding which is an epimatium.

The youngest material examined was in the megaspore-mother-cell

¹ Tison ('09) gives cases in which this supply bundle is absent altogether, but such have not been observed by the writer.

² Stiles ('08), p. 216.

³ Tison ('09), p. 150.

⁴ Bertrand ('78), in a paper on ovular integuments, gives a figure of the ovule in which a vascular bundle, presumably the ovular supply, extends through the greater length of the epimatium. This representation is, however, without foundation in fact.

⁵ Stiles ('08), p. 216, Figs. 33, 34.

stage. At this time the ovule is inserted nearer the tip of the scale than the cone axis, being about three-fifths of the length of the scale from the cone axis. It is erect at this time, the micropyle facing directly upwards (Pl. XLVI, Fig. 9; Text-fig. 8, *e*). As in *Saxegothaea*, the integument and epimatium are in close connexion, and at this stage are only free from one another for about their upper half. The integument and epimatium both project a good way beyond the top of the nucellus. The integument is much longer on the side towards the cone axis and remote from the epimatium than on the other, and in every ovule examined the upper part of it had bent round through more than a right angle, so that it was actually pointing towards the scale on this side (Pl. XLVI, Fig. 9).

The single megaspore-mother-cell is seated in about the middle of the nucellus, there being about seven layers of cells above it in median section. The cells surrounding it are not much differentiated from the outer cells of the nucellus at this stage.

At a later stage examined by Thomson,¹ the ovule has become quite reversed so that the micropyle faces the cone axis.

The writer has examined a still later stage collected on mountain tops in Tasmania. The cone scales become swollen and fleshy and of a fine red colour; they retain their individuality, not fusing together partially as in *Saxegothaea*. The seed is very small, being from 2 to 3 millimetres long and a little less in width; the lower side is flat, while the upper is convex; the seed thus has the shape of a somewhat flattened tetrahedron. The seed-coat differentiates into an outer thin membranous layer and an inner, thicker, hard sclerenchymatous layer.

The vascular structure of the cone axis consists of a ring of bundles from which the sporophyll bundles arise by division as in *Saxegothaea*. As in the vegetative stems of this plant there are no resin canals, so there are none in the cone axis. Worsdell² has described the vascular system of this cone scale as consisting of two distinct bundles very close together: a lower one serving the sporophyll, and an upper one serving the ovule. According to Thomson³ a single bundle leaves the cone axis and gives off a single supply bundle from its upper surface; the orientation of the xylem and phloem of the latter is inverse as compared with that of the sporophyll bundle. In the old scales I have examined, a single bundle leaves the axis of the cone, and the ovular supply appears on its upper surface very shortly after the entrance of the sporophyll supply into the sporophyll. It lies so close to the latter, however, even up to the insertion of the ovule, that ovular and sporophyll supply might be considered one bundle. Ultimately, the ovular supply bends obliquely upwards and bifurcates near the base of the ovule, the divisions entering the base of the integument. A large resin duct, or

¹ Thomson ('09?), p. 349.

² Worsdell ('99), p. 538.

³ Thomson ('09?), p. 349.

rather resin gland, for it ends blindly in both directions, is present on the under side of the sporophyll bundle.

V. *Dacrydium*.

i. *D. Franklini*. The megasporangiate strobili of this plant are terminal on the branches bearing them, and consist each of a lax spike of eight or nine megasporophylls separated by conspicuous internodes.¹ Each sporophyll is a small structure, in the stage examined about 1.5 mm. long and about 1 mm. wide, and is somewhat triangular in shape, and bears a single ovule medianly placed on the upper surface. Strasburger,² who has recorded some observations on this species, states that the ovule arises in the axil of the sporophyll. In the material examined by the writer the ovule was towards the tip of the sporophyll, much as in *Microcachrys*. In another matter the sporophyll is very reminiscent of that of the latter genus, for it contains a resin cavity which ends blindly in both directions, resin canals being absent in the cone axis as in the vegetative stem.

The ovule in the stage examined was about half-reversed; that is, its axis made an angle of about half a right angle with the cone scale, the micropyle pointing inwards. As in *Saxegothaea* and *Microcachrys* the nucellus is free from the integument for most of its length, and the epimatium only partially surrounds the integument just as in those genera. It certainly does not completely surround the integument, as Tison asserts to be the case in *Dacrydium*.³ The tip of the sporophyll curves up into a point just behind the epimatium, and gives much the appearance of a third integument, and in this respect again it is not unlike *Microcachrys*.

The axis of the fructification contains a ring of five or six small bundles, from which those of the sporophylls are given off. At about the level of the extreme base of the slightly decurrent sporophyll a resin duct appears on the phloem side of the bundle nearest the sporophyll. A very little higher up this bundle divides into three, the two lateral ones being smaller. The central bundle first passes out into the sporophyll accompanied on its under side by a resin canal, and a very little higher up the two lateral ones pass out also. These form the ovular supply and have their xylem and phloem with inverse orientation, as in *Saxegothaea* and *Microcachrys*. As in these genera also they are not accompanied by resin ducts (Pl. XLVII, Fig. 22). The two ovular supply bundles terminate below the nucellus. At the stages examined the xylem of the sporophylls is very little lignified. It is noteworthy that the ovular supply bundles attach themselves laterally to the sporophyll bundle at the extreme base of the sporophyll, much as is the case with the lateral bundles of the ovular

¹ For figures see Parlatores ('64), Tav. II, Figs. 40-54.

² Strasburger ('79), p. 76.

³ Tison ('09), p. 147.

supply of *Saxegothaea*, where, however, the insertion is higher up the scale. Occasionally, in *D. Franklini*, one of the ovular supply bundles attaches itself to a bundle of the cone axis other than its own sporophyll bundle.

ii. *D. cupressinum*. In this species the fertile branch terminates in a few spirally arranged scales, the uppermost of which bears a single ovule. A case was observed in which there were two fertile sporophylls on the branch. The scales differ but little from the foliage leaves; they are somewhat shorter and are lanceolate rather than linear, the transition from the linear foliage leaf to the lanceolate fertile sporophyll being gradual.

On the upper surface of the sporophyll and near its base is borne an outgrowth which arches over the ovule in the form of a hood (Text-fig. 8, *f*). This is the epimatium, and the solitary ovule is borne on this and not on the scale itself as in *Dacrydium Franklini*. Owing to lack of material the position of the ovule in the very young state cannot be recorded.

The ovule itself is rather remarkable. The nucellus is a conical structure, and is completely surrounded by a very remarkable inner integument. This consists of four distinct layers: a single outer layer of sclerenchymatous cells forming a kind of epidermis; inside this a layer of anticlinally elongated cells filled with a brown tannin-like substance; a mass of very thick-walled cells inside this, which diminishes regularly in thickness from the micropyle towards the chalaza; and, finally, on the nucellus side there is a region of parenchymatous cells, which increases in thickness as the sclerenchymatous layer diminishes. The micropyle in the stage examined consisted of a very narrow tube, but this was after pollination.

The epimatium is a much larger structure than in the species already described, and, as has been already indicated, bears the ovule on its upper surface, the latter being inserted a short distance above the junction of megasporophyll and epimatium. The latter, like the inner integument, contains a good deal of sclerenchyma. As in *Saxegothaea*, *Microcachrys*, and *Dacrydium Franklini*, it only partially encloses the ovule. It is, however, not pressed closely against the inner integument as in those species, and in a longitudinal section through the 'strobilus' reminds one of the ovuliferous scale of *Pinus* rather than of a Podocarpean epimatium. There can, however, be no doubt of its homology with the latter.

The vascular system of the cone scale and axis in *D. cupressinum* is similar to that of *D. Franklini*. The axis below the insertion of the fertile sporophyll contains a small ring of about three vascular bundles, each with a resin canal on its outer side. One bundle of the ring divides into three bundles, the lateral ones bending round so as to lie side by side on the inside of the median bundle. Each of these bundles is provided with a resin canal. The group of three passes into the sporophyll, and the two upper ones then pass into the epimatium and terminate at the base of the ovule.

VI. *Podocarpus*.

i. *Eupodocarpus*.¹ The early development of the female fructification has been traced by Strasburger² in the case of *Podocarpus chinensis*, Wall. (*P. macrophyllus*, subsp. *maki*, Sieb.). The ovulate structure is described as arising in the axil of the sporophyll, the integument as growing up round the nucellus, while the horseshoe-shaped aril arises later.

Some young fructifications of *P. latifolius* collected by Mr. Saxton yielded the youngest stages of my material. The ovular stalk is short and the ovule at its apex is almost perpendicular to the megasporophyll, and is not reversed. The integument and epimatium are only free at the tip (Pl. XLVI, Fig. 11, and Text-fig. 8, *g*). In this species the ovular stalk never elongates very much; by the time the reduction division takes place the ovule is, however, completely inverted (Text-fig. 8, *h*, *k*, and cf. with *l*). Later the bases of the four 'cone' scales become fused together into one fleshy mass.

The ovulate structure of *Podocarpus macrophyllus* is like that of *P. latifolius* in general appearance, but two fertile megasporophylls are perhaps of more frequent occurrence than in that species. The fleshy receptacle is formed in this species as in the last (Pl. XLVI, Fig. 10). The seed-coat is differentiated into two layers; a harder and thicker outer layer which, however, cannot be described as woody, and a softer inner layer which cannot be aptly described as either fleshy or membranous.

The vascular structure of the female fructification has already been described by Mr. Brooks and the writer³ in the case of *Podocarpus spinulosus*, (Sm.) R. Br., *P. alpinus*, R. Br., and a third species. These observations have now been supplemented by further ones on *P. macrophyllus* and *P. latifolius*.

In *P. macrophyllus*, as in species previously examined, a single bundle supplies the megasporophyll, while the ovular supply below the point at which the stalk becomes free from the sporophyll consists of two vascular bundles, the xylem and phloem of which are inversely orientated as compared with the xylem and phloem of the sporophyll bundle. These two bundles, by division of one or both, give rise to a row of three or four small bundles (Text-fig. 4, *a-d*). They are accompanied by a row of small canals, about one canal to each bundle, though this relation is not strictly maintained. Towards the chalazal end of the ovule, if the supply bundles number four, one of the bundles at the end of the row may die out, or bend round the ovule in a tangential direction and descend towards the micropyle.

¹ For figures of the female fructifications of *Podocarpus chilinus*, *P. elongatus*, and *P. coriaceus*, see Richard ('26), Pl. I; and for photographs of these structures in *P. elatus* and *P. spinulosus*, see Baker and Smith ('10), pp. 432, 444.

² Strasburger ('79), p. 77.

³ Brooks and Stiles ('10), p. 311.

Thus at the chalazal end there are only three of the supply bundles present. Of these the median bundle bends over the top of the ovule, and in so doing divides into two (Text-fig. 4,*g*), while the lateral bundles bend round through a right angle (Text-fig. 4,*f*). All these bundles descend towards the micropyle,

TEXT-FIG. 4. *a-g.* Diagrams of a series of transverse sections through the ovule of *Podocarpus macrophyllus*. $\times 18$.

and in so doing any single bundle may divide (Text-fig. 4, *e, f*). They die out about half-way between the chalaza and the micropyle.

A conspicuous feature in the ovule of *P. macrophyllus* is the presence of a large number of canals in the ovule apparently unrelated to the vascular

supply. These canals form roughly two rings concentric with the micropyle and nucellus (Text-figs. 4, *d-f*).

The vascular supply of the ovule in *P. macrophyllus* is very similar to that of *P. spinulosus*,¹ the chief difference being in the much greater distance the bundles descend towards the micropyle in *P. macrophyllus*.

The vascular supply of the ovulate structure of *P. latifolius* is simpler than that of *P. macrophyllus*. The sporophyll bundle is accompanied by a great deal of transfusion tissue, and in the upper part of its course consists entirely of transfusion elements (Pl. XLVII, Fig. 23). The ovular supply at the base of the stalk consists of two bundles as in other species, but these bundles do not divide further until the chalaza is reached (Text-fig. 5, *a-c*). Here each bundle divides into two, and the outer ones bend round through about a right angle and descend a very short way towards the micropyle (Text-figs. 5, *c* and *d*). The inner bundles proceed further towards the top of the ovule, where they ultimately meet and end in a mass of transfusion tracheides. A small bundle descends from this mass a short way (Text-fig. 5, *e*), but does not reach the level at which the ascending bundles fork. As in *P. macrophyllus*, there is here a large development of canals concentric with the micropyle and nucellus, but two distinct rings cannot always be made out.

It is clear that there is a good deal of variation in the vascular structure of the ovule throughout the section *Eupodocarpus*, and probably an examination of a large number of cases would reveal the presence of a certain amount of variation among the individuals of one species. The essential facts seem clear; the ovular supply consists of two bundles with inverse orientation as regards the sporophyll bundle. These two bundles sometimes divide between the base of the ovular stalk and chalaza, and nearly always in the region of the latter, into a more or less complicated system. This division has probably arisen owing to the needs of a well-developed conducting system for the development of the large ovules and seeds. It has already been suggested that the same cause is responsible for the complete independence of the vascular supply of the ovule from that of the sporophyll.²

Having regard to the state of affairs in *Dacrydium cupressinum*, where the ovule is actually borne on the epimatium, I feel disposed to consider the ovular stalk as a further development of that structure. In *Podocarpus*, therefore, the ovule has been carried up a long way on to the epimatium, but the latter is almost completely fused with the integument, a point in which it differs markedly from *Dacrydium cupressinum*.

The vascular system of the ovule of *Podocarpus* is therefore to be regarded as a further development from that of the more primitive *Podocarpeae*. In a previous paper Mr. Brooks and the writer³ stated that there was

¹ Brooks and Stiles ('10), Pl. XXI, Figs. 15-18.

² l. c., p. 314.

³ l. c., p. 315.

TEXT-FIG. 5. a-e. Diagrams of a series of transverse sections through the ovule of *Podocarpus latifolius*.

not sufficient data to decide to what extent the ovular supply in *Podocarpus* was to be homologized with that of other Gymnosperms.¹ If the origin of the ovular vascular system of *Podocarpus* suggested above is correct, it is obvious that the presence of a well-developed vascular system in the ovules of that genus is to be regarded as a fresh development, and is not homologous with that in any older Gymnosperms.

ii. *Nageia*. In *Podocarpus nagi* the fertile branches arise in the axils of ordinary foliage leaves (Pl. XLVII, Fig. 24). Each branch is about 1.5 cm. long and bears about six pairs of decussately arranged scales; one of the uppermost pair bears the solitary ovule. The stalk is short as compared with this structure in some species of *Eupodocarpus*, and is fused at its base with the megasporophyll. The general appearance is that of an ovule terminating the shoot (Pl. XLVII, Fig. 24). The ovule is large compared with that of *P. macrophyllus*; thus ovules collected on July 13, when wall formation had just commenced in the prothallus, were a centimetre long. At this time they are somewhat pear-shaped, the greatest transverse diameter being towards the upper or chalazal end of the ovule. Later, as the ovule becomes the seed, the latter becomes more spherical in shape (Fig. 24), and in material collected on October 5, which contained embryos with well differentiated cotyledons and radicle, the seed is a sphere about 1.5 cm. in diameter.

As in other species, there are two integuments which are only free from one another for an extremely short distance at the micropylar end. Owing to the extent to which fusion of parts has taken place, it is not possible to define the limits of stalk and epimatium. In all the ovules I have seen there is on the side of the ovule remote from the stalk, and about three times as far from the micropylar end as from the chalazal end, a small projecting point which suggests the termination of a leaf or scale. Occasionally, there is more than one such point, as in the case figured in Pl. XLVII, Fig. 24. There is, however, nothing in the internal structure to suggest a meaning for this, nor is there any suggestion of a difference between the tissues of the stalk and epimatium; in the youngest stage examined the tissues of epimatium and stalk are quite similar: this is at about the time of wall formation in the prothallus. The integument and epimatium are at this time quite differentiated from one another, the cells of the epimatium being thicker walled with smaller nuclei, while the integument consists of smaller thinner walled cells with relatively larger nuclei. In the epimatium are numerous canals, as in the species of *Eupodocarpus* examined; these occur in all parts of the epimatium, but are most numerous around its inner limit (Text-fig. 6).

As the ovule develops into the seed both integuments become differentiated into two layers, so that microscopically four layers can be recognized in the seed-coat; a naked-eye examination, however, only

¹ Oliver ('03); Stopes ('04); Arber, A. ('10); Oliver and Salisbury ('11).

reveals two layers, the outer soft semi-fleshy layer (formed from the epimatium) and the inner woody layer (formed from the integument). By the time the seed contains a young embryo the outer layers of the integument are already becoming thickened and lignified, and are clearly differentiated from the epimatium. The inner layers remain thin and parenchymatous. The thickening and lignification appear to commence at the micropylar end, the chalazal region being the last to become lignified.

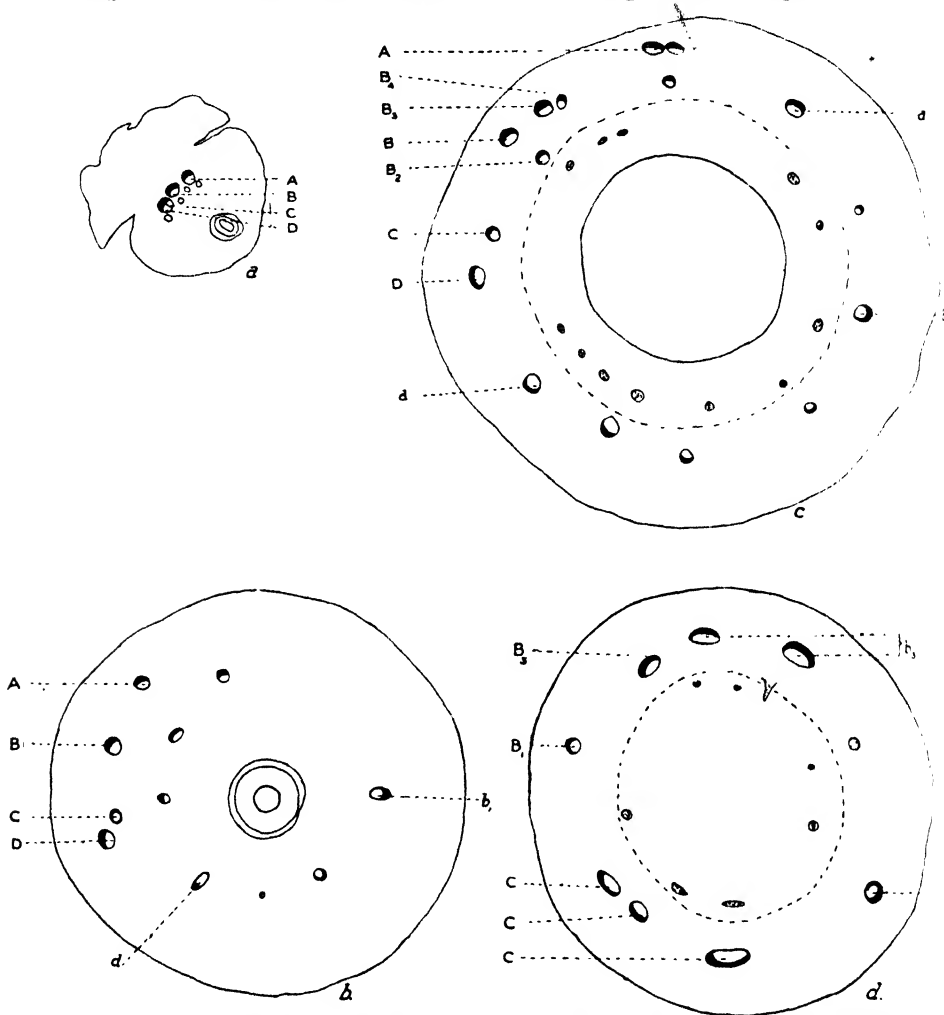

The vascular system of the ovulate structure of *Podocarpus nagi* appears to be more complicated than that previously described for the ovule of any Conifer. The sporophyll contains a row of four or five bundles, and is thus parallel veined like the foliage leaves. The ovular supply at the base of the ovular stalk consists of a row of three or four bundles (Text-fig. 7, *a*) having their xylem and phloem orientated inversely as compared with the sporophyll bundles. These bundles ascend towards the chalaza on the sporophyll side of the ovule, although they may sometimes be laterally displaced. As in *P. macrophyllus*, one of the two middle bundles if there are four present, or the median one if there are three, ascends

TEXT-FIG. 6. Diagrammatic representation of a transverse section through an ovule of *Podocarpus nagi*, showing the distribution of canals. The dotted line marks the outer limit of the integument. $\times 8$.

to the chalaza, and bending over the top of the ovule descends on the other side towards the micropyle. As in *P. macrophyllus* and *P. spinulosus*, this bundle divides into two after passing over the top of the ovule, although one of the two may soon die out. However, whereas in the species of *Eupodocarpus* cited the median ascending bundle does not divide between the stalk and the chalaza, in *P. nagi* it may do so. Thus in Text-fig. 7, *c*, the bundles marked B_2 , B_3 , B_4 , have all arisen by division of B . The bundles lateral to the main bundle which passes over the chalazal end of the ovule bend round the side of the ovule as in *P. macrophyllus*, and descend towards the micropyle. Thus in the series shown the bundles A , B_3 , C , and D , bend round at various levels and descend towards the micropyle; in this part of their course they are marked a , b_3 , c , and d (Text-fig. 7, *c*, *d*). As in *P. macrophyllus*, these descending bundles may divide. They descend almost to the micropylar region (Text-fig. 7, *b*), and in this respect differ

from species of *Eupodocarpus* so far examined. In the outer layers of the integument in the young ovules there is a ring of what appear to be

TEXT-FIG. 7. Diagrams of transverse sections through an ovule of *Podocarpus nagi* to show the distribution of vascular tissue. *a*, Near the micropylar end. *b*, A little higher up. *c*, Through the middle of the ovule. *d*, Towards the chalazal end. A-D, ascending vascular bundles. *a-d*, descending vascular bundles.

undifferentiated vascular bundles connected with the vascular bundles of the epimatium by means of undifferentiated or only partly differentiated strands.¹ Later these strands become more noticeable, until in the old seed

¹ Compare the state of affairs in *Torreya*, where the supply of the inner integument is similarly undifferentiated (Oliver ('08), p. 469). On general grounds, however, it does not seem possible to connect the structure of the Torreyan with that of the Nageian ovule.

they stand out distinctly on the outside of the woody integument after removal of the softer epimatium.

The ovule of *Podocarpus nagi* has thus an exceedingly complicated structure, both as regards the differentiation of the seed-coat into four layers, and as regards the vascular system. Everything goes to show that this is a derived and not a primitive condition. The vascular system is extremely unlike that in the ovule of any other genus of Gymnosperms, but can be compared with that of *Podocarpus macrophyllus*. It is more complicated than in that species, but the ground-plan is the same, and the further development is no doubt connected with the large size of the seed. Further evidence in support of the condition being a derived one is found in the greater extent of fusion between the parts; here the integument and epimatium are scarcely free from one another, while the megasporophyll is fused for part of its length with the ovular stalk.

It is possible that this is the species vaguely described by Favre¹ under the name of *P. chinensis*. It has been suggested that this species might throw light on the homology of the vascular system of the ovule of *Podocarpus* with that of other Gymnospermous ovules.² Whether this be that species or not it furnishes additional evidence to that already advanced in the course of this section of the present paper, that the vascular system of the ovule of *Podocarpus* is not homologous with that of the ovules of the older Gymnosperms described by various writers. It would seem that the ovular structure in the Podocarpeae has been evolved within the group, and it is in the genus which on general grounds one would consider the least primitive that one finds the most complex development.

ix. FEMALE GAMETOPHYTE.

It is with regard to the female gametophyte and embryology that the greatest gap in our knowledge of the Podocarpeae occurs. Of the female gametophyte of *Pherosphaera* we know nothing; in the case of *Saxegothaea*, *Microcachrys*, and *Dacrydium* our knowledge is limited to a few isolated observations on the megaspore membrane.³ In *Phyllocladus* and *Podocarpus* a general outline of the gametophytic history is known in one species of each genus (*Ph. sp.* and *P. coriaceus*). Owing to the kindness of Dr. M. C. Stopes and Mr. Saxton I have been enabled to examine gametophytic material of two species of the *Eupodocarpus* section of *Podocarpus* (*P. macrophyllus* and *P. latifolius*), and one species of the section *Nageia* (*P. nagi*). The earliest stages were found in ovules of *P. latifolius*. The megaspore increases in size, and its nucleus divides, so that the free nuclei

¹ Favre ('65), p. 379.

² Brooks and Stiles ('10), p. 315.

³ Since this paper was written the writer has published a few facts relating to the Gametophytes *Dacrydium* and *Stiles* ('11).

formed by successive divisions come to lie in the parietal layer of cytoplasm surrounding the central vacuole.

During the development of the young prothallus the layers of tapetal cells come to be more sharply marked off from the outer cells of the nucellus. Wall formation was not observed, but from the disposition of the cells before the appearance of the archegonia, there can be no doubt that the ingrowing primary prothallial cells are formed as in other Conifers. Up to the time of formation of the archegonia the cells of the prothallus are all uninucleate; no sign of any binucleate condition was observed such as Lawson¹ found in *Cryptomeria*.

The archegonia arise as superficial cells at the apical end of the prothallus. Coker found that these numbered from five to ten in *P. coriaceus*; there is a similar number in the case of *P. macrophyllus*, but in *P. latifolius*, in the only case examined, there were as many as fourteen archegonia, while in each of the two ovules of *P. nagi* which contained archegonia the number was nineteen. Each archegonium is surrounded by a well-defined layer of jacket cells; these are conspicuous on account of their denser cytoplasm and larger nuclei. Occasionally, in *P. macrophyllus*, two archegonia occur within a common jacket, a fact of interest in comparison with *Phyllocladus*, where the same phenomenon has been observed. In *P. nagi*, to judge from the two cases examined, the phenomenon is more marked, as many as three archegonia being surrounded by a common jacket. The distribution of the archegonia in *Podocarpus* is thus like that in the Abietineae and Taxeae, but shows an approach to the state found in *Cunninghamia*,³ where the archegonia form a ring all enclosed in a common jacket, and surrounding a central mass of sterile tissue.

Coker has observed a ventral-canal-nucleus in *P. coriaceus*.⁴ In *P. macrophyllus* a well-defined ventral-canal-nucleus was not seen, but a safranin-staining mass present in the upper part of some archegonia may have been the disorganizing ventral-canal-nucleus. There is no evidence of this nucleus being cut off by a wall.

In *P. coriaceus*⁵ the neck consists of from two to twenty-five cells. Although such an extreme variation was not noticed in *P. macrophyllus*, yet the variation in number is certainly considerable in the mature archegonia, and as many as eighteen cells have been counted in the neck of one archegonium.⁶

Before fertilization the egg nucleus undoubtedly undergoes rapid increase in size. Unfortunately, measurements are not available for the young and old egg nucleus in the same species. In *P. latifolius* the diameter of the nucleus of the young archegonium is about 25 μ , while in

¹ Lawson ('04), p. 427.

² Young ('07), p. 87.

³ Miyake ('11), p. 11.

⁴ Coker ('02), p. 98.

⁵ l. c.

⁶ The structure of the archegonium neck would thus appear to differ markedly from that of *Phyllocladus* and *Dacrydium*. See Young ('10) and Stiles ('11).

P. macrophyllus the egg just before fertilization (Pl. XLVIII, Fig. 31) is about $45\ \mu$ or $50\ \mu$ in diameter.

Before fertilization takes place the nuclei of the prothallus cells begin to divide, but the products of division are not cut off by cell-walls, and as the process may be and generally is repeated more than once, the prothallus cells in the old seeds may contain as many as eight nuclei. This is evidently a phenomenon of general occurrence in the genus, as it takes place in all species that have so far been examined, namely, *P. coriaceus* by Coker, and *P. nagi*, *P. macrophyllus*, *P. elatus*, and *P. latifolius*, by the writer.

The development of more than one megaspore in an ovule is a phenomenon that has been observed in several Coniferous genera;¹ it has been recorded for *Podocarpus* by Coker in *P. coriaceus*.² In both *P. latifolius* and *P. macrophyllus* an example of this has been found among the writer's material; in the former case the prothalli were in a young stage before wall formation had commenced, but in the case observed in *P. macrophyllus* both prothalli had produced archegonia, and one contained a pro-embryo.

In *Phyllocladus*,³ *Saxegothaea*,⁴ *Microcachrys*,⁵ and *Dacrydium laxifolium*⁶ a thick megaspore membrane of the usual type is developed, but in the two species of *Podocarpus* examined by Thomson, *P. coriaceus* and *P. macrophyllus*, subsp. *maki* (*P. Makoyi*, *P. chinensis*, or *P. sinensis*), no trace of a megaspore coat could be found. From the species examined in the course of this work it is evident there is great variation in the genus as regards this structure. In *P. macrophyllus* and *P. nagi* the membrane is very poorly developed, and never appears to be more than $1\ \mu$ thick. Only an isolated late stage has been observed in the case of *P. elatus*, and here also the membrane was very poorly developed. *P. latifolius*, on the other hand, is in marked contrast to these species. At about the 32-nucleate stage of the prothallus the megaspore membrane is well under $1\ \mu$ thick, while by the time the neck-cells are cut off from the central cells of the archegonia the membrane forms a thick coat about $4.2\ \mu$ thick. It thins out towards the apical part of the prothallus, and is not more than $2\ \mu$ thick in the region of the archegonia. By the time the pro-embryos are developing the membrane becomes thinner, and is then about $2.5\ \mu$ thick in the middle region of the prothallus.

X. MALE GAMETOPHYTE.

A. Early History (Structure of Pollen).

The early history of the male gametophyte, from the microspore stage up to the time of shedding of the pollen, has been investigated in species of all genera of the Podocarpeae except *Pherosphaera*. The later history from

¹ e. g. *Sequoia* (Lawson, '04¹, p. 10); *Callitris* (Saxton, '10, p. 559).

⁴ Norén ('08), p. 115.

⁵ Thomson ('09²), p. 349.

⁶ Thomson ('05¹).

the beginning of pollen-tube development up to fertilization has only been observed in two cases: in *Podocarpus coriaceus*¹ and *Phyllocladus* sp.²

A most excellent general account of the early stages of development has already been published by Coulter and Chamberlain,³ and as the additional species examined by the writer behave similarly in this respect to those already observed, only a brief account of this part of the subject is necessary.

As regards gross structure, the pollen-grains of *Saxegothaea*⁴ are wingless; those of *Microcachrys* possess wings which are, however, small and variable in size and number, three being the most frequent number met with. In *Phyllocladus*, *Dacrydium*, and *Podocarpus* the wings are on the whole larger and are two in number, although three wings are found exceptionally in *Podocarpus ferruginea*,⁵ and normally in *Podocarpus dacrydioides*.⁶

The feature of the gametophyte which has attracted most attention is the comparatively large development of prothallial tissue, a feature first noticed by Thibout⁷ in *Podocarpus polystachyus*. In all the species so far investigated two prothallial cells are cut off successively, as in the Abietineae. In *Saxegothaea*⁸ the second prothallial cell always divides into two daughter-cells, and the first often divides as well. This prothallial complex of three or four cells persists up to the time of pollination, which is as far as the development of the male gametophyte has been observed. An exactly similar condition probably obtains in *Microcachrys*.⁹ An essentially similar condition has been found in *Dacrydium Bidwillii*, where, as a rule, only the second prothallial cell divides, and in *D. cupressinum* and *D. laxifolium*, where generally both prothallial cells divide.¹⁰ A less active condition prevails in *Phyllocladus*,¹¹ where usually neither cell divides, although the second occasionally does so.

In *Podocarpus* there is apparently a more variable condition. In *P. coriaceus*, Coker¹² found that the primary prothallial cells might divide amitotically. Jeffrey and Chrysler¹³ found in *P. polystachyus*, *P. ferrugineus*, and *P. dacrydioides* that both the prothallial cells might undergo two successive divisions, making a total of eight prothallial cells. Burlingame¹⁴ recorded a similar condition in *P. Totara*, var. *Hallii*, but reported a great deal of variation in the number of prothallial cells produced, namely, from one to eight, six being the most usual number. Mr. Brooks and the writer have found that as many as eight prothallial cells may be produced in *P. spinulosus*.¹⁵ As many as eight prothallial cells are also produced in *P. andinus*.

¹⁵ Brooks and Stiles ('10), p. 309.

After the cutting off of the two primary prothallial cells, the antheridial cell divides into the tube-cell and the generative cell. The latter is cut off from the former in much the same way as the primary prothallial cells. This division is followed by the division of the generative cell into what may be called the stalk-cell and the body-cell, but the division in all the Podocarpeae is an anticlinal one, so that the products of division lie side by side. Jeffrey and Chrysler have described in *Podocarpus ferrugineus* and *P. polystachyus*¹ an appearance as of a second derivative of the generative cell besides the so-called stalk-cell, and a similar appearance was noted by Mr. Brooks and the writer in *P. spinulosus*.² Miss Young has suggested³ that this appearance is due to the partial encircling of the body-cell by the stalk-cell, and this may well be so in *P. spinulosus*.

In all the Podocarpeae the limiting membranes of the prothallial cells and stalk-cell break down, and the nuclei come to lie free in the general cytoplasm. Thus, at the time the grain is shed the body-cell is the only one surrounded by a definite membrane. In *Podocarpus spinulosus* it was observed that at this stage the tube-nucleus is the largest in the grain, and the same is true of *P. andinus* and *P. latifolius*. In no instance in *P. andinus* were more than eleven nuclei observed in one pollen-grain, so there is presumably no second derivative of the generative nucleus in this species.

B. Later History (Development of Pollen-tube).

The development of the gametophyte beyond the stage just described has been observed in very few cases. Miss Young⁴ has observed stages in *Dacrydium laxifolium* and *D. intermedium* in which the pollen-tubes have commenced to grow through the nucellus. Only in two cases, however, has the development been followed further, in *Podocarpus coriaceus*⁵ and in *Phyllocladus* sp.⁶ These are the species in which the least development of prothallial tissue has so far been recorded, so that special interest attaches to the investigation of the later stages of the gametophyte in forms more typical of the order in respect of prothallial development. Observations have been made on the later history of the microgametophyte in *Dacrydium cupressinum*, *Podocarpus macrophyllus*, *P. latifolius*, and *P. nagi*. As in the case of the female gametophyte, it is to be regretted that the difficulties of collection of three of these species did not permit of the use of fixatives suitable for cytological work.

I. *Dacrydium cupressinum*. In this species it would appear that fertilization takes place a year after pollination. Ovules collected near Wellington, New Zealand, in July—that is, in the middle of the resting

⁵ Young ('07).

⁶ Young ('10), p. 84.

period—all showed pollen-tubes that had penetrated a considerable way through the nucellus.

On germination of the pollen-grain the inner layer of the wall bursts through the outer and forms the pollen-tube. Miss Young¹ has described the entry into the pollen-tube of the tube, stalk, and prothallial nuclei in *D. intermedium*, the body-cell remaining behind in the grain. The same thing takes place in the case of *D. cupressinum*. Although the tubes had penetrated a long way into the nucellus, in every case examined the body-cell remained behind in the grain (Pl. XLVIII, Fig. 25). In most cases the tube itself had grown straight down the nucellus and showed no sign of branching. Five or six nuclei were found in most of the tubes besides the nucleus of the body-cell. In the longer tubes, one nucleus, which occupied a position near the growing end of the tube, was much larger than the rest, and was probably the tube-nucleus. The remaining nuclei were indistinguishable from one another, and would be the stalk-nucleus and prothallial nuclei; there would thus be three or four of the latter. Four is the number found by Miss Young in the pollen-grain when ready for shedding, so, unlike *Agathis*, no further divisions occur among the prothallial nuclei after the shedding of the pollen. In one case a peculiar phenomenon was noticed. The growing nucellar tissue had apparently pressed against the pollen-tube so as to pinch off as it were the upper part attached to the pollen-grain, and thus containing the body-cell, from the lower part containing the tube-nucleus. In this case the tube-nucleus had presumably divided, for two large nuclei were found together near the tip of the tube in the place generally occupied by the solitary tube-nucleus (Pl. XLVIII, Fig. 26). Either nucleus of the pair was as large as an ordinary tube nucleus. This is, as far as I am aware, the only case so far recorded of the division of the tube-nucleus. In the pollen-grain and in the upper part of the tube starch grains are very abundant. Unfortunately, later stages of gametophytic development have not been available, so no further information can be given in regard to this genus in this connexion.²

II. *Eupodocarpus*. Material of two species of this subgenus has been used in this investigation; these species are *Podocarpus latifolius* and *P. macrophyllus*. Only early stages of the former species were available, and the following description applies almost entirely to *P. macrophyllus*.

The pollen-grains alight in a slightly concave receptacle formed by the apex of the nucellus. It was observed that in one case in *P. macrophyllus* the tube from a pollen-grain, that had come to rest at one extremity of the nucellus, grew along the top of the latter until it reached the middle of the concave portion. In all cases observed the pollen-tubes, after entering the nucellus, grow straight down until they reach the surface of the female

¹ Young ('07), p. 193.

² In *Dacrydium Colensoi* the body-cell nucleus gives rise to two unequal male nuclei (Stiles, '11).

prothallus. Here they expand in a remarkable manner so as to cover almost completely the upper region of the prothallus. From this expanded portion branches grow down in all directions (Pl. XLVIII, Fig. 27). The pollen-tube wall is rather thick, about twice as thick in fact as the megaspore membrane. At this stage wall formation was taking place in the female prothallus.

The body-cell is a conspicuous object, consisting of a dense mass of cytoplasm containing a large nucleus. As described for *P. coriaceus*,¹ and as is also the case in *P. nagi*, the nucleolus is the only part which shows any marked tendency to take the safranin stain. The nucleus at this stage was always excentrically placed in the cytoplasm. The cell itself is not necessarily spherical; in one case it was conical, with the nucleus at the base of the cone, and giving the impression of a moving cell with the nucleus in front.

Small nuclei are found in the tube—in one case they numbered five—while a mass in the pollen-grain staining densely with safranin suggests that some nuclei never leave the grain and disorganize there. No distinction could be made out between the prothallial, stalk-, and tube-nuclei; all the small nuclei in the tube appeared similar. Sometimes two or three of these small nuclei were clustered near the body-cell, as was found in the observed cases of *P. nagi*; but this was not always the case, for sometimes the body-cell was quite by itself. At this stage the body-cell is of considerable size.

No further change is noticeable in the gametophyte until the division of the body-cell. This evidently took place about July 20, for in one ovule collected on this date, of four pollen-tubes which had penetrated the nucellus, one contained an undivided body-cell, while in each of the other three the body-cell had undergone division. Here, as described for *P. coriaceus*,² the division of the body-cell results in the formation of two unequal male nuclei (Pl. XLVIII, Figs. 28, 29, 31). The functional one is found embedded in the middle of the body-cell cytoplasm; the other moves, apparently in a very short space of time, to the side of the cytoplasm, and often that side remote from the female prothallus. The functional male nucleus takes deeply the safranin or haematoxylin stain, being in this respect in marked contrast to the body-cell nucleus. The non-functional male nucleus gradually undergoes degeneration. Several ovules showed very prettily the male nuclei just outside an archegonium (Fig. 31). The functional male is still embedded in the middle of the body-cell cytoplasm, while the degenerate male nucleus is still obvious. In all cases observed at this stage it was remarkable that small nuclei, sometimes as many as six in number, were always observed clustered against the body-cell (Pl. XLVIII, Figs. 29 and 30). Whether they are the original prothallial, stalk-, and tube-nuclei, or whether some of these degenerate, while others in the neighbourhood survive and

¹ Coker ('02), p. 95.

² l. c.

divide, is a question that could not be definitely decided, but the facts suggest the former alternative.

III. *Podocarpus nagi*. Owing to the exceedingly small quantity of material available of this species the observations are of a very meagre description. The youngest material examined was collected by Dr. Stopes at Tokyo on July 13. The ovules were abundantly supplied with pollen-tubes, as many as eight having penetrated through one nucellus. Between this and the female prothallus they formed so complicated a tangle that it was found impossible to distinguish between the various tubes in a series of sections. Indeed, the number of pollen-tubes could only be found by counting the number of body-cells contained in them, so in the unlikely event of there being more than one body-cell in one tube the number of tubes would be correspondingly lower. Under these circumstances it was found difficult to estimate the number of prothallial nuclei in one tube; in one case, however, eight small nuclei were found near a body-cell in one tube, while in several other cases at least six nuclei were present. Allowing for the presence of the stalk- and tube-nuclei, which by this time are indistinguishable from the prothallial nuclei, there may be at least as many as six prothallial nuclei in the pollen-tube at this stage.

The further course of events seems to follow closely that in *P. macrophyllus*, two male nuclei being produced, one of which comes to lie centrally in the body-cell cytoplasm, while the other is non-functional, and degenerates on the outside of the body-cell cytoplasm.

xi. EMBRYOLOGY.

The embryology of *Podocarpus coriaceus* has been described by Coker,¹ and that of *P. macrophyllus* is similar. The fusion-nucleus sinks to the basal part of the archegonium and there undergoes successive divisions, so that at least sixteen free nuclei are formed before wall formation takes place. While these divisions are proceeding the basal part of the archegonium wall swells up and becomes conspicuous owing to its power of staining with safranin. This is shown in Pl. XLVIII, Fig. 32, which is a drawing of a section through two archegonia, in one of which the pro-embryo is undergoing the third division, while the other is in the eight-nucleate stage. (All the nuclei are of course not shown in a single section.) The stage directly after wall formation was not observed, but no doubt the same tiers of cells are formed as in *P. coriaceus*.

The embryo consists of a single cell for some time after the suspensors have commenced to elongate. Coker has observed the formation of several embryos from a single egg in *P. coriaceus*; there was no case of this seen in *P. macrophyllus*. The embryo later produces a large cylindrical mass

¹ Coker ('02), p. 100.

of tissue which ultimately differentiates into the radicle and the two cotyledons (Pl. XLVI, Figs. 12-14). As the latter in the course of their growth destroy the prothallus cells a plug of prothallus tissue is left between them and presents a striking appearance (Pl. XLVI, Fig. 14).

In the mature seed the procambial strands are already obvious, and it is evident that the cotyledons will each contain two vascular bundles at some distance from one another (Pl. XLVI, Fig. 13).

xii. SEEDLING STRUCTURE.

As far as I am aware the only recorded observations on seedling structure of the Podocarpeae are the fragmentary ones of Geyler¹ and Van Tieghem² on *Phyllocladus*, and those of Hill and de Fraine³ on a single species of *Podocarpus*, *P. chinensis* (*P. macrophyllus*, subsp. *maki*). Further observations on this part of the subject are therefore needed; in this work, however, no material of seedlings was available.

From the observations referred to it appears that in *P. macrophyllus*, subsp. *maki* there are two cotyledons, each traversed by a pair of vascular bundles endarch and collateral in nature. Transfusion tissue is developed laterally. The primary root is diarch, each pole of the primary xylem being continuous with the fused pair of xylem-strands of one cotyledon. The same arrangement probably obtains in *Phyllocladus*, but of other genera we know nothing.

xiii. GEOGRAPHICAL DISTRIBUTION.

The Podocarpeae have a very interesting distribution. *Pherosphaera* has two species, one of which is found only in the mountains of New South Wales, while the other occurs exclusively on the mountains of Tasmania. The genus *Microcachrys* has the same very limited range as the latter species, while *Saxegothea* occurs only on the Chilian Andes. *Dacrydium* is essentially an island type, being almost limited to the islands of the Malay and Australasian region; one species, however (*D. Fonkii*), occurs in the Andes of Chili. The distribution of *Phyllocladus* is similar to that of *Dacrydium*, but is more restricted in its range. In marked contrast to the other genera is *Podocarpus*. This must be regarded as the dominant Conifer in the Southern Hemisphere, as it occurs in South America, the West Indian Islands, South and Central Africa, Australia, Tasmania, New Zealand, and the Australasian and Malay Archipelagoes. It stretches into the Northern Hemisphere in China, Japan, the Malay Peninsula, Burma, and India. On the whole it may be said that *Podocarpus* occupies the place in the Southern Hemisphere that is occupied in the Northern Hemisphere by *Pinus*. These two genera must be regarded, both from the point of view of numbers of species and of wide geographical distribution, as the successful Conifers of the present day.

¹ Geyler, T. H. ('81).

² Van Tieghem ('70).

³ Hill, T. G., and de Fraine, E. ('08), p. 694.

Perhaps the most noticeable feature of the distribution of the living *Podocarpeae* is its similarity to that of the *Araucarieae*.¹ This has been regarded² as of significance in regard to the view of the near relationship of these two orders. We know, however, so little of the causes of present-day geographical distribution that it is doubtful what the significance of this similarity of geographical distribution is. The *Araucarieae* were probably abundant in the Northern Hemisphere in past times,³ but on the other hand little is known of the past distribution of the *Podocarpeae*. It has been suggested that the *Podocarpeae* may have been a southern offshoot of the *Araucarieae*,⁴ but there does not seem to be evidence either in support of, or against this view, from the facts of distribution.

xiv. FOSSIL *PODOCARPEAE*.

Very little is known as to the existence of *Podocarpeae* in past times, although many plant remains have been referred to this order. These fossils fall into three groups: impressions of leaves and branches, petrified wood, and impressions of cones, cone scales, and seeds.

I. Impressions of Leaves and Branches.

A good many impressions of leaves and branches have been referred to *Podocarpus* or allied genera; the more noteworthy of these records are as follows:

Mesozoic. Under the generic name of *Protophyllocladus* Berry has separated the mid and late Cretaceous species formerly included in the genus *Thinnfeldia*.⁵ A relationship to the recent *Phyllocladus* cannot, however, be regarded as by any means proved, for the characters on which Berry relies for identification, namely size and shape, petiolation, and venation, do not even show that the impressions are those of phylloclades. Indeed, Berry himself speaks of them as leaves, and mentions that Knowlton formerly pointed out the resemblance of *Protophyllocladus lanceolatus*, (Knowlton) Berry, to various species of *Podocarpus*.

From the Potomac or Younger Mesozoic Flora of the United States Fontaine has described fourteen species of *Nageiopsis*.⁶ The leaves of this genus are parallel-veined, and show a general resemblance to the leaves of *Podocarpus* § *Nageia*. In a revision of the genus *Nageiopsis*, Berry⁷ has reduced Fontaine's fourteen species to three. Other species have been referred to the same genus by Seward, one from the Wealden⁸ and another from the Inferior Oolite of Yorkshire.⁹ However, the parallel

⁸ Fontaine ('89), p. 195, et seq.

⁹ Seward ('95), p. 211.

venation of the leaves, the persistence of the latter, and the non-convergence to a union of the veins at the tip of the leaf are scarcely sufficient evidence of a Nageian affinity. Indeed, *Nageiopsis anglica*, the Yorkshire specimen, is regarded by both Seward and Berry as possibly of Araucarian affinity.

A second genus of Fontaine's¹ from the Potomac is *Phyllocladopsis*. From Fontaine's figure, however, there is little evidence of Phyllocladean affinity.

From the Cretaceous of New Zealand Ettingshausen has described and figured various leaves which he refers to the genera *Podocarpium* and *Dacrydinium*.² The evidence of a Podocarpean affinity is however slight, as the leaves do not differ in any essential feature from those of any Conifer with a *Taxus*-like leaf. The impression named by the same writer *Ginkgocladus Novae-Zelandiae*³ is interesting, as it is apparently part of a phylloclade which might quite well have belonged to a *Phyllocladus*. As in other cases, however, the evidence is not definite.

Tertiary. Leaves from Tertiary beds referred to *Podocarpus* and *Dacrydium* have been described by Gardner from England,⁴ and by Ettingshausen from Australia⁵ and New Zealand.⁶ These cases are specially mentioned, as fruits in each of these three instances were found occurring with the leaves. As regards the latter it can only be said that although they might be Podocarpean leaves, the evidence is not sufficient to prove they might not have belonged to some other Coniferous genus. Similarly, the impression named *Phyllocladus asplenioides* by Ettingshausen⁷ appears to resemble a *Phyllocladus*, but this does not seem to be sufficient indication of relationship.

If all these references of leaf impressions are correct it means that forms near to the modern *Phyllocladus*, *Dacrydium*, and *Podocarpus* were in existence in Mesozoic times in Britain, in North America, and in New Zealand. But it is well known how unsatisfactory are references based on leaf impressions, and this is especially so in the case of the Coniferae, where throughout the group there is such uniformity of type as regards leaf structure. Even references of recent plants based on leaf characters have been very incorrect; thus the plant named by Sir W. J. Hooker *Podocarpus? Diffenbachii*⁸ ultimately turned out to be a species of *Veronica*. As Professor Seward has said, 'Tempted by a resemblance in the form of the leaves, one is often inclined to assume a relationship with existing Conifers which rests on wholly insufficient evidence.'⁹

⁹ Hooker, Sir W. J. ('43), No. 547.

II. Petrified Wood.

Gothan¹ has recently described several examples of petrified wood which he ascribes to the genera *Podocarpoxylon* and *Phyllocladoxylon* on account of the structure of the wood, special stress being laid on the medullary ray pitting. Another species has also been described by Kubart under the name of *Podocarpoxylon Schwendae*.² These woods certainly appear to resemble existing species of Podocarpeae as far as the structure of the wood is concerned; the difficulty lies in determining how far the structure of the Podocarpean woods examined by Gothan can be regarded as characteristic of the Podocarpeae, recent and fossil. A similar wood structure is known to exist in forms not very nearly related, and it is of course possible that this may be the case here. At present, therefore, it seems best not to regard as proved the references of petrified wood to a Podocarpean affinity.

III. Impressions of Cones, Cone Scales, and Seeds.

Ettingshausen has described an impression from the Cretaceous of New Zealand as a fruit of *Podocarpium Unger*,³ while from the Tertiary of Australia⁴ and New Zealand⁵ fruits referred to species of *Podocarpus* have been described by the same writer. None of the figures of these species can, however, be regarded as at all convincing of Podocarpean affinity.

Two fruits referred to *Podocarpus* have been figured by Gardner as occurring in the British Eocene Flora.⁶ These figures certainly show a resemblance to *Podocarpus* seeds, but unfortunately not much detail is evident to make certain their reference.

Of great interest are certain fossils that have been described by Professor Nathorst. The genus *Carpolithes*,⁷ as Nathorst says, shows much resemblance to the recent form *Podocarpus spicatus* in that a number of seeds are arranged on a spike.

Two fructifications of Rhaetic age recently described by Professor Nathorst are suggested by him as having possibly a Podocarpean affinity.⁸ They are *Stachyotaxus* and *Palissya*. There seems to be good evidence of an epimatium in the former genus at any rate, although it does not seem to be so asymmetrical as the typical Podocarpean epimatium. In any case these genera differ exceedingly from any recent Podocarpean fructification, for *Stachyotaxus* had two ovules to the cone scale, while *Palissya* had as many as 10 or 12 to the scale, and it has been shown

¹ Gothan ('05), ('07), ('08).

⁷ Gardner ('83-6).

⁸ Nathorst ('08).

that the most characteristic feature of the Podocarpeae is the single ovule borne medianly in relation to the cone scale. It may be of course that we have in these fossils connecting links between the Podocarpeae and other orders, but at the present time such considerations are at best only conjectures.

A very interesting petrified cone has been described by Hollick and Jeffrey from the Cretaceous of Kreischerville under the name of *Strobilites micrasporophorus*.¹ The cones were small and slender, while each sporophyll bore two sporangia containing microspores, each with two wings. The resemblance to a Podocarpean male cone is obvious, while Hollick and Jeffrey's figures are very reminiscent of the structure of the microsporophyll of *Podocarpus andinus*. The authors regard it as belonging to a 'generalized araucarineous type, nearer in the structure of its male sporophylls to the Abietinae, than are any of the existing Araucarineae'.² Similarly, it is also nearer to the Podocarpeae than are any of the existing Araucarineae, and to the writer it seems quite possible that it combines features of all three orders, and is in this sense a synthetic type.

Prominence has been given in the past to the similarity of the fossil cone *Walchia filiciformis*³ to the Araucarieae.⁴ This may serve to emphasize the connexion between the Araucarieae and Podocarpeae, for the arguments that are used in favour of the relationship of *Walchia* with the Araucarieae may be used equally well in support of a relationship between *Walchia* and *Saxegothaea*.

Thus the consideration of the fossils referred to the Podocarpeae afford little or no evidence either as to the course of phylogeny in the order, or as regards past geographical distribution, and this is due to the unsatisfactory nature of the plant remains referred to an affinity with the order.

This absence of evidence, however, must not be regarded as equivalent to evidence of absence in past times. The present distribution of the Podocarpeae is almost entirely a Southern one, while it is chiefly the rocks in the Northern Hemisphere that have been explored for fossil plant remains. As Burlingame remarks of the Podocarpeae, 'We know but little of the plant remains of those parts of the world in which these remains would be most likely to be found.'⁵

xv. INTER-RELATIONSHIPS OF THE GENERA AND SPECIES.

That the six genera included in the Podocarpeae in this paper form a natural group cannot, I think, be doubted when the sum of their characters is taken into consideration. The structure of the wood of the stem, the

¹ Hollick and Jeffrey ('09), p. 66.

² l. c., p. 68.

³ Zeiller ('92), p. 99, Pl. XV.

⁴ Seward and Ford ('06), p. 373.

⁵ Burlingame ('08), p. 175.

anatomy of the leaves, the remarkable uniformity of structure exhibited by the male cones, the constant relationship of a single medianly placed ovule to a megasporophyll, the simple character of the latter, and the development of prothallial tissue in the male gametophyte,¹ all give evidence of the natural relationship of the genera here included in the Podocarpeae. That we must look for the nearest approach to the common ancestor of them all among the types with the megasporophylls aggregated into cones seems obvious. Apart from the fact that the fructifications of *Dacrydium* and *Podocarpus* give evidence of their reduction from more perfect cones,² it is the genera *Pherosphaera*, *Microcachrys*, and *Saxegothaea* which have a very limited distribution, and in every group of vascular plants it is as a rule among such genera of restricted range that we expect to find the more primitive members of the group. Many species and wide geographical range are the indications of a successful genus, and success in the struggle for existence means the evolution of characters capable of struggling with modern conditions. For this reason, although it is possible, yet it is extremely improbable that a genus with a wide range and many species will approach so nearly the primitive type of its order as the genera with few species and restricted range, which are probably old types making their last stand against newer conditions.

Again, it is in the structure of these species with female cones that we find most indications of primitiveness. The presence of a certain amount of centripetal wood in the axes of both the male and female cones of *Saxegothaea*, together with the gradual transition from foliage leaves to sporophylls in the case of the female cones, support this view.

The evidence derived from the development of ovulate structures affords fairly conclusive proof that the ovule was originally borne *erect* in the axil of the sporophyll, for it probably arises in this position in all the genera, although its position may be altered by later growth (Text-fig. 8). It was probably surrounded by a single integument, as it remains presumably throughout the whole course of its development in *Pherosphaera*.

The male cones are so uniform throughout this order that they afford little evidence as to the inter-relationships of the genera. The transverse dehiscence of the sporangia of *Saxegothaea* is probably more primitive than the oblique dehiscence in most of the species of *Podocarpus*. The wood of the stem is remarkably uniform throughout the order, but suggests that an arrangement of bordered pits in contact is primitive in the order.

From the account already given of the structure of the leaves of the Podocarpeae,³ it is evident that, with the exception of *Nageia*, all the leaves examined are modifications of one type. The central type is the leaf of *Saxegothaea* or *Podocarpus andinus*. There is a single vascular bundle with well-marked transfusion tissue developed right and left of the xylem, and

¹ *Pherosphaera* is still unknown in respect of the male gametophyte.

² Brooks and Stiles ('10), p. 314.

³ p. 453.

TEXT-FIG. 8. Diagrammatic representation of megasporophylls to show the relation of ovule and sporophyll throughout the Podocarpeae. *a*, *Pherosphaera* (after Pilger, '03); *b*, *Phyllocladus* (young stage, after Robertson, '08); *c*, *Saxegothaea* (young stage, after Norén, '08); *d*, *Saxegothaea* (older stage, after Norén, '08); *e*, *Microcachrys* (young stage); *f*, *Dacrydium cupressinum* (young stage); *g*, *Podocarpus latifolius* (young stage); *h, k*, *Podocarpus latifolius* (older stages); *l*, *Podocarpus spinulosus*; *m*, *Dacrycarpus* (after Pilger, '03).

with a single functional resin canal on the under side. In the leaves of *Podocarpus macrophyllus* and similar ones, the effect of increase in size has probably rendered necessary the development of the accessory transfusion tissue for strengthening purposes. In the larger single-nerved leaves also the single resin canal is replaced by three smaller ones. If Bertrand's description is correct, *Podocarpus vitiensis* would appear to be derived from the *P. macrophyllus* type of leaf, by the removal of the two lateral resin canals away from the median one.

In other species of the order a reverse change has occurred: reduction of leaf surface. Stages in this reduction we see in *Microcachrys*, *Dacrydium cupressinum*, *D. Franklini*, and *Phyllocladus*, the last being the most reduced type of leaf in the order. The juvenile leaves of *Dacrydium* thus approach more nearly the primitive form than those of the adult state, as would be expected.¹ It is also interesting that the first leaves of the seedling of *Phyllocladus* are flat green needles, the transition between these and the very reduced leaves of the adult state being gradual.²

In spite of their characteristic venation, the leaves of *Nageia* have a very similar internal structure to the others. A single resin canal underneath the phloem of each vascular bundle, and the development of transfusion tissue on either side of the xylem, occur exactly as in the other species. There can be no doubt that the *Nageia* type and the remaining types of leaf in the Podocarpeae have had an immediate common origin.

There are two possible alternatives; either the parallel-veined type is primitive in the order, and the uninerved type has been derived from it by reduction, or the *Nageia* type has originated from the *Saxegothaea* type in response to demands for extra leaf surface, as the type of *Podocarpus macrophyllus* has, only with a different result.

The evidence in favour of the first hypothesis is practically limited to the fact that parallel-veined leaves are common in the Araucariaceae, while this piece of evidence is strengthened by the growing opinion that the Araucariaceae and Podocarpeae are nearly related groups of Conifers. Moreover, some Araucarian leaves with only one vein show evidence of having been reduced from a wider parallel-veined leaf.³ The leaves of *Cordaites* also are parallel-veined, and at present the more general opinion of botanists is that the Cordaitales and Coniferales are descended from a common ancestor.

But this resemblance of the leaves of *Agathis* to those of *Nageia* is only a superficial one. The internal structure of the leaves of *Agathis* is quite different from that of *Nageia*, especially as regards the distribution of the

¹ Cf. Goebel ('00, p. 154), who says with regard to the leaves of the Cupressineae, which in external characters closely resemble those of *Dacrydium*, 'the juvenile forms of these plants must undoubtedly be regarded as more primitive.'

² Geyler ('81), p. 209; Coulter and Chamberlain ('10), p. 227, Fig. 256, e, f.

³ Seward and Ford ('06), p. 350.

canals. In *Agathis* these alternate with the vascular bundles, whereas in *Nageia*, as has been already observed, a single resin canal is present under each vascular bundle, and from the constancy of this character throughout the order it seems reasonable to attach importance to it. There is thus no convincing evidence that within the Podocarpeae the single-veined leaf has been derived from the many-veined one.

On the other hand, the evidence in favour of the greater primitiveness of the uninerved leaf seems more convincing. In the first place, with regard to leaves within the order, we find single-nerved leaves occurring in all the genera, while plurinerved leaves are found in one section of one genus only, and that genus the one which on general grounds must be admitted to be the least primitive in the order. In the second place, leaves of a closely similar structure are found in all other orders of Coniferae. In *Araucaria Rulei*¹ there is a single resin canal beneath the single vascular bundle as in the Podocarpeae, and, moreover, of all the Araucariaceae it is this species which approaches most nearly *Saxegothaea*, not only in this respect, but also in the structure of the microsporangium,² in the gradual transition between leaves and megasporophylls,³ and in the vascular anatomy of the megasporophyll.⁴ It is also of significance that Seward and Ford regard the leaf of *A. Rulei* as constituting in some measure a link between the two sections of the genus *Araucaria*.⁵ In the Taxaceae also a leaf with a very similar structure prevails. The leaf of *Taxus* scarcely differs from that of *Saxegothaea* except in the absence of the resin canal from the former. Among the Abietineae the leaves of *Tsuga Mertensiana* and *T. Pattoniana* closely resemble those of *Saxegothaea*, while the leaves of other species may well be derivable from this type. Similarly, among the remaining orders, Taxodiaceae and Cupressineae, leaves with a not very different structure are found. These facts seem to me to point to this type of leaf as not only primitive in the Podocarpeae, but in the Coniferae as a whole.⁶ It is of course possible here, as elsewhere, to invoke reduction, but it seems an extraordinary thing if in all the Coniferous phyla the reduction from the primitive type has been so great, and yet has produced so nearly the same result in each case.

From these considerations it seems to the writer probable that the *Saxegothaea* type of leaf is the primitive one in this order, and that the *Nageia* type has probably been derived from the single-veined leaf, not merely during the course of phylogeny of the Podocarpeae, but during that of the genus *Podocarpus* itself.

The primitive Podocarpean plant can then be pictured as a tree, bearing probably spirally arranged leaves of a Yew- or *Saxegothaea*-like

⁶ Compare the remarks of Coulter and Chamberlain ('10), p. 225.

appearance, and with its reproductive shoots bearing male and female cones, with the sporophylls spirally arranged. On the upper parts of the reproductive shoots there was a gradual transition between foliage leaves and sporophylls. Each microsporophyll bore two sporangia, while each megasporophyll bore in its axil a single erect ovule surrounded by a single integument.

From this primitive type we have had two main lines of development. In *Pherosphaera* there has been reduction in the size of the leaves and in the number of sporophylls in the cone; the megasporangium has, however, retained its primitive character. In *Phyllocladus* the reduction has proceeded still further, and there has occurred the special development of stems into phylloclades, physiologically to replace the leaves, here reduced to small insignificant scales. The ovule has also been clothed by a second integument completely surrounding the inner. The prothallial tissue in the male gametophyte consists of two or occasionally three cells; while in the small number of archegonia in the female gametophyte we perhaps have another reduction phenomenon. Owing to our absolute ignorance of the gametophytes of *Pherosphaera*, it is impossible to say whether in this respect *Phyllocladus* is further reduced than its otherwise more primitive relation.

Along the other line of descent we have intercalary growth taking place at the base of the megasporophyll, resulting in the removal of the ovule from the cone axis, and in many cases causing also its greater or less inversion. Probably correlated with this is the development of the incomplete outer integument or epimatium, for this is not present in any other phylum of Conifers, nor in the other Podocarpean line of descent. Whether this epimatium is an outgrowth of ovular or sporophyll tissue, it is at present impossible to say. The evidence of development in *Saxegothaea* and *Microcachrys* suggests the former, while a somewhat older state of *Dacrydium cupressinum* suggests the latter. The most primitive genus of this phylum is *Saxegothaea*, where the cone is still well developed. This is a somewhat smaller structure in *Microcachrys*, but is still a compact cone. The latter genus has also suffered reduction in its leaves and in the suppression of resin canals in the stem, though these are still present in the leaves and megasporophylls.

In *Dacrydium Franklini* the megasporangiate strobilus consists of about eight megasporophylls separated by appreciable internodes. The ovule is partially inverted, and the incomplete outer integument or epimatium is present, as in *Saxegothaea* and *Microcachrys*. As in the latter genus, resin canals are absent from the stem, but are present in the leaves and megasporophylls; in fact the internal structure of this plant, especially as regards the megasporophyll, is remarkably like *Microcachrys*. Curiously enough, both are limited in their distribution to Tasmania, though one is a small

straggling mountain shrub, while the other is one of the tallest of forest trees.

In other species of *Dacrydium*, such as *D. cupressinum*, the female fructification contains but a single sporophyll, and so is reduced to the extreme limit. Occasionally, two fertile sporophylls may be borne on one 'strobilus'. The ovule has rather the appearance of being borne on the epimatium, but whether this is due to an outgrowth of the scale below the epimatium, or to intercalary growth of the basal part of the epimatium, cannot at present be said. In any case it is a new development not found in the more primitive members of the order or genus. The complicated structure of the inner integument is probably also a new development. The stems here contain resin canals as well as the leaves.

So far all the genera to which reference has been made in this section have the nucellus, integument, and epimatium free from one another, at least for a good part of their length. In the remaining genus, *Podocarpus*, the integument and epimatium are only free from one another for a very short distance in the neighbourhood of the micropyle. In the section *Eupodocarpus* the nucellus is free from the integument, at least in the species I have had an opportunity of examining, for about half its length. The characteristics of this line of evolution are fusion of parts and reduction of the female strobilus.

The two species, *P. andinus* and *P. spicatus*, in which the megasporangiate strobilus consists of about eight sporophylls on an elongated axis, are presumably to be considered the most primitive, reduction of the strobilus having proceeded to a less degree than in any other species. It is worthy of note also that the leaves are of the *Saxegothaea* type, at any rate in *P. andinus*, while their external appearance suggests a similar structure in the case of *P. spicatus*.

In the section *Eupodocarpus* the fructification is reduced to three pairs of decussately arranged scales, of which the two upper pairs fuse to form the receptacle. Usually only one or two sporophylls are fertile. In the section *Nageia* the fructification is similarly reduced, while the peculiar venation indicates this section as a distinct offshoot of the pre-*Eupodocarpus* stock. *Microcarpus* with its single species would appear to be a reduced type on the *Nageia* line of descent. Finally, *Dacrycarpus* would appear to be the most specialized of them all as far as fusion of parts goes, for the megasporophyll is involved in the fusion. On the other hand, whereas in *Eupodocarpus*, and still more in *Nageia*, there is a tendency towards increased leaf surface, in *Dacrycarpus*, and also in *Microcarpus*, there is a reduction in this respect.

The suggested scheme indicating the inter-relationships of the genera and some of the species of the Podocarpeae is therefore as follows:¹

¹ In this scheme genera and species shown above the oblique broken line exhibit fusion of parts in the ovulate structures; while those to the right of the vertical broken line have undergone reduction in their leaves.

xvi. RELATIONS OF THE PODOCARPEAE TO OTHER CONIFERAE;
PHYLOGENY.

The question of the inter-relationships of the various phyla within the Coniferae is one on which very diverse opinions are held. The following quotation from the New Edition of Professors Coulter and Chamberlain's 'Morphology of Gymnosperms' shows how various are the views held with regard to the natural position of the Taxaceae (Taxaceae and Podocarpeae). 'They have been called the oldest living conifers and the most recent; they have been connected with *Ginkgo* through *Cephalotaxus* and with *Cordaites* on account of the structure of the ovuliferous shoot of *Taxus*; and the podocarps have been related to the araucarians through *Dacrydium* and *Saxegothaea*.'¹

During the last few years the opinion has been rapidly gaining ground that the Podocarpeae and the Araucarieae are directly descended from a common ancestor, the connecting link between the two orders being found in *Saxegothaea*. The first suggestion of this connexion really dates from as far back as Lindley, who actually classed *Saxegothaea* as one of the Pinaceae on account of its similarity to *Agathis*.² Of late years the first suggestion of a revival of this view appears as a result of Miss Young's work on the male gametophyte of *Dacrydium*; this writer being struck with the development of prothallial tissue in the Podocarpeae, Araucarieae,

¹ Coulter and Chamberlain ('10), p. 350.

² Lindley ('58), p. 229 a.

and Abietineae, suggested in cautious terms the possibility of a common ancestry for the three orders.¹ The investigation of *Saxegothaea* enabled a more definite statement to be made, so that Dr. Norén and the present writer in 1908 put forward independently the view that the two orders Podocarpeae and Araucarieae are related through *Saxegothaea*. Mr. Thomson and M. Tison, also working independently on *Saxegothaea*, have reached a similar conclusion. As the resemblance between *Saxegothaea* and the Araucarieae is not confined to a single character, but extends to the external features of the female cones, the internal structure of the cone scales, the male gametophyte, and, though not to so marked an extent, to the structure of the microsporangium and the wood of the stem, and in the case of *Araucaria Rulei* to the leaf, there can, I think, be little doubt that the resemblance is an indication of real affinities. One point of resemblance between the two orders, namely, the inversion of the ovule, appears to be due to parallel evolution. The primitive position of the ovule in the Podocarpeae, as Miss Young justly observes,² appears to be erect and axillary, as pointed out in the preceding paragraph.

The only recent paper in which an opposed view is taken is that of Miss Gerry,³ who thinks that her work on the distribution of 'bars of Sanio' in the Coniferae indicates a relationship of the Podocarpeae with the Abietineae rather than with the Araucarieae. The evidence consists in the fact that 'bars of Sanio' are recorded as occurring in the tracheides of the xylem, either of stem or root, but not necessarily of both, in all recent Conifers except *Araucaria* and *Agathis*. Whether this is actually the case cannot be decided for certain, as, judging from the statements in Miss Gerry's paper, only one species of each genus appears to have been examined (at least no more are described), out of the fourteen species of *Araucaria* and ten of *Agathis*. Nor is the additional evidence derived from fossils any more convincing, for although it is stated that 'bars of Sanio' are absent from fossil Araucarian woods and present in woods of an Abietineous affinity, yet the statement means little, for in no case have the so-called Araucarian woods been found in connexion with reproductive organs that are undoubtedly Araucarian, which would alone render certain their reference. As an example of this, mention may be made of Professor Jeffrey's remarks on *Geinitzia gracillima*.⁴ The 'purely systematic botanists' referred the plant to *Sequoia*. The author of the paper also says that the cone scales alone, although furnishing him with ample evidence of Araucarian relationships, 'might by those less experienced in the details of Coniferous anatomy still be considered as belonging to the strobili of the Taxodineae or Cupressineae.' Next we learn that 'the pits in no case are contiguous or in more than a single row', which means, of course, that the pitting is

¹ Young ('07), p. 194.

² Gerry ('10), p. 122.

³ Young ('10), p. 93.

⁴ Jeffrey ('11), p. 21.

unlike that occurring in undoubted Araucarieae. Nevertheless Professor Jeffrey finds 'bars of Sanio' absent, and so concludes that the plant is one of the Araucarieae, and further that it furnishes 'evidence for the derivation of the Araucarian stock from an ancestry essentially resembling the existing Abietineae'. Sinnott's *Paracedroxylon*¹ is regarded as 'a new type of Araucarian wood' for the same reason. Indeed, this reference to an Araucarian affinity seems even more unsatisfactory than that of *Geinitzia*.

But even if it be allowed that Araucarian wood is characterized by an absence of 'bars of Sanio', it would seem to be an utterly insufficient reason to assert, therefore, the nearer connexion of the Podocarpeae with the Abietineae than with the Araucarieae. In the first place, Miss Gerry's observations go to show that while 'bars of Sanio' are absent in Araucarieae they are not so abundant in the Podocarpeae as in the Abietineae.² Again, it would be quite likely that 'bars of Sanio' should cease to be developed along the Araucarian line of descent and yet remain in the Podocarpean. In fact, when the striking resemblance of the reproductive organs of *Saxegothaea* and the Araucarieae in more than one respect is considered, together with the less-marked resemblances in the vegetative organs, it must be admitted by every impartial critic acquainted with the facts of the case as they are at present known, that this resemblance far outweighs in phylogenetic value the dissimilarity in the case of the 'bars of Sanio'.

A more difficult question is that regarding the relationship of the Podocarpeae and the Taxeae. A relationship between the two orders has for long been assumed by the retention of both in the one family Taxaceae. Mr. Brooks and the writer in a previous paper³ expressed the opinion that evidence of relationship between the two orders was at present not very clear, though *Phyllocladus* might be a connecting link. M. Tison⁴ has stated that he has evidence that the Taxeae are derived from the Cupressineae, but as far as the writer is aware this evidence has not yet been published. Miss Young's recent work on *Phyllocladus* shows conclusively, as Mr. Brooks and the writer suggested might be the case, that this genus is one of the Podocarpeae rather than intermediate between that order and the Taxeae.⁵ In the latter the structure of the wood of the stem, the character of the microsporophyll, the position of the ovules in *Taxus* and *Torreya* and the number appertaining to one megasporophyll in *Cephalotaxus*, the absence of prothallial tissue in the male gametophyte, and the absence or poor development of the megaspore membrane⁶ are all characters in marked contrast to the equivalent ones in the Podocarpeae. Our knowledge here is at present inadequate to enable a definite statement to be made; it

¹ Sinnott ('09), p. 170.

⁶ Thomson ('05¹), p. 43.

is at least safe to say that there is as yet little evidence of any near connexion of the Taxeae and Podocarpeae.

Workers on gametophytic structure have found several points of similarity between the Abietineae and Podocarpeae.¹ In the first place, prothallial cells are developed in the male gametophytes of each order, but whereas these are evanescent structures in the Abietineae, in the Podocarpeae they are generally more numerous and may persist up to the time of fertilization. The distribution and arrangement of the archegonia is also similar, and a third point of resemblance is found in the reduction of the functional male nuclei to one. As regards sporophytic characters, male cones and microsporangia are similarly constructed in the two groups, while in each order the pollen-grains are winged. This last point appears to be another case of parallel evolution, for in the Podocarpeae the wings seem to have arisen within the group itself, for the pollen of *Saxegothaea* is wingless, while in *Microcachrys* the wings are imperfectly developed.² Among the Abietineae also the genus *Pseudotsuga* has wingless pollen.³ As regards the distribution of the archegonia we find a similar arrangement in the Taxeae and in *Sciadopitys*,⁴ while the reduction of the functional males to one is probably to be correlated with the absence of archegonial complexes.⁵ On the other hand, there are great dissimilarities in the structure of the wood of the stem, and in the female fructification. The relative phylogenetic value of different characters is always a difficult thing to estimate, and personal opinions on such a question will probably always vary to some extent. The opinion of most workers is that it is to the reproductive structures, rather than vegetative characters, such as wood structure, that we should look for indications of relationship. In the case under consideration the differences between the simple cone scale of the more primitive Podocarpeae bearing a single ovule, and the more complicated 'pièces du cône' of the Abietineae each bearing two ovules, indicate that the relationship between the two orders cannot be a very near one. On the other hand, there are several characters which seem to indicate a common ancestry of the two orders, chief among which must be reckoned the similarity of the microsporophylls, the distribution of archegonia in the female gametophyte, the development of prothallial tissue in the male gametophyte, and the inversion of the ovules. In the last two instances the facts indicate that the Abietineae have advanced much further from the common ancestor than the Podocarpeae, for the prothallial tissue is reduced not only in amount but also in the length of time it persists, while the inversion of the ovules is much more complete. The position of the ovule on an outgrowth of the scale in *Podocarpus*, and especially the position

¹ Coker ('02), p. 102; Young ('07), p. 194; Burlingame ('08), p. 175.

⁴ Lawson ('10), p. 412.

⁵ Lawson ('07²), p. 292.

of the ovule in *Dacrydium cupressinum* on the epimatium, which is here developed to a greater extent than the megasporophyll, are very suggestive of a possible origin of the ovuliferous scale in the Abietineae. If the epimatium of *Dacrydium cupressinum* is called an ovuliferous scale we practically have the state of affairs in the Abietineae. It is, of course, not by any means suggested that *Pinus* is descended from *Dacrydium*, nor for that matter that any of the Abietineae have descended from any of the Podocarpeae, or indeed any living Coniferous group from any other as we know them, but *Dacrydium* and *Pinus* may have inherited the same potentialities from the same ancestor. These considerations thus suggest that the Abietineae have sprung from the same primitive stock as the Podocarpean-Araucarian phylum, but in the respects mentioned above have developed much further from their common ancestors than the Podocarpeae, while in the formation of perfect cones they have retained a primitive character lost in the more recent Podocarpean genera, but still present in the more primitive members of the order.

The point of view taken in the preceding paragraph involves the derivation of the complicated ovulate structure of the Abietineae from a simple sporophyll. This is, however, not at all a generally accepted hypothesis, for many botanists have thought that the simple cone scale has been derived by reduction from the more complicated double structure.

The view that the single cone scale groups have been derived from ancestors essentially resembling the existing Abietineae depends for its support largely on abnormalities, and on the vascular structure of the cone scales. The abnormalities consist mostly of structures sometimes found in members of the Abietineae in which the normal cone scale is replaced by a bract bearing in its axil a structure more or less like the short shoot of *Pinus*.¹ From this it has been argued that the double cone scale of the Abietineae is to be regarded as derived from the fertile equivalent of such a brachyblast shoot, and various well-known modifications of this view have been put forward.² But abnormalities, especially when they are supposed to be more or less of the nature of reversions, afford by themselves unsatisfactory evidence of phylogeny. As to the evidence of the vascular supply of the cone scales, this depends on the fact that in all groups of Conifers there is inverse orientation of the ovular supply as compared with the lower series of bundles serving the sporophyll (or the lower 'bract' scale in the case of the Abietineae). In most cases the ovular supply and sporophyll supply are independent of one another from the cone axis. These facts are supposed to point to the double nature of the apparently single cone scales of the Araucarieae and Podocarpeae, the two scales as we have them in the Abietineae being very closely fused together. The opinion that the facts do not point to this conclusion in the Araucarieae and Podocarpeae

¹ See Coulter and Chamberlain ('10), p. 245 et seq.

² See Worsdell ('00), p. 39.

has already been expressed by all recent workers on their cone scales,¹ and the evidence is against the double nature of the cone scale in these groups. Indeed the more primitive Podocarpeae are less like the Abietineae in respect of the cone scale than the more modern ones. There is indeed a suggestion of doubleness in *Dacrydium cupressinum* and *Podocarpus*, and here it has most clearly arisen within the group.

So we are left with the alternatives of supposing the forms with double cone scales as derived from a single-scaled ancestor, or of supposing the two lines of descent to be quite distinct. That different groups of Conifers have descended from different Pteridophytic or Pteridospermic ancestors seems to the writer to be quite impossible.

There are at present two views as to the phylogeny of the Conifers: the more popular one that regards the Conifers and Cordaitales as on the same line of descent, and the view that it is in the Lycopodialean alliance that we find the nearest approach to the ancestors of the Coniferae of to-day. Dr. Scott has made out the best case for the origin of the Araucarian alliance from Cordaitales-like ancestors, and the chief points of his argument are as follows: ²

1. The stem structure of the Araucarieae is Cordaitalean.
2. The roots are like those of *Cordaites*.
3. The leaves are parallel-veined.
4. The staminate strobili and sporangia are like those of *Cordaites*.

Now if the Araucarieae and Podocarpeae are such nearly related groups as the writer supposes them, in considering the Cordaitalean origin of the Coniferae the Podocarpeae must be regarded as of as great importance as the Araucarieae.

Now in the first place the stem structure of the Podocarpeae, although of a simple coniferous type, is not at all Cordaitalean, except as regards the distribution of the primary vascular bundles, a point of resemblance which can be extended to many other forms. As regards the wood there is no reason why the Cordaitalean and Podocarpean types of wood should not have been derived from the same type; on the other hand, there is no evidence from this character of a connexion between the two orders.

In the second place the roots of the Podocarpeae, in so far as they have been examined, are not particularly reminiscent of the roots of the Cordaitales. It is true, indeed, that they are no more reminiscent of Lycopod roots; at least they furnish no definite evidence of a Cordaitalean origin. One interesting fact about the roots of the Podocarpeae is the possession of tubercles and mycorrhiza which have been compared by Osborn with the mycorrhiza in *Amyelon*, the root of *Cordaites*. He says

¹ Seward and Ford ('06); Stiles ('08), p. 218; Thomson ('09), p. 352; Tison ('09), p. 155.
² Scott ('09), p. 653.

'... the Coniferae generally have an ectotropic mycorrhiza. It need not, therefore, be a matter of surprise that their Paleozoic ancestors should have had a similar relationship.'¹ This of course assumes the Cordaitalean origin of the Conifers, but when it is considered of what general occurrence among vascular plants is the presence of mycorrhiza, there seems no reason to regard its presence in two groups as any indication of relationship.

The third point, the parallel venation of the leaves, has been dealt with in a previous section of this paper.² It was there shown that the evidence was in favour of the primitiveness of the single-veined leaf in the Podocarpeae in particular, and the Coniferae in general, so that in this case the evidence is directly against the Cordaitales theory.

Finally, the last piece of evidence supposed to favour the Cordaitalean origin of the Conifers, that the staminate strobili and sporangia of the Araucarieae are like those of the Cordaitales, no more favours this view when the Podocarpeae are taken into consideration, than the three preceding pieces of evidence, for the strobili and sporangia of the Podocarpeae are quite unlike those of the Cordaitales. It is interesting also that Hollick and Jeffrey's fossil cone, *Strobilites microsporophorus*, which those authors think may be in some ways intermediate between Araucarieae and Abietineae, closely resembles the male cone of the Podocarpeae and is also quite unlike the staminate strobili of *Cordaites*.

Thus, if it is correct, as it seems to the author, to regard the modern coniferous groups as terminating a bunch of radiating lines of evolution from a common ancestor, it seems quite impossible to regard that ancestor as approaching at all nearly the Cordaitales, for in one group, the Podocarpeae, the more primitive members, which exhibit undoubted resemblances to other groups, Araucarieae and Abietineae, as well as exhibiting other features which must be regarded as primitive, are unlike, in almost every character, the Cordaitales as at present known.

One is therefore led to a consideration of the opposed and rather unpopular view of the Lycopodialean origin of the Conifers. This view has received strong support from Campbell³ from a general consideration of the Conifers, and from Seward and Ford⁴ as regards the Araucarieae alone.

The most important piece of evidence in support of this view is derived from a comparison of the cones of the Lycopodiales and the Coniferae. In the Lycopodiales the sporophylls are aggregated into cones, and each sporophyll bears a single sporangium approximately in its axil; in some cases it is true the sporangium arises from stem tissue, but generalizing it may be said that the characteristic of the Lycopodialean phylum is the

¹ Osborn ('09), p. 608.

³ Campbell ('05), pp. 534, 604.

² p. 492.

⁴ Seward and Ford ('06), p. 385.

possession of sporophylls with the single sporangium borne medianly in relation to the sporophyll.¹

Now in the Podocarpeae and in the Araucarieae, the relation of ovule to megasporophyll is the same. Each sporophyll bears a single sporangium medianly on its upper surface. In most cases in the Podocarpeae the sporangium in its later stages appears on the surface of the sporophyll and not in its axil, and moreover is usually more or less reversed. In every case so far investigated, however, the evidence points to the fact that the sporangium in the very young strobilus does actually arise in the axil of the sporophyll, and in an erect position; it is only later in its ontogeny that it becomes reversed and carried away from the axis. In fact, in the youngest stages, which are almost certainly more primitive than the older, the condition is identical with that in the Lycopodiales. Among the latter the genus *Spencerites* affords an interesting comparison with the Podocarpeae, for here the sporangium is borne on the upper side of the sporophyll away from the axis, and, moreover, may be regarded as reversed.

The chief evolutionary tendency in the Podocarpeae, as has already been pointed out, is reduction in the number of sporophylls in the female strobilus. What are regarded as the more primitive members of the order still, however, retain their sporophylls in cones, and so approach more nearly the majority of Lycopods than do the more specialized Podocarpeae.

The microsporophylls also are easily comparable with those of the Lycopods. The sporophylls are still aggregated into cones, but whereas in the Lycopods there is constantly a single microsporangium in the axil of each microsporophyll, in the Podocarpeae there are constantly two borne on the under side. This difference is not a very serious one. That septation of a single sporangium into more than one has taken place in other cases is more than probable. Indeed, the two sporangia forming the synangium of *Tmesipteris*, and the three sporangia in the sporangiophore of *Psilotum*, are considered by some botanists as derived in this way² from the single sporangium as it exists in the Lycopod, and in *Lepidostrobus Brownii* and in *Isoetes* we have cases in which this septation by means of sterilization of formerly sporogenous tissue has proceeded only partially towards completion.³ Indeed, such a case of incipient septation may be present in the genus *Lycopodium* itself, as in *Lycopodium clavatum*.⁴

The shifting of the sporangia to the under side presents little difficulty to the view under consideration. Shifting of the position of the sporangia in regard to the sporophyll has certainly taken place in other cases. It is possible, though indeed not by any means certain, that in the Ferns the position of the sori has shifted from a marginal to a superficial one.⁵

¹ Bower ('08), p. 326.

² l. c., p. 427.

³ l. c., pp. 326, 697.

⁴ Sykes ('08), p. 50, Text-fig. 7, ix.

⁵ Bower ('08), p. 663.

Among the Equisetales in *Palaeostachya* the sporangiophores are found on the upper side of the sporophyll, while in *Cingularia* the sporangia are below the sporophylls. In this case the value of the analogy is perhaps lessened to some extent through the doubt which exists as to the correct reference to the Equisetales of *Cingularia*; the argument, however, still holds good if that genus really belongs to the Sphenophyllales. Moreover, if the microsporophylls and megasporophylls are actually homologous with one another, and all workers on the Podocarpeae are agreed that the female scale is actually a simple sporophyll, a shifting of the sporangium to the other side of the sporophyll must have taken place in the evolution of one or other kind of sporophyll; unless, indeed, the homosporous ancestor bore sporangia on both sides of the sporophyll, a state of affairs which, having regard to the relation of sporangia to sporophylls in all orders of the Pteridophyta, one must regard as extremely unlikely.

Nor is the possession of the seed-habit in the Conifers to be regarded as evidence against the Lycopodialean ancestry of these forms, as Professor Seward and Miss Ford have already pointed out.¹ The seed-habit had already been evolved in the Lycopodiales in Palaeozoic times, as in the cases of *Lepidocarpon* and *Miadesmia*; in the recent genus *Selaginella*, some approach to it appears in *Selaginella apus* and *S. rupestris*,² while one of its accompanying phenomena, the reduction of the number of spores in the megasporangium, occurs in several species.³ There is thus abundant evidence that the potentiality of seed-production existed in this phylum as well as in the Fern phylum.

The vascular anatomy of the sporophylls affords an interesting comparison between the two orders. In the Lycopods the sporangium supply consists of a single medianly placed vascular bundle. In the living genera there is no special sporangial supply apart from this, but in some species of the genus *Lycopodium* there is evidence of the remains of a median sporangial supply given off from the upper surface of the sporophyll bundle.⁴ This is the state of affairs which exists in the young state of the megasporophyll in *Saxegothaea* and *Microcachrys*;⁵ later it is much modified in the former case owing to the development of ovular bundles which attach themselves laterally to the sporophyll bundle. In the more modified fructification of *Dacrydium Franklini* the central median bundle of the ovular supply is lost, and the lateral bundles alone form the ovular supply; in the species of *Podocarpus* examined these two lateral supply bundles are carried down into the axis of the strobilus independently of the sporophyll bundle. That this condition is to be accounted for by the greater relative

importance of the ovule as compared with the sporophyll has already been suggested by Mr. R. B. Thomson,¹ and by Mr. Brooks and the writer.²

The vascular supply of the microsporophyll of the Podocarpeae is just the same as that of the Lycopodiales as far as its distribution is concerned.

As regards vegetative organs further evidence in support of the view under discussion is derived from a consideration of the leaves. The characteristic of the leaves of living Lycopods and many of the fossil ones is their relative smallness and their possession of a single median vascular bundle. Arguments have been advanced already in the course of this paper to show that the primitive type of coniferous leaf was the common uninerved type characteristic of all Conifers except a few Araucariaceae and the *Nageia* section of *Podocarpus*. Some single-veined Araucarian leaves, it is true, have probably been reduced from broader leaves,³ but there is no evidence of this in the leaves of any of the Podocarpeae or of any other order. The slight tendency to form wider leaves with parallel veins, as exhibited in *Agathis* and *Podocarpus* § *Nageia*, may be compared with the still slighter tendency to the same thing in *Sigillaria*, where in some species (*Sigillariopsis*) the leaves were traversed by two parallel veins.⁴

The presence of leaf-gaps in the stele of the Coniferales has been regarded by some botanists as affording important evidence in the consideration of the origin of the Conifers. This line of argument was first used by Professor Jeffrey in 1902, when he inferred that the Coniferales were descended from the Fern-plexus on the ground that foliar gaps occur in the stele of both these groups, but are absent in the Lycopodiales.⁵ Coulter and Chamberlain regard this argument as a very strong one, for in discussing the objections to Seward and Ford's view of the Lycopodialean origin of the Araucariaceae they say: 'Perhaps the most fundamental objection is the presence in araucarians of foliar gaps and of wood indistinguishable from that of Cordaitales.'⁶

It is clear that this objection is based on the assumption that the presence or absence of leaf-gaps in the stele is a character fixed and unalterable in the phylum, an assumption for which, although it is so generally accepted as a fact, there is no supporting evidence. There certainly is evidence that in the evolution of the Lycopodialean vascular system, just as in the Cycadofilices,⁷ one of the most important tendencies was the elimination of primary centripetal wood. Thus Dr. Scott remarks, 'A gradual transition may be traced from the protostelic type, through the medullated forms of *Lepidodendron* and the ribbed *Sigillarias*, to the smooth-barked *Sigillarias*, in which the ring of wood separates, more or less com-

pletely, into distinct bundles.¹ In such a series we have the ancient *Lepidodendron pettycurense*,² with its solid xylem core, *L. selaginoides* (= *L. vasculare*),³ where parenchyma was intermingled with the tracheides in the middle of the stele, and *L. Wunschianum*,⁴ where a large pith occupied the middle of the stem, and the primary xylem was reduced to a comparatively small ring surrounding the pith. A further reduction of primary xylem is exhibited in *Sigillaria spinulosa*, by the partial division of the narrow ring of primary xylem into bundles, and ultimately in *S. Menardi* the xylem was completely split up into separate bundles, the primary parts of which were very small compared with the size of the stem, for in Brongniart's specimen the pith was about 15 mm. across, while the ring of bundles, the greater part of which was secondary wood, was only about 1 mm. in thickness.⁵

Thus in the evolution of the *Sigillaria Menardi* type of stele from the exarch protostele of the earlier *Lepidodendrons*, such as *L. rhodamense* and *L. pettycurense*, the chief tendency has been towards elimination of the primary centripetal wood, which was replaced by secondary centrifugal wood. If we suppose this tendency to have full play we shall at length reach a condition in which the centripetal xylem of the stem has disappeared altogether. The stele in its primary state will then consist of a ring of bundles, each consisting of little more than the proxylem elements, the great mass of wood in the stem being secondary. Under these circumstances it is not only possible but likely that the mode of insertion of the leaf-traces will differ from their mode of insertion on a stele containing much primary centripetal wood.

Thus it appears to the writer that the presence of leaf-gaps in the stele of the Coniferales is a character that cannot be legitimately used as an argument against the derivation of this group of plants from an ancestor without leaf-gaps in the stele.

As regards the structure of the elements themselves the nature of the pitting of the tracheides furnishes an argument against the Lycopodialean ancestry of the Conifers, but here it seems that in Renault's *Sigillariopsis Descaisnei* there were pitted tracheides as well as scalariform ones,⁶ though the approach to a coniferous type does not seem very near.

The presence of a double leaf-trace in the Abietinae has been looked upon as furnishing an important piece of evidence in favour of the Cordaitalean relationship of the Coniferae. But in a similar way the presence of a single leaf-trace in the Podocarpeae (except *Nageia*) may be regarded as furnishing equally important evidence in the opposite direction.

Gametophytic and embryonic structures have not been considered in

this discussion, as exceedingly little is known about these structures in either Cordaitales or fossil Lycopodiales. It is worthy of note that Campbell, who is most competent to speak on this matter, says, 'In the character of the sporangium and the early development of the prothallium, *Selaginella* undoubtedly shows the closest affinity to the Spermatophytes, especially the Gymnosperms, of any Pteridophyte.'¹

The phylogenetic importance of the presence of a suspensor in the embryo of both Lycopods and Conifers is now considerably lessened, owing to the discovery of a suspensor in some of the Ophioglossales² and in *Danaea*.³

During the last few years there has been a growing tendency to take for granted the Cordaitalean ancestry of the Coniferales. The favourable reception accorded to this view is no doubt largely due to the acceptance of the Čelakovskian or some similar idea of the brachyblast nature of the ovulate structure of the Abietineae. The Abietineae were at first the most prominently studied Conifers, and it was natural to explain the simple cone-scaled forms studied later in terms of the more complex Abietinae. Satisfactory evidence has, however, yet to be produced in favour of the more primitive nature of the double cone scale, and to the writer the evidence seems to point in the reverse direction, namely, to the primitiveness in the Coniferales of a type bearing female cones composed of aggregations of simple sporophylls, each sporophyll bearing a single erect axillary ovule. Such a type is not found to-day, the various coniferous orders having all departed more or less from it in different directions. This supposed primitive Conifer is very suggestive of the Lycopodiales, but is not reminiscent of the Cordaitales. Further discoveries may necessitate a modification or the withdrawal of this view, but the evidence at present available is, in the opinion of the writer, much in favour of the Lycopodialean ancestry of the Conifers.

xvii. SUMMARY.

1. *Vegetative Organs.* In the Podocarpeae the stem in its primary condition contains a ring of endarch collateral vascular bundles, these in some, and perhaps in all, being very small. Generally there is a resin canal in the cortex outside each vascular bundle.

Except in *Podocarpus* § *Nageia* the leaf-trace consists of a single strand. In *Podocarpus nagi* there is a triple leaf-trace.

Except in *Podocarpus* § *Nageia* there is a single median vascular bundle throughout the length of the leaf. This strand is accompanied by two lateral masses of transfusion tracheides, and usually by a single resin canal on the under or phloem side. Sometimes this single canal is replaced by three

¹ Campbell ('05), p. 534.

² Lyon, H. L. ('05), p. 455; Bower ('08), p. 471; Lang ('10), p. 611.

³ Campbell ('09), p. 691.

canals. In *Nageia* the leaf is parallel-veined, but each bundle is accompanied by transfusion tissue and a single resin canal as in the single-veined species. In the larger leaved species of the latter accessory transfusion tissue is developed.

2. *Spore-producing Members.* The male cones are very uniform structures throughout the Podocarpeae, each cone consisting of a number of usually spirally arranged sporophylls, each of which bears two microsporangia. In *Saxegothaea* the microspores are without wings; in *Microcachrys* the wings are variable in number and ill-developed; in *Phyllocladus*, *Dacrydium*, and *Podocarpus* there are usually two wings on the microspore, though cases are known in which there are three wings.

The megasporophylls are characterized by the constant relation of one median ovule to the sporophyll. There can be little doubt that the original position of this was an erect axillary one, a position retained to-day by *Pherosphaera* and probably *Phyllocladus*. In most of the genera there has been a considerable alteration from this position due to intercalary growth at the base of the sporophyll. This has resulted in *Saxegothaea* and *Microcachrys* in the inversion of the ovule, and its removal to a situation on the upper surface of the sporophyll remote from the axis. Probably correlated with the inversion of the ovule is the development of the incomplete outer integument or epimatium. In some species of *Dacrydium* the ovule has shifted its position so as to be inserted on the epimatium. In *Podocarpus* fusion of parts has taken place, the integument, epimatium, and nucellus being partly fused in *Eupodocarpus*; the fusion has proceeded further in *Nageia*, and to the greatest extent in *Dacrycarpus*. Another novelty in *Podocarpus* is the development of the ovular stalk. This may be regarded as a further development of the epimatium. In *Phyllocladus*, where the ovule has retained its erect position, there has resulted the development of a second integument which symmetrically surrounds the inner one.

Another evolutionary tendency has been towards the reduction of the female cone to a single fertile sporophyll.

3. *Gametophytes.* The female prothallus has been examined in *Podocarpus*, *Dacrydium*, and *Phyllocladus*. The archegonia occur at the apical end of the prothallus, and as far as at present known to the number of from one to four in *Phyllocladus* and *Dacrydium*, from five to ten in *Podocarpus coriaceus* and *P. macrophyllus* to as many as nineteen in *P. nagi*. Each archegonium is surrounded by a separate layer of jacket-cells, but in the species examined cases have been observed of two or more archegonia surrounded by a common jacket, and this may be the rule in *P. nagi*; a sufficient number of cases has, however, not been examined.

The male gametophyte is characterized by the development of several prothallial cells. These vary in number from two, the usual number in *Phyllocladus*, to eight, a common number in *Podocarpus*. The pollen-tubes

in *Podocarpus* are remarkable for their large size and the extent of their branching between the nucellus and the prothallus. The body-cell nucleus divides into two male nuclei, only one of which is functional.

4. A short account is given of the present state of our knowledge of the Embryology, Seedling Structure, and Geographical Distribution of the Podocarpeae, and of the records of fossil plant remains referred to the order.

5. *Theoretical Considerations.* An attempt is made to show the probable lines of evolution in the Podocarpeae, and that the Podocarpeae are probably related to the Araucarieae, and, though to a much less extent, to the Abietineae. Evidence has yet to be produced before a close connexion between the Podocarpeae and Taxeae can be recognized. A consideration of the available evidence shows that there is much to be said for the view that regards the Coniferales as descendants of Palaeozoic Lycopodialeans ancestors.

On the Development of the Female Strobilus in *Podocarpus*.

BY

L. S. GIBBS, F.L.S.

With Plates XLIX-LIII.

INTRODUCTION.

BEFORE starting for New Zealand and Fiji in 1907, Professor Farmer suggested that it would be a good opportunity for collecting material of the Podocarpoideae, in order to work out the morphology of the so-called 'epimatium', 'aril', or integuments, characteristic of this group. Very little field work soon showed that the study of dried material on which the accepted morphological conception of this family of the Conifers had for the most part been based, had led to conclusions which an investigation of fresh material might considerably modify. Opportunity was therefore sought to collect all available stages in *Phyllocladus*, *Dacrydium*, and *Podocarpus* species. On return a certain amount of work was done which gave valuable data for collecting fresh material on a subsequent expedition to North Borneo in 1909.

The results of both collections are embodied in this paper.

In the following table the list is given of the species collected, with localities and dates, and the stages of the ovules on each occasion. It is hoped this will afford some indication to future workers, as to sequence of development.

Material collected when travelling must necessarily be incomplete, and the methods can only be rough and ready. In this case it was mostly fixed in formalin, and subsequently run up in the laboratory to 75 per cent. alcohol, in which, with the addition of some glycerine, it was preserved.

For the youngest stages this process answered very well, but with the growth of the female gametophyte before fertilization the formalin does not penetrate the ovular envelope quickly enough, and a contraction of the extremely delicate tissue of the prothallus results. Dissecting out the nucellus would therefore be the only satisfactory method, but an impossible one to carry out in the field.

In the species in which the seed-coat remains unmodified prior to fertilization, in the little material available, archegonia were well shown. On the other hand, in those species which develop a stony layer and show a lignification of the integument before fertilization the material, though excellent for the morphology of the strobilus, was useless for embryological detail.

There is, consequently, in this paper a gap in the sequence of the development of the female gametophyte of the different species described, viz. from the enlargement of the macrospore to the archegonium stage, just prior to fertilization. As far as one can judge from imperfect material these stages seem to agree essentially with what has been observed in other families of the Coniferae.

As soon as embryo formation begins, so much starch is laid down in the prothallus that contraction is eliminated and the stages can be followed.

It will be understood, therefore, that where a point could be substantiated in the embryological development it has been given, in the hope that it may prove of comparative value to future workers, but this investigation is primarily on the morphological side.

The systematic arrangement of the species enumerated in this paper is based on Pilger's Monograph of the Taxaceae in Engler's 'Pflanzenfamilien' series. How far the results of the present investigation modify that arrangement, in the opinion of the author, will be shown at the end of the paper.

A table of the species collected is appended, giving locality, date, and ovular development.

MATERIAL COLLECTED IN PODOCARPUS, L'Hérit.

'Ovulum, cum carpidio connatum, carpidium ovulum apiculo obtuso superans.'

Embryo, cotyledons undifferentiated.
P. nivalis, Hook. Mt. Cook, S. Island, New Zealand. Jan. 1908.
Megaspore. Embryo with cotyledons.

In the above table 'nucellus' indicates the homogeneous nucellus of pre-pollination stage, as shown in Figs. 77 and 80, Pl. LIII.

The pollination stage is indicated as 'pollen-grains' when the latter are only seen in the micropylar cavity, or resting on the nucellus, and as 'pollen-tube' when the tubes are penetrating the apex of the nucellus.

In the female gametophyte these stages would correspond to the

differentiation of the megaspore and the first free cell-divisions in the enlarging prothallus.

Pre-fertilization shows the female gametophyte filled with endosperm and archegonial initials, or fully developed archegonia at the apex of the prothallus. In pre-fertilization the pollen-tubes have penetrated the stigmatic apex of the nucellus, and with the male prothallus rest over the apex of the female gametophyte (Fig. 18, Pl. L).

In the following pages, the ♀ inflorescence of *Podocarpus* is described as a fully organized strobilus, thus following Bennett and Brown (2), Sperk (50), Bertrand (3), and Tison (57). As this point of view has not previously been accepted by the generality of botanists, it is perhaps as well to give a key to homologize familiar terminology in this genus, as given by Pilger in his Monograph, with that used in this paper.

The different parts of the female flower and axis have, up to the present, always been looked upon as so distinct that even portions of the same organ exact different names.

Inflorescence.	Female	Strobilus.
flower.		
Branch in <i>Dacrycarpus</i> ,		Stalk in <i>Eupodocarpus</i> .
<i>Nageia</i> , and <i>Stachycarpus</i> .		Peduncle.
Scales		Scale leaves of the peduncle in <i>Dacrycarpus</i> , <i>Nageia</i> , and <i>Stachycarpus</i> .
Scale leaves		Bracts.
Receptaculum		Swollen bract bases in <i>Dacrycarpus</i> and <i>Eupodocarpus</i> .
Carpel		Lamina of fertile bract.
{ Epimatium		Lamina of the ovuliferous scale.
{ 'Stumpfer Fortsatz'		Conical apex of the ovuliferous scale (= semi-circular ridge of <i>P. vitiensis</i>).

By the fertile bract is meant the bract of the strobilus in the axil of which the ovuliferous scale arises.

It must be explained that in Pilger's terminology 'receptaculum' stands for the bases of all the bracts of the cone when subsequent swelling sets in, as is the case in *Eupodocarpus* and to a lesser degree in *Dacrycarpus*.

When this secondary swelling does not take place as in *Stachycarpus* (Pl. L, Figs. 28 and 29), though the bract bases are equally well developed in the young stages (Pl. L, Figs. 25 and 27), in the maturer stages the laminae are caducous, instead of persisting as points as in the two sections above quoted; the bract bases are therefore spoken of as 'scars'.

The 'carpel' is described by Pilger as developing out of one of the scale leaves. That is to say, one portion only, i. e. the lamina, is spe-

cialized as a carpel. There is, however, no vascular connexion between that lamina and the ovular supplies, and it is difficult to see how the carpellary function obtains either when it is free as in *Eupodocarpus*, or when fused with the ovuliferous scale as in *Dacrycarpus*.

This 'carpel' or bract lamina is described as a much reduced and extraordinary small carpel; it is, however, unmodified in the youngest stage in all the sections, even when fused with the lamina of the ovuliferous scale, and does not develop with the ovule, except where there is fusion, and may even be shed entirely, as in § STACHYCARPUS, before the fertilization stage.

The 'epimatium' or ovuliferous scale is considered to be a ligula-like 'excrecence' of the 'carpel'; but here again the vascular system of the 'excrecence' bears no relation to that of the so-called carpel, but maintains complete independence, even where there is fusion of both laminae (Pl. XLIX, Figs. 8 and 9).

The 'carpel' is also served by one vascular strand only (Pl. LIII, Fig. 77) with normal orientation, whereas the 'excrecence' generally shows two (Pl. LIII, Fig. 77), and exceptionally four (Pl. LIII, Fig. 73), all with inverted orientation.

As it is usual to distinguish the sporangium-bearing member in the Coniferae as the ovuliferous scale, that name has been adhered to in this paper.

Pilger's diagnosis for each section is inserted before the description of the species which come under the same, to emphasize better the systematic position, and also for purposes of comparison.

HISTORICAL SUMMARY OF THE LITERATURE.

The literature on the structure of the strobilus or 'female flower' of *Podocarpus* is so voluminous, and the views held on the subject so divergent, that it has been thought advisable to give a summary of the principle work on the subject. It is the sum total of this work which is embodied in our knowledge and opinions of the group at the present day.

With one or two exceptions the bulk of this work has been carried out on herbarium specimens, mostly collected in localities not easily accessible and chiefly in mature condition. It is not surprising, therefore, that interpretations based on laborious work on incomplete material should have resulted in many conflicting theories.

As it is desired to restrict this investigation to *Podocarpus*, all work on the other genera in Taxaceae, where not strictly comparative, has been omitted. This position also applies to all references to the morphological value of the megasporophyll or ovuliferous scale in the Coniferae in general. The voluminous literature on that subject has been admirably summarized by Worsdell (60), and recent investigators disclaim all intention of entering into that vexed question.

The first species of *Podocarpus* known to science was *P. elongata*, L'Hér., from the Cape of Good Hope. It was described by Solander in 1788 (49, p. 415) as *Taxus elongata*, Sol.

L'Héritier, in 1807 (31, p. 580), refers this species to *Podocarpus*, giving the diagnosis as 'Nux ovata, 1-locularis, receptaculum firmo semi-immersa'.

R. Brown, in 1814 (11, p. 47), describes *Podocarpus* as a double cupula, the external one (carpel) forming the drupa, with an aperture near its base or point of insertion. The inner cupula (ovary) is entirely enclosed in the outer one and similarly inverted. He speaks of stigma, style, and fruit.

Richard, in 1826 (41), describes the female flower in this genus as anatropous, the funicle being only slightly indicated. This reversion (p. 125) is due to its being fused for its whole length with a unilateral, fleshy disc, produced at the apex, which corresponds to the base of the flower. This disc may be one of the scales of the involucre, adhering to and forming part of the flower. The pistil is enclosed in a single envelope, corresponding to the calyx, which, however, consists of two portions, an inner one, which thickens and becomes hard, and an outer fleshy one.

Blume, in 1827 (5, p. 88), gives the diagnosis for *P. bracteata*, Bl., as 'Ovarium basi squamula semicinctum. Stigma laterale, sessile'.

Bennett and Brown, in 1838 (2, p. 36), in referring to the position of the Podocarpoideae, write: 'The analogy of the scale with that which supports the seeds in the genus *Pinus* appears originally to have escaped the observation of the elder Richard. It is singular that so unessential a character as the general solitary position of the ovuliferous scale should have induced all the authors who have attempted an arrangement of the Coniferae to separate *Podocarpus* and *Dacrydium* from the true Pines and to associate them with the Yew.

'Their true position is in the Abietineae. The inverted ovula bears the same relation to the supporting scale as in the genera of that group.'

Endlicher, in 1840 (22, p. 262), considered *Podocarpus* as bearing a single anatropous ovule, inserted on a fleshy disc, but later, in 1847 (23, p. 204), he accepts R. Brown's gymnospermous theory, and describes the inflorescence as composed of fertile scales in a lax spike, one or two flowered, the subtending bracts coalescing with the fleshy rachis, their apex alone remaining free. The solitary ovule with two integuments is reversed and sessile near the apex of the fertile scale, with which it is fused in its whole length.

Payer, in 1860 (39, p. 60), describes the female flower as composed of a superior ovary surmounted by a style. This ovary is unilocular, with a naked ovule attached to the base of the cavity.

Eichler, in 1863 (19, p. 430), considered the outer investment of the female flower as an outer integument fused with the inner, and the whole

flower therefore equivalent in organization to an anatropous ovule. Later, in 1875 (20, p. 62), he accepted Strasburger's 'cupula' theory.

In 1889 (21, p. 46), in the 'Pflanzenfamilien', he describes, without hesitation, (definitely) the seeds in Podocarpeae as anatropous, a funicle being indicated in *Podocarpus* only; and in this genus two integuments are also present, which are fused together.

Parlatore, in 1864 (38, p. 19), considers the ♀ 'amenta' of the Podocarpeae as presenting a similar type of organization to the Conifers. The female flower he describes as reversed and enclosed in two involucre; the inner urceolate, with a circular orifice at the apex, is formed from the upper bracts, the outer from the two subtending bracteoles, which are fused with each other and the inner involucre.

He apparently considers the nucellus as an ovary.

Favre, in 1865 (24, p. 382), pronounces the flower to be an erect anatropous ovule, with an inner and outer integument, the latter penetrated by a raphe, which terminates in an 'expansion chalazienne'. The ovule is surrounded by the two almost completely fused integuments.

Brongniart, in 1866 (9, p. 239), describes the female branch as terminated by three scales fused together for most of their length, of which one bears an erect anatropous ovule.

Carrière, in 1867 (12, p. 644), describes the ovuliferous scales of *Podocarpus* as naked, or accompanied at the base by a cymbiform bract.

The solitary fruit, inserted on the middle of the scale, or a little below the apex, is free or adnate, broader at the base, with a double integument, the exterior sometimes completely adhering (adnate) to the interior one.

The latter is prolonged in a tube which projects on the outside ('faisant saillie en dehors').

Sperk, in 1869 (50, p. 69), looks upon the structure of the 'stalk' of the flower and the scale into which it merges as partly analogous to the structure of the ovuliferous scale of the Abietineae, with which, as in *Podocarpus*, there is a fusion of the ovary with the scale, also a reversal of the ovary on all sides. On this scale the ovary is sessile and surrounded by an involucre, which he designates as a carpel. A difference only lies in the degree of the reversion, that is to say, in the thickness of the carpel ('Fruchthülle').

This difference is explained in the structure of the inflorescence. In *Podocarpus* there is more play for unrestricted development than in the Abietineae, where the cones exercise a restricting pressure.

Braun, in 1869 (7, p. 740), was the first to point out, from a study of an abnormal development of the leaves on a branch of *P. chinensis*, Wall., grown in the Botanic Garden in Berlin, that the so-called receptaculum (Endlicher) or discus (Hooker) of the Podocarps, described as the fusion of fleshy bracts with the axis, is in reality due to the swollen bases of those

bracts, which become fleshy on maturity, when the free end of each bract can still be distinguished.

Van Tieghem, in 1869 (58, p. 279), is satisfied that the 'stalk' is of foliar structure, the first leaf of an axillary bud which does not develop further.

This 'leaf' is turned towards the dorsal side to form there an anatropous ovule.

Strasburger, in 1872 (52, p. 24), sums up the Taxaceae as being characterized (with the exception possibly of *Cephalotaxus*) by the absence of true strobilus formation.

The Podocarps are distinct from the Taxaceae in that their flowers occur mostly singly, and, with the exception of *Phyllocladus*, are more or less fused with the bracts and more or less reversed.

He does not accept the outer envelope of *Podocarpus*, or the analogous structure in *Dacrydium* and *Phyllocladus*, as an integument, but looks upon it as a 'cupula', a sort of discoid proliferation of the axis of the flower.

In 1879 (53, p. 78) he describes the outer envelope in *Podocarpus* as an arillus, in preference to integument, as it certainly corresponds to the arillus of the Taxaceae. The ovule (p. 79), though resembling an anatropous ovule, cannot be described as such, because the stalk of the latter, the funicle, is always an integral part of the ovule.

In *Podocarpus*, on the contrary, the stalk, bent over in its apical portion, which bears the ovule, is really the axis of the secondary shoot, consisting of a terminal sessile ovule.

Baillon, in 1873 (1, p. 506) in a concise paper, goes thoroughly into the development of *Podocarpus sinensis*, Wall., and from the study of the organogeny entirely refutes the anatropous ovule theory.

As he succinctly states, in the ordinary course of development of an ovule with two integuments (to which, so far, no exception is known), the nucellus appears first to be followed by the inner (secondine) and then the outer (primine) integument.

In the case of *Podocarpus*, however, as he conclusively proves in a series of excellent figures, of these three portions it is the 'primine' which pre-exists the two other portions; the nucellus appearing next, and finally the 'envelope' which is thus interposed between the two other parts.

Sachs, in 1874 (45), describes the little flowering shoots of *Podocarpus* as consisting of a stalk-like axis, swollen above, which bears three pairs of decussate scales.

The axis terminates between the upper pair, the anatropous ovules, with the two integuments (p. 507), being borne in the axils of the second pair, which may be looked upon as carpels, if such are in any way considered necessary.

Bertrand, in 1878 (3, p. 57), describes the ovules of the Gymnosperms

as always orthotropous, erect in the Gnetaceae, Taxineae, Cupressineae and *Cycas*, horizontal in the other Cycads and *Saxegothaea*, reversed in *Podocarpus*, Pineae, Araucariae, and Sequoiae.

In *Podocarpus*, he describes the fertile bract as carrying a large ovuliferous scale, which covers, like a hood, a reversed orthotropous ovule with one integument, and which is fused its whole length with the scale.

From the Abietineae to the Taxineae, through *Saxegothaea* and the Podocarps, he traces a general tendency of the ovuliferous scale to surround, in hood-like fashion, the ovule or ovules which it carries, fusing more and more till finally it merges in the ovular integument in *Torreya* and *Cephalotaxus*.

Schumann, in 1902 (46, p. 60), looks upon *Podocarpus* as not only distinguished by anatropous ovules, taking the bract at the base as a carpel, but these ovules also possess two integuments, of which it can be determined with 'positive certainty' that the second has arisen from the aril. The sequence of these conclusions is rather involved, and he himself refers to the difficulty in arriving at the same, dried material being alone available.

Worsdell, W. C., in 1900 (60, p. 42), cites *Podocarpus* as an anatropous ovule which is fused with the bract, and extends far beyond the latter, owing to its being carried up on a long stalk. It has two integuments, of which the outer is fleshy or coloured. In some species the bracts and axis are fused into a succulent whole.

Pilger, in 1903 (40, p. 2), describes the ovule of the Podocarpoideae as reversed, with the micropyle lying towards the base of the carpel, furnished with an 'epimatium', i. e. an excrescence in various ways connected with the carpel ('excrecentia carpidii vario modo connata'). The testa of the seed is formed from the integument and 'epimatium'.

He thus gets over the difficulty of the morphological nature of the protective envelope of the Podocarp seeds, by designating it an organ *sui generis*, peculiar to the genus Podocarpoideae, consequently of so much importance that the systematic sequence in this group is arranged according to its degree of development. This, through *Dacrydium*, *Microcachrys*, and *Saxegothaea*, attains its maximum in *Podocarpus*, in which family it is curved and completely fused with the integument.

He considers it incorrect to call the 'epimatium' an outer integument, and so create a contrast ('Gegensatz') to the Pinaceae, which is also the case with the Taxaceae. To describe the ovule of *Podocarpus* as anatropous is also questionable ('angängig'), as that constitutes an inadmissible ('unzulässig') comparison with the Angiosperms, necessitating a laterally fused funicle, whereas the ovule hangs direct from the 'epimatium', which surrounds it on both sides.

Pilger concludes (p. 38) that the Podocarps show greater affinity to the

Abietineae than to the Taxoideae, but defers the discussion of the relationship of the 'epimatium' to the ovuliferous scale of the Abietineae ('Ich muss aber die Discussion dieser Angelegenheiten, besonders des Verhältnisses des Epimatiums zu der Fruchtschuppe der Abietineen, einer allgemeinen Einleitung zu den Coniferen überlassen').

Thomson, 1905 (55, p. 43), looks upon the female flower of *Podocarpus* as an anatropous ovule with two well-differentiated integuments, an inner woody and an outer fleshy one.

The fertile bracts are also united in some species to form a 'receptaculum' which becomes berry-like at maturity.

Tison, in 1909 (57, p. 155), working on *Saxegothaea conspicua*, Lindl., finds that the so-called aril of earlier botanists or the 'epimatium' of Pilger is really the ovuliferous scale of the other Conifers, the summit of which is developed to protect the ovule, the coalescence of the different parts of the female cone being less than the other genera.

This reduction of the cone is carried further in *Microcachrys*, where there is less development of the fertile bract above the ovule, whose base is partially protected by the ovuliferous scale.

In the other *Podocarps* the reduction is much greater, there being only one or two fertile bracts which develop below the ovule, whereas the ovuliferous scale takes on a much greater development, completely encircling the ovule, thus simulating a second integument. Tison recognizes the justice of Bertrand's (3) conclusions.

This view is entirely borne out by the results of the present investigation, which had been already arrived at in 1908, in working out the Fiji and New Zealand *Podocarpus* material collected in 1907.

Coulter and Chamberlain, 1910 (18, p. 323), describe the ovule of *Podocarpus* as inverted and stipitate, arising conspicuously above the bracts.

Young, in 1910 (61), considers the cone (with the exception of *Saxegothaea* and *Microcachrys*) replaced in *Podocarpus* by the single apparently terminal ovule and a few rudimentary scales. The ovule is provided with an arillus or 'epimatium'.

Finally Brooks and Stiles, in 1910 (10), describe *Podocarpus spinulosa* as anatropous, the nucellus surrounded by two integuments, the inner one being fused for half its length with the nucellus, the outer or 'epimatium' being free from the inner at the micropylar end and on the off-side. On the other it is either not present or fused with the 'stalk'.

In a postscript is added, 'Moreover, however, only on Tison's view can it be considered as proved that the "epimatium" completely surrounds the ovule in *Podocarpus*.'

They disclaim Tison's results with emphasis.

DESCRIPTION OF SPECIES.

§ DACRYCARPUS.

Flores terminaei terminales: receptaculum parvulum, verruculosum, carpidium fertile unicum, cum ovulo tota longitudine connatum, ovulum breviter apice obtuso superans.

In § DACRYCARPUS we get a very reduced strobilus, but the most highly organized in *Podocarpus* itself. The cone consists of a peduncle or 'fertile branch', clothed with scale leaves, terminated by the strobilus of two to four bracts, of which one to three of the apical ones may be fertile.

The lamina of the fertile bract or 'carpel' is fused with that of the ovuliferous scale or 'epimatium', and bears a solitary ovule, medianly placed, on its ventral surface near the apex.

In the sterile bracts the laminae are long in comparison with those in the other sections, terete, and through not showing secondary development, remain distinct and green.

The bract bases, on the other hand, though unmodified in the early stages, subsequently swell up, fuse, and change colour, the entire surface showing verruculose swellings. Subsequent growth in the ovuliferous scale carries it well above the bract bases, and it forms with the lamina of the fertile bract the whole protective covering of the ovule, which it surrounds and enfolds completely.

P. imbricata.

Morphology. This species was first described by Blume (5, p. 89) in 1827. It is figured by Bennett and Brown (2, p. 35, t. 10) and by Blume (5, 218, t. 172, f. 2 et 172 B. f. 2). These plates give a very good idea of the foliage of the tree and its dimorphic habit, and both show the same condition as material collected at Buitenzorg in December (Pl. XLIX, Fig. 1), viz. last year's strobilus with this year's above it.

P. imbricata is a graceful forest tree, about 70 ft. high, with straight trunk and compact crown, occurring plentifully in the mixed montane forests of Fiji, and recorded for New Caledonia, New Hebrides, the Malay Archipelago, and N. Burma. Seen in the virgin forest of Java and on the sheltered slopes of Kinabalu in N. Borneo, the tree assumes a larger size and a more branching and spreading habit, with the crown not so markedly compact as observed in Fiji. It is a true mesophyllous mixed forest type, and occurs always singly. As it runs up the exposed slopes of Kinabalu, however, it is finally, in the sclerophyllous dwarf forest subsummit zone (11,500 ft.), reduced to a compact shrub 5-6 ft. high, where, associated with *Phyllocladus hypophyllus*, Hook., *Dacrydium Gibbseae*, Stapf., and *Podocarpus*

brevifolia, Stapf., it forms one of the chief constituents of that association. There the ultimate branches are erect, the terminal portion showing the cupressoid form of leaves, but arranged radially and five-seriate.

In the mixed forest of lower altitudes the graceful young shoots are always pendulous at the ends of the branches, bearing dorsiventral cupressoid leaves, delicate and light green in colour, and biseriate in arrangement (Fig. 1, *cup. l.*). It is this drooping habit which gives such a pleasing and characteristic 'Taxodium' appearance to the tree. The youth form is characterized by the biseriate leaves, and the ultimate branches are not drooping. This youth form was seen in Fiji up to 10 ft. high, the axis of the stem and of the branches being alone clothed with the imbricate leaves. These two forms of leaf are distinct in anatomical structure, the cupressoid being characterized by groups of idioblasts in the mesophyll.

The strobili terminate small lateral peduncles, which arise in the axils of the imbricating foliage leaves of the stem. These peduncles, bearing only imbricating leaves, are curved just below the strobilus in the younger stage, but straighten later (Fig. 1, *strob. 1* and 2). The leaves subtending the strobilus pass gradually into the bracts of the latter and spread out round it in both the Fijian (Fig. 4, *s. l.*) and Buitenzorg material (Figs. 1 and 3, *s. l.*), though not in that from the subsummit zone of Kinabalu (Fig. 7, *s. l.*).

The strobilus, as far as seen, may consist of two to four bracts (Figs. 4, 5, and 7) of no specific arrangement; the laminae of these bracts are long and terete, the bases swollen and verruculose.

Pilger (40, p. 15) describes the 'receptaculum' in this species as formed of two bract bases, of which the lamina of one is fertile. Where there are two bracts to the strobilus, they are apparently opposite (Figs. 3, 7, and 8); and usually one is fertile, as Pilger describes, but twice in the limited material collected both have been found fertile (Fig. 2), and Blume (6) describes two, and rare cases of three being fertile. In the present case (Fig. 2) the two fertile bracts oppose a dorsal to a ventral surface, instead of a ventral to a ventral surface.

This suggests that the opposite position is one of convenience, due to the exigencies of packing, and that the bracts really continue the spiral arrangement (Fig. 4) of the scale leaves of the peduncle, as these show a gradual transition from the small leaves clothing the peduncle to the larger ones immediately subtending the strobilus (Figs. 3 and 7). This transition is not so marked in later stages (Fig. 4) as the relative difference in size is masked by the growth of the strobilus; but it shows a resemblance to *Saxegothaea* as figured by Norén (36), and Tison (57, Pl. IX, Fig. 7).

The lamina of the fertile bract is fused with the ovuliferous scale (Figs. 6 and 8) to the apex of the latter. The apex of the lamina in the very young stage is quite free and distinct (Figs. 2, 7, and 8). In one case it projected far above the scale (Fig. 3, *lam. f. br.*). In later stages it may

persist as a point (Fig. 4, *lam. f. br.*) or become quite merged with the tissue of the ovuliferous scale (Fig. 6, *lam. f. br.*).

Histology. In a longitudinal section of a strobilus in the gametophyte stage (Fig. 8) the lamina of the bract is seen to have the apex quite distinct with two lines of stomata. A single normally orientated vascular bundle, starting from a plate of tracheides under the epidermal tissue, runs down the whole length of the fertile bract to the swollen base. It is accompanied by a resin canal with well-developed epithelium (Fig. 8 *c, epi.*) on the dorsal side. A well-marked cuticularized epidermis with a hypodermal sclerotic layer (Fig. 8 *a, h. f.*) covers the lamina of the bract, and is continued uninterruptedly round that of the ovuliferous scale.

This sclerotic layer is also present in the foliage leaves of both cupressoid and imbricate forms, being only interrupted by the stomata, which occur in four rows, two on the ventral and two on the dorsal faces, and seems limited in *Podocarpus* to § DACRYCARPUS. Thomson (56, p. 349) records a hypodermal sclerotic layer for the megasporophyll and the vegetative leaf of *Microcachrys*.

The swollen base of the bract is limited by the verruculose outgrowths (Fig. 8 *b*) which densely cover this portion. They may also characterize the base of the ovuliferous scale (Fig. 5), which is modified like the bract bases, fusing with them completely. This figure is taken from a strobilus on a tree in the Singapore Botanic Gardens, which was covered with young cones in December. Mr. Ridley informed me that this tree never set seed. The ovules proved all sterile, showing no proper nucellus formation. The epidermal layer of these bract bases is cuticularized, and the cells show dense tannin contents like those of the lamina, but there is no hypodermal sclerenchyma. The other cells are thin-walled, large, and practically devoid of contents. They suggest water-storage tissue, and this may possibly be the function of the so-called swollen 'receptacle' throughout the genus. This tissue is well developed, as we have seen, in post-pollination (Figs. 2, 3, 4, and 7), and increases in size with the growth of the ovule, the increase being due to proliferation of the mesophyll cells.

The structure of the sterile bract resembles that of the fertile. The lamina shows a cuticularized epidermis and hypodermal fibrous layer, and the vascular bundle terminates in a group of tracheides and is accompanied by a resin canal with epithelium. The swollen base is equally verruculose. These swellings are characteristic of § DACRYCARPUS and possibly increase the surface of the water-storage tissue, which is much less developed in this section than in § EUPODOCARPUS, and is entirely absent in § NAGEIA and § STACHYCARPUS.

The ovuliferous scale completely encloses the ovule, and is fused with the integument throughout its whole length, except in the region of the micropyle. It shows the same structure in its epidermal, hypodermal, and

mesophyll tissues as the lamina of the bract. Most of the cells of the mesophyll show tannin and associated starch contents, and many also are packed with starch.

The vascular system consists of two bundles with inverse orientation, each accompanied by a resin canal with epithelium. They unite to form a ring at the base of the ovule, but separate again and remain distinct to the base of the bracts, where the bundles run with normal orientation on to the ring of leaf-traces of the strobilus.

This converse orientation is effected by the rotation of the two bundles as they descend the scale, where they form an arc, the phloem gradually diverging outwards and the xylem converging towards the centre (Pl. LIII, Fig. 77).

This rotation increases in the passage down the bract bases, until the two bundles run on the ring of collateral bundles of the strobilus, one on each side of the strand of the fertile bract, with normal orientation. The ovular supply bundles in *Saxegothaca*, as figured by Tison (57, Pl. X, D), insert themselves with a similar semi-rotation on to the single vascular strand of the fertile bract, but in *Podocarpus* the bundles remain distinct.

The *integument* stands out well from the tissue of the ovuliferous scale, owing to its smaller and more regularly arranged cells. At its free portion, which forms the micropyle (Pl. XLIX, Fig. 8, *o. s. int.*), the epidermal layer of cells is densely filled with starch and tannin. In the free apex at the micropyle the sub-epidermal cells are strongly lignified, staining with safranin, are pitted, showing spiral thickening, and elongated in a vertical direction (Pl. LI, Fig. 58, *a.*). This feature is characteristic of all the species examined. The base of the integument is well defined by a zone of nutritive cells. Of these cells some are packed with starch, while others contain both starch and tannin, the starch grains showing up conspicuously with iodine, by their blue coloration, through the tannin (Pl. XLIX, Fig. 8, *tan.* and *st. c.*). A similar zone occurs at the base of the nucellus, a fact Tison has also recorded for *Saxegothaca* (57, p. 144), designating them 'cellules tannifères'; but he does not specify the presence of starch. These cells appear to be initiated at the same stage in both genera, viz. at pollination, with the enlarging megaspore; but in *Podocarpus*, in conjunction with the zone at the base of the integument, their number increases with the growth of the female gametophyte until starch formation is initiated in the prothallus. Saxton (44, p. 559) in *Callitris* mentions, in relation to the absence of any kind of tapetum in that genus, that 'physiologically its place is taken possibly by the basal part of the nucellus, the cells of which are densely packed with contents'. He further adds that growth of the nucellus takes place mainly in this basal part. This also holds for both integument and nucellus in *Podocarpus*.

The *nucellus* is much contracted in all material at this stage (Fig. 8, *nuc.*), but pollen-tubes can be traced in the apex, whose development, judging from other material, would coincide with free nuclear division in the female gametophyte.

In Fig. 6 a longitudinal section of the ovule in the archegonium stage shows the lamina of the fertile bract no longer so distinct, it having elongated and stretched with the growth of the ovuliferous scale; it is served by one bundle with normal orientation arising from a hypodermal group of tracheides. The mesophyll cells show lignified thickening of the cell-walls, reacting to phloroglucin (Fig. 6 *c*). This lignification is also seen in the mesophyll of the ovuliferous scale, in which the two vascular bundles, on expanding in a ring round the base of the ovule, send secondary branches into the lamina of the scale. This development, which marks a later stage than shown in Fig. 8, extends half-way down the lamina which surrounds the ovular tissues (Fig. 6, *in. v. b. o.s.*).

The nutritive cells of the *integument* and *nucellus* show considerable increase in number (Fig. 6, *tan.* and *st. c.*) and the micropyle is closed, a result effected by proliferation of tissue in the basal portion of the ovuliferous scale and the elongation of the lamina of the same. The integument shows slight peripheral lignification of the cell-walls.

The cells of the stigmatic apex of the *nucellus* show dense starch contents. Stopes and Fujii (51, p. 11) note in *Pinus* the deposition of starch in considerable quantities in the tip of the nucellus, in very young ovules in which archegonia were not present. This is also the case in *Podocarpus* (Fig. 6, *nuc. st.*). Starch is initiated with the formation of the macrospore, and its presence is no doubt related to the growth of the pollen-tubes, which, however, do not absorb it entirely, as some is generally present even when the nucellus itself is reduced to this apical portion, which persists as a cap to the prothallus (Pl. L, Fig. 38, *nuc. cap.*). The periphery of the nucellus is marked by large cells with very little contents, whereas the two or three parietal layers of smaller tabular cells which surround the female gametophyte, and are constantly being absorbed by the growth of the latter, show large and active nuclei and denser staining contents, forming a well-marked tapetum.

Coker (15, p. 103) in *P. coriacea* records the complete absence of any tapetum and 'spongy layer', but in the present investigation it was found in every species from the earliest stages till the laying down of starch in the prothallus and in embryo development.

The female gametophyte has increased at the expense of the nucellus, and in this stage contains five archegonia. These are situated at the apex of the prothallus, and are very long and attenuated, each being surrounded by a well-marked jacket layer of denser staining cells with large and active nuclei. Archegonia are separated from one another by sterile

prothallial tissue (Pl. XLIX, Fig. 6, *arch.*), and are long and tapering, similar in shape to those described by Lawson in *Sciadopitys verticillata* (30, p. 413), and in *Cephalotaxus Fortunei* by Coker (17, p. 5). All the five archegonia are in the maturation stage, when according to Blackman (4, p. 404) the uniformly reticulated nucleus increases enormously in size and moves into the centre of the egg (Fig. 6 *a*, *e.n.*) Lawson (30, p. 44) describes the same result in *Sciadopitys verticillata*, where the egg nucleus enlarges enormously and moves down to the centre of the cell. The protoplasm of the archegonia is much vacuolated, and contains densely staining proteid bodies.

As far as could be ascertained in the scanty material available the neck cells (Fig. 6 *a*, *n.c.*) consist of two to six cells. Coker (15, p. 98) gives them as from two to twenty-five in *P. coriacea*. Below the archegonia there is a central cylinder of small-celled tissue (Fig. 6, *cen. cyl.*) which Coker has also described for *P. coriacea* (l. c., p. 96). The cells of the prothallus are mostly binucleate. Saxton (36, p. 175) records in *Widdringtonia* that this binucleate condition in the prothallus is initiated on the maturation of the oosphere. The cells increase in size towards the periphery, which is limited by an epidermal layer of small uninucleate cells with denser staining contents. This modified epidermal layer, which remains almost free from starch, is characteristic of all species examined (Pl. LI, Fig. 39 *b*). Coker (15, p. 97) has described a similar layer for *P. coriacea*, and suggests that it is modified for secretion and correlated with the absence of a spongy layer in that species; but in all the *Podocarpus* material examined in the present instance, well-marked 'spongy tissue' or tapetum was invariably present (Pl. LIII, Figs. 74 and 75) in conjunction with the differentiated epidermal layer. Pl. XLIX, Fig. 6 shows the prothallus contracted on one side, due to imperfect fixation, the tissue being so very delicate before starch formation is well under way. Contraction is also seen between the necks of the archegonia, where the tissue often becomes folded by pressure and projects, forming a point at the apex of the gametophyte (Pl. L, Fig. 37). This contraction, in microtome sections, often gives the appearance of the archegonia lying in pits.

The prothallus is surrounded by a delicate two-layered megaspore membrane, of which the fibrous layer turns yellow both with iodine and chloro-zinc iodine. The whole membrane can be dissected off the prothallus in its entirety.

In every species examined a megaspore membrane was found to be present. This membrane is conspicuous in microtome sections, taking a mauve-red colour in gentian violet and Bismarck brown (Pl. LIII, Figs. 74 and 75), and staining red in safranin when dissected off. It resists the action of iodine and sulphuric acid, but in every case responded to the iron sulphate test for tannin.

Coker (15) records no megaspore membrane for *P. coriacea*. Thomson (55, p. 42) in *P. coriacea* remarks on the absence of this membrane in the early embryo stage, and also in *P. Mokoyi* in mature condition, and questions if the coat is present in the earliest stages. He concludes that *Dacrydium*, in which the megaspore membrane is well developed, must be much more primitive than *Podocarpus* from the supposed absence of this feature of the latter (l.c., p. 54). In the present case it has been seen in normal development in every species examined, which suggests that *P. coriacea* is an exception in the order in this respect, as it is also in the absence of a tapetum.

The one prothallus available from Fijian material, dissected out of a normally developed strobilus, proved to be sterile. A cavity immediately above the small-celled central cylinder replaced the archegonia. No tracheides occurred in this tissue, in which the cells were two to four nucleate. The larger peripheral cells were uni- to binucleate and contained very few starch grains. There were, however, many tannin cells, which was not the case in the one described above, from Buitenzorg.

A sterile prothallus from the subsummit zone of Kinabalu (11,500 ft.), dark brown in colour on the surface, showed on sectioning almost every cell with tannin contents, the central cylinder being alone excepted.

In another prothallus, of which the name of the species was lost, seven archegonia were present, two being in one jacket (Fig. 6 b). In this case there was no contraction of tissue, and the archegonia lay with their necks plane to the apical surface of the prothallus in two distinct groups.

Podocarpus dacrydioides.

Morphology. This species, familiarly called Kahikatea or White Pine, is a well-known New Zealand tree. In this list it is the only species which grows gregariously, forming dense forests in swampy localities, and predominating along river beds, where, before the usual drastic clearing on so-called 'settlement', it must have been a valuable agent in fixing shingle banks, which now spread unrestricted over miles of country. In the mixed forest it takes its chance with the other members of an association, in which no one species seems able to prevail. It is a slender tree, with the straight trunk and the small conical crown so characteristic of the New Zealand mixed forest type. According to Checseman (14, p. 651) the tree may attain the height of 150 feet, and he describes the wood as straight-grained and easily worked, but not durable if exposed to damp. It is general in lowland forest through the three islands.

The young strobili are very abundantly produced in October and November. They are minute, but conspicuous from the waxy bloom

which completely covers them, and are borne on peduncles about 5 mm. long, which may either terminate a shoot, as Tison figures for *Saxegothaea* (57, Pl. IX, Fig. 6), or they may form little lateral branches, as in *P. imbricata*. The peduncle is clothed with imbricating scale leaves (Fig. 10, s. l.), of which those immediately subtending the strobilus are larger and more spreading (Figs. 10 and 11, s. l.).

The bracts may be two (Fig. 11, *brs.*) or three (Figs. 10 and 12), with long terete free laminae, which remain erect or open out. The swollen bases are verruculose as in *P. imbricata*. There is one fertile bract, the lamina of which is fused with the ovuliferous scale to the point of insertion of the ovule (Figs. 9, 10, and 13). The extreme apex of the lamina is more or less free in the younger stages (Figs. 9 and 10), but becomes completely fused as growth continues (Figs. 12 and 13). Fig. 10 is in the pollination stage.

Histology. A longitudinal section of the ovule shows the lamina of the bract with its normally orientated vascular bundle ending in a group of tracheides (Fig. 9, *v. b. br.*). The epidermis and hypodermal sclerotic layer is continuous with that of the lamina of the ovuliferous scale as in *P. imbricata*. The hypodermal layer, as in that species, also characterizes the foliage leaves, where it is only interrupted under the stomata which occur in four lines, two on each surface of the leaf. This layer is recorded by Van Tieghem (59) for the leaves of both these species. The inverted vascular supply of the ovule runs down the ovuliferous scale in two bundles, as previously described, forming a ring round the base of the nucellus (Figs. 9 and 13), but in *P. dacrydioides* they were not seen to send branches into the lamina of the scale. These bundles run separately, as in *P. imbricata*, to the base of the bracts, gradually rotating as they descend, till they insert themselves normally on to the ring of bundles of the strobilus. They are each accompanied by a resin canal with epithelium. These canals, in the region of the ovule, limit the tissue of the integument from that of the ovuliferous scale (Figs. 9 and 13, *r. c.*).

Pilger (40, p. 23) describes the upper portion of the integument as being very thin in this species and the large resin canals as lying in the outer seed-coat ('äussere Samenschicht'), presumably the 'epimatium', i. e. lamina of the ovuliferous scale. In the younger stages (Figs. 9 and 13, *r. c.*) it will be seen that there is nothing abnormal in the texture or size of the integument or the position of the resin canals, which are, as Pilger states, very large in this species.

The *integument* shows the usual differentiation of cells, those in the region of the base being marked by starch and tannin contents which also characterize the epidermis of the free apex at the micropyle (Pl. LIII, Figs. 77 and 78).

The nutritive zone of tannin cells is present at the base of the nucellus,

and the stigmatic surface of the apex shows pollen-grains lodged on it, and the cells dense starch contents.

The megaspore cell divides about the time of pollination, as described by Miyake in *Cunninghamia* (34) and by Miyake and Yasui in *Pseudolarix* (35). It is limited by the slightly cuticularized megaspore membrane (Pl. XLIX, Fig. 9, *m. m.*) and shows nuclear division. The cells of the nucellus surrounding the female gametophyte form two or three tapetal layers of smaller rectangular cells with denser contents and more active nuclei, which are constantly being absorbed by the growing megaspore (Fig. 9, *tap.*). In an older stage (Fig. 13) where the female gametophyte is much enlarged, filling the centre of the nucellus, the former is too contracted to make out the exact stage, but no cell-walls can be traced in the endosperm, which is definitely outlined by the megaspore membrane. Starch and tannin are present in the cells of the stigmatic apex of the nucellus. The tapetum, showing disintegration of cells, limits the cavity formed by the prothallus. The usual nutritive region of tannin and starch cells is seen at the base of the nucellus and of the integument (Fig. 13, *tan.* and *st. c.*).

§ NAGEIA.

In § NAGEIA and § STACHYCARPUS, in the species described, the cone consists of a peduncle, or so-called 'fertile branch', clothed with scale leaves, and succeeded by six to eight strap-shaped bracts, of fleshy consistency, with their long bases fused with the axis.

The apparent opposite and decussate arrangement of the younger stages is subsequently lost on elongation of the axis, as the bract laminae are shed before fertilization, leaving only scars which show a spiral sequence.

The strobilus organization is therefore limited to the younger stages; there is no secondary modification of the bract bases, so that the 'receptaculum' is described as not being developed.

P. vitiensis.

P. vitiensis was provisionally placed in § NAGEIA by Pilger (40, p. 59) on the strength of its vegetative leaves being opposite and broad towards the base. He admits that the leaves are narrower than those of the other species in this section, also that the ♂ flowers do not agree. The ♀ flowers were unknown to him and are now described for the first time.

In a former paper (26, p. 182) the position of this species in § NAGEIA is questioned, and its inclusion in § STACHYCARPUS suggested, from the similarity in habit and in the position of the ♂ and ♀ flowers to *P. ferruginea*. On anatomical investigation the leaves in *P. vitiensis* were found to possess one vein, whereas it is one of the distinguishing features of § NAGEIA that in that section alone the leaves are pluri-veined (40, p. 5).

In the strobilus, however, the stone cells, which according to Pilger

(l. c., p. 23) are peculiar to § STACHYCARPUS (Pl. LIII, Fig. 75) in the seed-coat, proved absent in *P. vitiensis*.

The peduncle of *P. nagi*, as figured by Pilger (40, p. 61, Fig. D) and in material examined at the British Museum, is thick and shows scars, suggesting a resemblance to older stages of *P. vitiensis* (Pl. XLIX, Fig. 16), but it is difficult in this group to draw conclusions from dried or mature material.

The branching of the peduncle, so accentuated in the Fijian plant (Fig. 14), is also to a certain degree represented in § NAGEIA.

It is therefore thought advisable to follow Pilger, and leave *P. vitiensis* provisionally in § NAGEIA, though the very characteristic branching of the peduncle (Fig. 14), the four vascular bundles of the ovuliferous scale (Pl. LIII, Fig. 73), and the semicircular ridge which terminates it (Pl. XLIX, Fig. 16, *o. s.*), together with the beak-like prolongation of the nucellus into the micropyle, are features which seem to distinguish it from all the other sections (Pl. L, Fig. 18, *nuc.*).

Morphology. This species, the Dakua Salu Salu of the Fijians, is the most beautiful forest tree of that country, or, in the writer's estimation, of the Conifers of the world. Moreover, the wood is the most valuable of the Fijian timbers, being not over hard and very durable. The magnificent symmetry of this species is striking. The splendid shaft, clothed in smooth white bark, rises sheer through the surrounding forest to expand in a crown of spreading branches, of which the ultimate shoots bear leaves so evenly arranged that they suggest pinnules on the frond of a huge fern. These leaves are light green in colour, coriaceous and shining in texture.

The strobili are borne on branching peduncles which arise on the axils of the lower leaves of the shoot in great profusion. The frond-like habit of the branches exposes the strobili, which are conspicuous from their bright magenta colour and glaucous bloom.

This colour, according to Cheeseman (14, p. 650), is also characteristic of *P. ferruginea*.

These strobili were collected from one tree, and show two stages, as already described for *P. imbricata* (see p. 525). The current year's cone shows the ovule in the unmodified nucellus or pre-pollination stage (Fig. 15), which can be compared with the longitudinal section given for *P. ferruginea*, the structure being identical in both cases (Pl. LIII, Fig. 77). These cones were found at the apex of the axis on the youngest wood, on which the leaves had not yet expanded.

In a few cases ovules in the dividing macrospore stage were found on the same axis as the older cones, as figured for *P. imbricata* (Pl. XLIX, Fig. 1, *strob.* 1 and 2). These older cones (Fig. 16) occur in the axils of the lower leaves of the secondary branches of the immediately older wood (Fig. 14, *strob.*). Whether this wood is last year's or not it would be impossible to decide from a single observation on a tropical tree of which no data for judging

the rate of growth are available. In the older cones the ovules show the prothallus contracted in every case. These ovules are in the pre-fertilization stage, as archegonia can be traced in the contracted prothallial tissue, and the pollen-tubes have completely penetrated the apex of the nucellus.

In *Podocarpus*, in all sections except § DACRYCARPUS, the 'epimatium' (lamina of the ovuliferous scale) is described (40, p. 18) as being free from the short fleshy point of the 'carpel' (lamina of the fertile bract), which the ovule greatly exceeds.

The 'carpels' are described by Pilger (40, p. 13) as extremely rudimentary, and of the scale-like leaves which in their entirety represent the 'female flower' of the Podocarpoideae (meist zu einem Teil fertil als Carpiden entwickelt) generally only one is fertile and can function as a 'carpel'. In § NAGEIA in some species a 'receptaculum' (l. c., p. 15) is developed, in others not. When there is no development the stalk of the 'receptaculum' is not naked but bears rudiments of scale leaves, while the scales (Schuppen) of the 'receptaculum' are not decussate, being present in greater numbers in spiral sequence (l. c., p. 16).

In *P. vitiensis* the peduncle is covered with imbricating scale leaves as described in the two former species, which do not appear 'rudimentary' when examined in this early stage. The strobilus consists of six to ten bracts (Fig. 15, *strob.*) which show the same spreading laminae and elongated bases fused with the axis of the peduncle general in the order. The terminal, or sometimes the two terminal bracts (Fig. 16, *f. br.*) are fertile. These bracts are sub-opposite and the laminae show a protective function in the young stage (Fig. 15, *o. s.*), folding over the fertile bract and the ovuliferous scale, and opening out later (Fig. 16, *s. br.*). To describe these bracts as scales is hardly logical, as their organization is entirely similar to that of the foliage leaf; also the spiral sequence of the scars of the caducous bract laminae seen on the mature peduncle may be due to subsequent development during the elongation of the axis. In this species the laminae of the bracts persist till the fertilization stage (Fig. 16, *f. br.*). A bract can hardly be described as a rudimentary scale merely because the lamina is caducous, the scars alone being present at maturity. This fact would rather point to an advance in economical organization, a useless member being shed when no longer required.

In Fig. 15 the lamina of the fertile bract encloses the ovuliferous scale (*f. br.* and *o. s.*) with ovule, reaching to the apex of the same. In longitudinal section of *P. ferruginea* in the same stage, the structure of which, with the exception of the broadened apex, is identical with that obtaining in *P. vitiensis*, the lamina of the fertile bract is seen to be perfectly free from that of the scale (Pl. LIII, Fig. 76). In Fig. 77 in transverse section the base of the bract is shown coalescing with the base of the scale, but, as in § DACRYCARPUS, there is no fusion of bundles; both vascular systems remain

distinct till they are separately inserted on the strobilus system. It is therefore obvious that one cannot describe the fertile bract properly as a 'carpel', considering that there is no vascular connexion with the ovular tissues.

In the older or pre-fertilization stage the ovuliferous scale has grown well above the bract (Fig. 16, *o. s.* and *f. br.*).

The scale or 'epimatium' can, however, hardly be described as greatly exceeding the 'carpel', nor can we speak of these 'carpels' as extremely rudimentary. They are, on the contrary, well-developed bracts, showing a transitory strobilus organization instead of a permanent one as in *Saxegothaea*. This organization is for the development and protection of the ovule till the ovuliferous scale can assume independent function.

The peculiar semicircular ridge formed by the apical portion of the ovuliferous scale is very prominent. Sometimes it projects in two or three points (Fig. 14, *o. s.*), but this effect is no doubt due to contraction of tissue. More than half the ovules sectioned were found to be full of tiny insect eggs, which replaced the integument.

Histology. In longitudinal section of the pre-fertilization stage the lamina of the fertile bract is now very inconspicuous in relation to the well-developed ovuliferous scale (Pl. L, Fig. 17, *lam. f. br.*).

The *ovuliferous scale* shows the same foliar structure as in § DACRYCARPUS. There is a cuticularized epidermis and well-developed mesophyll with many tannin cells, but as yet no lignified tissue in the scale which reacts to phloroglucin.

In transverse section of the dividing megaspore stage, taken through the centre of the nucellus, eight bundles are shown in the adherent lamina of the ovuliferous scale (Pl. LIII, Fig. 72). The vascular system of the ovuliferous scale consists of four distinct bundles with inverted orientation and accompanied by four resin canals, which arise in the apex of the scale, and form a ring-like expansion at the base of the ovule, where each bundle divides again, and the eight branches run down the adherent lamina of the ovuliferous scale surrounding the ovule.

The epidermal tannin layer of the micropylar apex of the *integument* is well shown, also the tanniferous nutritive zone at the base. A similar layer limits the nucellus, and phloem strands show on each side penetrating both zones of tannin cells. Surrounding the megaspore is a tapetum of several layers of cells.

In Fig. 73 a transverse section of the same series, taken through the micropyle, shows the four main bundles, which have again approached each other, on the axial side of the scale towards the base of the latter. On the opposite side the apical portion of the integument is seen, still limited by the zone of tannin cells. In the lamina of the ovuliferous scale which surrounds the integument, the resin canals belonging to the ring of vascular bundles shown in Fig. 72 are still apparent, as they are continued beyond

the strands. These resin canals must branch independently, as more canals appear in the lamina surrounding the ovule than there are vascular strands (Pl. LIII, Fig. 73).

In longitudinal section of the pre-fertilization stage the branches from the inverted vascular system surround the ovule in the lamina of the scale (Pl. L, Fig. 17, *v. b. o. s.*) and are seen running down to the micropyle. These strands end in the usual group of tracheides (Fig. 17, *tra.*). This branching of the vascular system to serve the lamina of the scale is also present in *P. imbricata* (Pl. XLIX, Fig. 6, *v. b. o. s.*). Several strands of phloem elements, of narrow elongated cells with densely staining contents, pass from the phloem of the bundles across each zone of nutritive tannin cells to the base of the nucellus (Pl. L, Fig. 17, *ph. str.*) as previously described in transverse section (Pl. LIII, Fig. 72), where they show on both sides penetrating the zone of tannin cells of the integument. The strand rising a little above the bract, which runs parallel to the vascular bundle for a short distance (Pl. L, Fig. 17), was present in every ovule sectioned. A phloem strand penetrating to the nucellus is also present in the ovules of *Agathis*, connecting them with the vascular supply, a fact which has been recorded by Worsdell.

The usual zone of starch and tannin cells limits the base of the *integument*, of which the apex shows elongated spirally thickened and pitted cells (Fig. 17, *lig. c. int.*).

The base of the *nucellus* is marked by another zone of tannin cells (Fig. 17, *tan.* and *st. c.*). The nucellus has a markedly long beak formed of serial rows of cells (Fig. 18, *nuc.*) which are not thickened but merely crushed at the extreme apex (Fig. 18, *stig. ap.*). This beak is penetrated by pollen-tubes which run more or less vertically down it. In one case the ♂ prothallus was seen in the archegonial cavity (Fig. 18, ♂ *pro.*), containing two generative nuclei with stalk and tube nucleus. In this stage, according to Lawson in *Sciadopitys verticillata* (30), there is an interval before actual penetration into the archegonia.

The nucellus is limited on the interior by two or three tapetal layers with disorganized cells surrounding the gametophyte (Fig. 17, *tap.*). The ♂ gametophyte has absorbed about two-thirds of the nucellus and (Fig. 17, *pro.*) shows a prolongation into the beak of the latter.

In all material obtained, though much contracted, a megaspore membrane is traceable (Fig. 17, *m. m.*).

§ STACHYCARPUS.

Receptaculum nullum; flores feminei spiciformes vel ovula 1-2 ad apicem ramulorum abbreviatorum.

P. spicata.

Morphology. *P. spicata*, the Matai or Black Pine of New Zealand, is a very graceful tree, with a round and densely branching crown, and

leaves unusually delicate in texture and dark in colour, with silvery undersides. It is general in forests throughout the country, up to 2,000 ft., according to Cheeseman (14, p. 651), who describes the wood as hard and durable.

The flowering shoots, both ♂ and ♀, are exceedingly numerous, but both in the Ohakune and Nelson material the ovules were mostly attacked by some insect grub, aborted and abnormally swollen.

Miyake, in *Abies balsamea* (33, p. 134), describes more than half the ovules examined as being infested by insect larvae; in early stages they were impossible to distinguish from those not infested. In the present instance *P. vitiensis* (l. c., p. 536) was found to be similarly infested. In a purely endemic species limited to a small country, where even in its native habitat it is only of local occurrence, such infection, spread over a series of years, would very soon work out its extinction. This is the case in California with *Pinus radiata*, now practically limited to the Monterey Peninsula, and to more or less isolated groups through the coast country, where it is subject to specialized insect attack. In accounting for the dominance or recession of species this very evident but passive factor, as far as the plant is concerned, is as a rule neglected, and most emphasis is laid on the possible active participation of the plants themselves in the struggle for existence, the survival of the fittest being attributed to superior organization and response to ontogenic requirements or to natural selection.

The flowering shoot consists of an elongated axis, borne in the axils of the foliage leaves of the young wood (Pl. L, Fig. 19, *strob.*). The shoots show the protective bud scales at the base; these are succeeded by apparently opposite and decussate modified leaves, an arrangement subsequently lost with the elongation of the axis. The laminae of these modified leaves are suppressed, the bases being adpressed to the stem axis (Fig. 20, *l.*). That these are modified leaves is shown in Fig. 21, where the laminae have grown out as ordinary foliage leaves. These leaves, as a rule reduced to their bases, are followed by the fertile bracts, exactly similar in structure, with the bases fused with the axis and laminae more or less suppressed. Above the bracts is an apical bud (Fig. 20, *ap. bud*) always pressed to one side by the development of the last fertile bract.

Pilger (40, pp. 13, 14) describes the ♀ flower in this species as a spike, consisting of a short limited branch, with a thin axis, bearing spirally arranged scale leaves at equal distance on it, which run down the axis, and at their base bear each an ovular rudiment. He describes the branch as bearing only 'carpels', but this 'Verhalten' is often modified so that the lowest leaves may be sterile. In the present instance the sterile leaves were invariably found to be present, as described above (Figs. 19, 20, 21, *l.*). The fertile bracts are given by Pilger as about 8, whereas Cheeseman (14, p. 650) gives them as 2-8.

In the present investigation, one axis was found with one fertile bract

(Fig. 21, *f. br.*) and a great many with 3-5 (Figs. 19 and 21). In every case the axis was terminated by a bud pushed on one side by the growth of the last fertile bract (Fig. 20, *ap. bud*). In no case, and a great deal of material was available, were the bud-scales and modified leaves of the axis and the apical bud absent.

In Fig. 21, where only one ovule was present, a cicatrized scar showed where the apical bud had been broken, or more probably eaten off. This fact had possibly caused the modified lower leaves to develop laminae and so grow out as ordinary foliage leaves.

In the ♂ shoots, as stated by Pilger, the same conditions obtain. Ten to thirty flowers are massed on an axis about 5 cm. long, where they may arise in the axils of small bracts only, or the shoot axis may bear foliage leaves at the base, which gradually pass into the bracts, the lowest flowers being borne in the axils of the foliage leaves, and an apical bud may develop (40, p. 10).

The ♀ 'spike' of *P. spicata* may be regarded as an entire strobilus, and fossil evidence may be referred to in support of this interpretation. Nathorst (62) describes in *Stachyotaxus septentrionalis*, C. A. Agardh, and *Stachyotaxus elegans*, Nath., an almost identical structure. He figures the strobilus of the former (62, Figs. 1 and 2, t. 2) and the resemblance is very striking; these figures show scale leaves densely clothing the peduncle, which are succeeded by a number of bracts, all of which are fertile, inserted at regular intervals on the axis. Nathorst refers to the similarity in structure of the ♀ shoot of this plant (which he rightly holds to be a *Dacrydium*) with *P. spicata* (62, p. 15). The ♂ strobili of *Stachyotaxus* show the elongation of the axis with the spacing of the sporophylls which is so striking in the ♀ strobilus in this genus. Nathorst figures these ♂ strobili with reserve, as they have not been found in organic connexion with *Stachyotaxus*, but they are so typically Dacrydioid that there can be little doubt that they belong to the same plant.

In § STACHYCARPUS the lamina of the fertile bract remains free from the ovuliferous scale, and does not keep pace with its growth, as described and figured in *P. vitiensis* (Fig. 27). The region of the ovuliferous scale referred to in the description of *P. vitiensis* as the semicircular ridge is in § STACHYCARPUS more prominently developed, and appears as a conical apex projecting from the free side of the ovuliferous scale above the place of insertion of the ovule. Pilger describes this pointed apex as a narrowing of the 'epimatium' into a blunt continuation ('stumpfen Fortsatz'), but as this continuation is furnished with two well-developed vascular strands with resin canals (Fig. 22, *v. b. o. s.*), and the foliar structure of the scale in the shape of epidermis, stomata, and stone cells is equally and continuously distributed, it seems to indicate that it is an integral portion of the scale itself. The greater development of this region may be related to the water

supply of the ovule, in the absence of all swelling and proliferation of tissue in the bract bases or so-called 'receptaculum' of the axis. A double apex is often apparent in the ovuliferous scale (Fig. 20, *o. s.*), this appearance being caused by contraction of the mesophyll tissue between the two vascular bundles, as previously noted for *P. vitiensis* (see p. 536).

Histology. In longitudinal section the ovuliferous scale is marked by a well-developed epidermis with stomata. Pilger (40, p. 23) notes that in § STACHYCARPUS a thick stone-cell area arises evidently from the integument, but it will be seen that this area arises in the ovuliferous scale (Fig. 22, *o. s. stone c.*), the cells occurring in groups of two or three (Fig. 22) at regular intervals in the mesophyll. In this species stone cells were not found in the foliage leaves. The vascular system tissue consists of bundles which arise in the above-described apex of the scale. They lie facing each other, or phloem to phloem, separated at the apex by a little mesophyll. The separation increases as they descend till they expand at the base of the ovule in a ring of branching strands. Each bundle then divides so that four strands, all showing inverted orientation, and accompanied by small resin canals, surround the ovule in the lamina of the ovuliferous scale. On the dorsal side, or midrib region, below the ovular insertion, the two bundles approach each other again, but laterally, that is to say, side to side, until in the micropylar region the xylems almost converge, the phloem gradually rotating outwards.

Phloem strands penetrate to the nucellus (Fig. 22, *ph. str.*) as described in *P. imbricata* and *P. vitiensis*.

The integument is outlined by tannin and starch cells round its whole periphery (Pl. LIII, Fig. 75), and at the apex, at the micropyle, shows ingrowth of lignified closing cells (Pl. L, Fig. 22 *a*, *lig. c. int.*), as Saxton has described for *Widdringtonia* (42, p. 32), the cells similarly showing no septation and not entirely closing the opening.

The apex of the nucellus is prolonged, the cells containing starch, and the cell-walls show slight collenchymatous thickening (Pl. LIII, Fig. 74). It is this difference in texture and contents which is the cause of the slight contraction apparent at the base of the apex (Pl. LIII, Fig. 75), which is sometimes so marked in species where the apex is long, that the nucellus appears bottle-shaped, and this cause must always be allowed for in the presence of apparently abnormal shape. Pollen-tubes are seen penetrating the stigmatic apex (Fig. 75). These tubes extend above the actual apex, still attached to the spore-case; the loose cells forming the stigmatic surface of the extreme apex on pollination gradually become contracted and pressed together, the upper portion of the tube being in consequence exposed.

The base is outlined by the nutritive zone (Fig. 74). The tapetum is well marked in the region of the growing gametophyte (Figs. 74 and 75), which in Fig. 75 has absorbed nearly the whole of the body of the nucellus.

In Fig. 75 the ♀ gametophyte is almost filled by the centripetal growth of the endosperm, in which cell-wall formation is beginning, but so much

contraction has taken place that the tissue is folded in and out, the outlines being traced by the megaspore membrane, which follows the folds (Fig. 75).

Of the two microphotographs of longitudinal sections given, Fig. 75 is older than Fig. 74, which shows the same stage as Pl. L, Fig. 22.

P. ferruginea.

Morphology. *P. ferruginea*, or Miro, is a very handsome New Zealand tree, which with *P. dacrydioides* forms an exception amongst the Podocarps of that country in not suggesting the Yew in foliage and a symmetrical habit.

The branches of this tree are not crowded and recall *P. vitiensis* in their rather horizontal spreading, and light green and shining leaves, with distichous arrangement. The fruit is also the same colour.

Cheeseman (14, p. 650) gives it as abundant throughout the country, the wood hard and compact, but not durable in exposed situations.

The strobili are borne on the apex of small lateral peduncles which arise in the axils of the lower foliage leaves of this year's wood (Fig. 24, *ped. strob.*), and as in *P. imbricata*, last year's ovules, in the pre-fertilization stage, and this year's with a homogeneous nucellus and dividing macrospore stage, were obtained on the same tree.

The lower portion of the peduncle of the strobilus is densely covered with imbricating scale leaves in the youngest stages, as in *P. vitiensis* (Fig. 27, *s.l.*). These scale leaves gradually pass into the bracts of the strobilus. The strobilus terminates the apex of the peduncle and is composed, as far as could be determined, of six to eight bracts of fleshy consistency, arranged in a decussate manner, with the bases fused with the axis, and with expanded laminae. One of the terminal pairs of bracts (Fig. 27, *f. br.*) or both (Fig. 28) are fertile.

The laminae of these bracts do not persist as long as in *P. vitiensis*, but soon fall off, including even the lamina of the fertile bract, leaving only cicatrized scars (Fig. 29, *scar lam. f. br.*), but the scale leaves of the peduncle persist.

Pilger (40, p. 14) emphasizes the spiral sequence of the bracts or 'carpels' in § STACHYCARPUS in comparison to their opposite and decussate position throughout the Eupodocarps, but the tendency is really the same in both cases, viz. an opposite and decussate arrangement due to economy in packing, in the youngest stages, which is gradually lost sight of on the elongation of the axis when the spiral phyllotaxy of the leaves come into play as the permanent arrangement.

These bracts surround and protect the fertile ones in the young state (Fig. 25, *br.*), expanding and reflexing later (Fig. 27, *s. brs.*). The lamina of the fertile bract at first covers the ovuliferous scale almost as if it were fused with it, as in § DACRYCARPUS. However, in longitudinal section it is

seen to be free from the latter (Pl. LIII, Fig. 76). Where two bracts are fertile, they appear to be opposite, but, as stated before, this is only a question of packing, as one is invariably younger than the other (Pl. L, Fig. 28, *o. s.*)¹

Histology. In a microphotograph of a radial longitudinal section of the youngest stage available (Pl. LIII, Fig. 76) the initial distribution of the tannin cells shows well. They are seen in three or four layers outlining the bases both of the fertile bract and scale, also the laminae of both, to continue in the epidermis only of the latter in the region of the micropyle, and in that of the integument and nucellus, where free (Fig. 76). This distribution is further emphasized in transverse section of the same stage, taken through the nucellus (Fig. 77)

There are, as yet, no tannin cells at the periphery and base of the integument and nucellus. This zone is initiated, as in *Saxegothaea* (57, p. 144), with the enlarging megaspore on pollination. In Fig. 76 the cells at the base of the ovule are in active division, the zone of growth being basal, as Saxton (44) describes for *Callitris*. The apical cells of the integument at the micropyle are not yet lignified.

The base of the ovuliferous scale on the ventral side shows swellings, which recall the structure of the scale bases in § DACRYCARPUS (Pl. XLIX, Figs. 8, 9, and 13).

Two bundles, with resin canals, showing the usual reversed orientation, run down the scale (Pl. LIII, Fig. 77). The course of the bundles is essentially as described for *P. spicata* (see p. 540). These bundles arise in the apex of the scale, which is produced (Pl. L, Fig. 29, *o. s.*), though not to the same extent as in *P. spicata*.

The two strands, each with a resin canal, do not exactly face each other in the extreme apex, as in the above species, but converge more or less as they descend the scale (Pl. LIII, Fig. 77), gradually rotating until the phloems are side by side. Then the strand of the fertile bract slips in between and the three bundles are inserted on the ring of distinct bundles in the strobilus.

In the fertilization stage from the same tree (Pl. L, Fig. 29, *o. s. scar brs.*) the ovuliferous scale rises well up above the bracts. The imbricating scale leaves of the peduncle still persist, but the laminae of the bracts of the strobilus have been shed, including that of the fertile bract, leaving only cicatrized scars.

¹ In *P. ferruginea* we get an interesting reduction in the organization of the strobilus as compared with that of *P. spicata*. The peduncle, clothed with scale leaves, is shortened, as is also the axis of the strobilus, on which the bracts are massed close together, and not only reduced in number but also in fertility, the lower ones being all sterile, with one or two of the apical bracts alone fertile, and there is no apical bud. This reduction is also indicated in the *Stachyotaxus* series, as in *S. elegans* (62, t. 3, Figs. 1 and 2). Nathorst figures the strobili in a similar lateral position, with the peduncle reduced in length and in the number of bracts, all of which are fertile, but, though still showing an appreciable interval between each bract, the spacing is more than in the case in *S. septentrionalis*.

In the *ovuliferous scale* groups of stone cells are arranged regularly in the mesophyll as in *P. spicata*, but, unlike that species, they also occur in the mesophyll of the foliage leaves. The vascular strands start from hypodermal groups of tracheides (Fig. 34) at the apex of the scale and spread ring-like round the base of the ovule, where a phloem strand penetrates to the base of the nucellus, as in *P. imbricata*, *vitiensis*, and *spicata*. The bundles show no secondary branching in the lamina of the scale (Fig. 29, *v. b. o. s.*).

The *integument* shows the greatest differentiation yet met with, as the peripheral zone of tannin cells tends to elongate laterally, broadening out towards the centre and tapering towards the micropyle (Fig. 29, *tan. c.*). This regular arrangement is peculiar to this species amongst all those included in the present investigation.

Of the *nucellus* all but the apex, of which the cells show thickening of the cell-walls and starch contents, is absorbed by the ♀ gametophyte. The apex is penetrated by numerous pollen-tubes, the spore-cases being still attached to the stigmatic surface. The pollen-tubes penetrate more or less vertically, crushing the tissue on either side as the contents become absorbed. In all species this crushing of the thick cell-walls gives a certain stability to the apex, which persists till the embryo stage, forming a little brown cap which can be removed from the apex of the ♀ prothallus when the latter is dissected out.

The ♀ *gametophyte* is very contracted in the material available, but cell-wall formation can be traced.

It is limited by a megaspore membrane of two layers, the outer one striate.

§ EUPODOCARPUS.

Flores feminei singuli axillares, sub-sessiles vel plerumque longius pedunculati; receptaculum evolutum, saepe basi foliolis 2 angustis instructum.

In § EUPODOCARPUS the strobilus occurs, as usual, in the axils of the lower foliage leaves of lateral shoots. In these shoots there is always a well-marked fertile area of about an inch to an inch and a half. Above and below this area no strobili are to be found. It is only noticeable in the young wood up to pollination stage, as after that the unfertilized strobili drop off in great numbers, and it is no longer apparent that every leaf in this limited region bears a cone in its axil.

The strobilus may be almost sessile or pedunculate. If pedunculate the peduncle is naked, the strobilus consisting of two to six bracts, the two lower ones in some species (which Pilger in his monograph places first, and whose presence he considers divides § EUPODOCARPUS into two large groups, geographically separated (40, p. 14)) being thin, strap-like, and generally unmodified. The upper bracts show the small laminae and relatively large bases, which swell up as growth proceeds, and fuse with

the axis and with each other, as previously described in § DACRYCARPUS. But in § EUPODOCARPUS the swelling is carried much further, resulting in a berry-like structure, in which the laminae are not traceable, or merely indicated by points.

This berry-like structure of swollen tissue forms the so-called 'receptaculum' which A. Braun (8, p. 740) was the first to reduce to its proper status.

That the two strap-like 'folioles' of Pilger really belong to the strobilus is seen in *P. spinulosa*, R.Br., where Pilger (40, p. 77, Fig. 15, H-L) shows that their bases may become swollen and so resemble the other bracts of the strobilus.

In their strap form these bracts are very caducous and so approach those which compose the strobilus in *P. vitiensis* and *P. ferruginea*.

Flores feminei infra receptaculum foliolis 2 parvis linearibus ornati.

P. clata.

Morphology. *P. clata* was found as a slender tree with sparingly branched crown in the montane mixed forests of Fiji, growing about 30-50 ft. high; on higher ridges, of shrubby habit, about 20 ft. and fruiting at 9-10 ft. The leaves are Willow-shaped, about 3 inches long, crowded towards the ends of the branches. The recorded distribution is for Queensland, New South Wales, and New Caledonia.

In this case also two stages were found on the same tree, as previously recorded for other species. The strobili arise in the axils of the lower leaves of the secondary branches of the young wood, and in September were in the pre-pollination or homogeneous nucellus, to the formation of the functioning megaspore stages (Figs. 30 and 32).

On the next oldest wood, the ovules were much larger, showing young embryos, with the cotyledons just forming, the bracts of the strobilus being already swollen and fused (Fig. 33).

This species shows the unmodified lower bracts (Fig. 33, *l. brs.*), which in the youngest stage are not so differentiated from the upper ones, and form an integral portion of the strobilus (Fig. 30, *l. brs.*) enclosing and protecting the upper bracts. They are evidently the reduced remains of the more highly organized bracts that obtain in *P. vitiensis* and *P. ferruginea*, whose function is also protective (Figs. 15, 25, and 27). No geminate cones were seen in this species.

In Fig. 30 the sterile bract has been removed to show the ovuliferous scale, with the lamina of the fertile bract well above it (*o. s.* and *f. br.*).

On the dorsal side of the same strobilus (Fig. 30 *a*) the fertile bract is seen to be unmodified in structure.

The ovule at this stage would show a homogeneous nucellus (Pl. LIII, Fig. 79). In Pl. L, Fig. 31, in an older stage, the bracts and the ovuliferous scale are about the same level, and the ovule would be showing sporogenous

tissue. In Fig. 31 *a* the lower bracts have been dissected off, exposing two bracts, one fertile, of which the laminae begin to show marked contraction and the bases are swelling up. In Fig. 31 *b* the micropyle of the ovule can be seen. In Fig. 32 the ovule is well above the bracts; there is more swelling in both the latter, with greater contraction of the laminae (Fig. 33, *lam.* and *br. bs.*). This would be approximately the dividing macrospore stage.

In Fig. 33 the embryo shows cotyledons differentiating. The unmodified lower bracts have expanded, and in most cases were already shed. The bract laminae are reduced to points, while the bases have swollen enormously. The structure of these bases is essentially the same as described in § DACRYCARPUS. The tissue shows the same uniform cells with colourless contents, freely interspersed with tannin cells, especially (Pl. LIII, Fig. 79) round the periphery. The increase in size is due to the proliferation of the mesophyll tissue cells, which with very thin walls and no cell contents suggest a water-storage function; the fact, too, of the very early development of this tissue points to some provision for the wants of the growing ovule, which in its isolated position is rather remote from the supplies of the sporophyte. The increase in this tissue, which characterizes the *Eupodocarps*, may be possibly correlated with the absence of scale leaves on the peduncle.

In § DACRYCARPUS, where the scale leaves are present, this tissue is reduced (Pl. XLIX, Figs. 4 and 12). In § STACHYCARPUS, where, though fused for their whole length to the peduncle, the bract bases do not swell up (Pl. L, Fig. 28), the provision in the younger stages is much better, as the bracts then are more numerous and more specialized, each is of fleshy consistency, larger scale leaves support the base of the strobilus, and these merge into the smaller and more densely imbricating scale leaves which clothe the peduncle.

Histology. It is interesting to compare a photomicrograph of the homogeneous nucellus, which would be represented in Fig. 31 and Pl. LIII, Fig. 79 of *P. elata*, with Fig. 76 of a slightly younger stage of *P. ferruginea*, in § STACHYCARPUS, as the different development of the bract bases, also variation in form of the ovuliferous scale in each section, can then be better appreciated.

Fig. 79 is a radial section and shows well the foliar structure of the scale, from which, as far as seen in *Eupodocarpus*, hypodermal fibres are absent, both from the ovuliferous scales and the foliage leaves. The beginning of the nutritive starch and tannin zones is present at the base of the integument and nucellus. This section also shows how distinct the organization of the ovuliferous scale is from that of the fertile bract, the former having no vascular connexion with the lamina or so-called 'carpel'.

In Fig. 79 the base of the ovuliferous scale is distinct and forms an integral portion of the strobilus, being pressed between the bract bases and fused with them. In the series of sections of the strobilus the three

vascular strands can be traced separately to the base of the same. This distinctiveness is shown in the section figured, by the separation of the two resin canals, viz. that of the sterile bract to the right and that of the ovuliferous scale in the centre. Only a trace of the vascular bundle of the fertile bract is visible (Fig. 79) to the left, but that is sufficient to show how widely it is separated from that of the ovuliferous scale with its inverted orientation.

In transverse section of the same stage, a microphotograph (Pl. LIII, Fig. 80) shows a section taken through the base of the nucellus where the two bundles spread round the base of the ovule. It is slightly oblique, but the foliar structure of the scale comes out well. The lamina of the fertile bract appears on the dorsal side to the left (Fig. 80).

A prothallus, showing an embryo, was sectioned. The structure was identical with that described for *P. imbricata* (see p. 530).

P. polystachya.

Morphology. This material was collected from a large tree growing in the Buitenzorg Botanic Gardens. The leaves are long and Willow-like, aggregated towards the end of the branches. The strobili arise in the axils of the foliage leaves and consist of apparently two bracts, of which one is fertile. The unmodified lower bracts are no longer present (Pl. L, Fig. 35). The ovules all show different stages of pro- and embryo formation (Figs. 36 and 37, and Pl. LI, Figs. 38 and 39).

Histology. Some of the ovules were much smaller, suggesting earlier stages (Pl. LI, Fig. 41), but, on sectioning, these showed sterile prothallia, in which pollen-tubes, however, had penetrated the whole length of the persistent apex of the nucellus in each case (Pl. LI, Fig. 42, *p. t.*).

In both fertile and sterile prothallia there is a well-marked epidermis, showing small uninucleate cells which contain little or no starch (Pl. LI, Fig. 39 *b, epi.*) with thickening of the outside cell-walls. Coker has also described and figured a similar layer for *P. coriacea* (15, p. 97). This epidermis in the sterile prothallia was folded in and out over the apex and even into the neck of the archegonial cavity, owing to contraction of prothallial tissue.

Below these convolutions is a cavity (Pl. LI, Fig. 42, *dis. arch.*) where the archegonia would normally occur, but of which no trace was to be seen. In the central cylinder of small cells which reached below the cavity to nearly the base of the prothallus were a great many tracheides (Fig. 42, *tra.*, and Fig. 43). Neither the central cylinder nor the rest of the prothallus contained starch in the cells, though most of them were binucleate. This absence of storage contents was strikingly shown in a similar prothallus cleared in cedar-wood oil. The transparency was so great that the cylinder of small cells showed clearly through the centre, giving a very slight opaque effect, otherwise the prothallus would have been invisible. On cutting,

it proved quite sterile, showing the apical cavity and just one or two tracheides in the central cylinder.

Coker (15, p. 97) gives a similar instance in *P. coriacea*. In that case there were two prothallia in one ovule; neither had formed archegonia, and in one three to four tracheides occurred in the central cylinder.

In the fertile prothallia the earliest stage is shown in Pl. L, Fig. 36, where many proembryos form a complex which has excavated a cavity in the prothallial tissue below the archegonia, from each of which a proembryo seems to be formed. This is also the case in *P. coriacea* (15, p. 101). These embryos were, with the suspensor tubes, rather contracted, but as far as could be made out resembled essentially those figured by Coker for that species.

One suspensor had penetrated vertically into the prothallus (Fig. 36, *sus.*), showing a tiny embryo of about twenty cells at the basal end (Fig. 36, *emb.*). Immediately below it, in the central cylinder, the cells were densely packed with starch (Fig. 36, *cen. cyl.*). All the cells of the cylinder were multinucleate, mostly containing four nuclei (Pl. LI, Fig. 40). This division must be very simultaneous, as the daughter nuclei are still enclosed in the limiting membrane. Miss L. Digby, in looking over the sections, came to the conclusion that the divisions are mitotic. This agrees with Coker's (15) and Miyake's (84, p. 10) conclusions. The large peripheral prothallial cells showed very little starch, but dividing nuclei.

In Pl. L, Fig. 37 the disorganized remains of the embryos and suspenders still persist (*dis. emb.* and *sus.*), but the cavity they lie in has shrunk, while the embryo has increased in size, the suspensor tubes being still traceable. Contraction of tissue is shown at the apex (Fig. 37) and similar contractions occur round the periphery of the prothallus, whose tissues are filled with starch.

In Pl. LI, Fig. 38 a section of the ovule with the ovuliferous scale is given. Stone cells are thickly scattered through the mesophyll, with no group arrangement. The vascular bundles show laminal branching (*v.b. v. s.*).

The integument has very much shrunk, centripetal lignification having begun in the cell-walls, while nothing remains of the nucellus but the cap (Fig. 38, *nuc. cap.*), still showing starch and traceable pollen-tubes.

The megaspore membrane, though present, is very difficult to see, and cannot be dissected off, but in sections a thin line of cuticle persists in iodine and sulphuric acid.

The cavity of the proembryo complex has quite closed up and the embryo is seen in the centre of the prothallus, with digested cell layers on each side, and a plug of the crushed and empty cells of the central cylinder at the base (Fig. 38, *cen. cyl.*). This embryo shows no differentiation.

In Fig. 39 the cotyledons are differentiated, also the root apex. The embryo shows resin canals surrounding the phloem, which are present even in the cotyledons. Pressed between the cotyledons and spreading

below them is the plug of the crushed axial tissue. The prothallial cells are packed with starch (Fig. 39, *st.*) which thins off towards the periphery, and where embryo digestion is in progress.

As many as eight nuclei may occur in the cells, which show up clearly in iron-alum and haematoxylin, counterstained with Congo-red (Fig. 39 *a, nuc.*)

In the Podocarps, in the endosperm tissue, all the nuclei seem to remain active, and their division suggests a correlation with the demands of starch formation, as this division is initiated at the beginning of the latter after fertilization and keeps pace with its demands.

P. bracteata.

P. bracteata, like the last species, was only seen in the Botanic Gardens of Buitenzorg. There it was a large tree, with very long narrow leaves. The leaves in this species are verticillately arranged and very large, about four inches long and three-quarters of an inch broad, markedly dark green in colour. Pilger (40, p. 80) has sunk *P. bracteata*, Bl., in *P. neriifolia*, Don, but as the plant was labelled by the former name, that designation is naturally adhered to. Only mature cones were collected.

The strobili occur singly in the axils of the foliage leaves on very short peduncles, the bract bases being much swollen, full size, and of a dull purple colour, with all trace of individual parts entirely lost (Fig. 44, *br. bs.*). The mature seed-coat is thick and resisting; lignification takes place in the cells of the integument, and involves the adjacent tissues of the ovuliferous scale as well.

Histology. The youngest prothallus in longitudinal section shows the hypocotyl with root-cap of the embryo nearly reaching to the apex (Fig. 45, *hyp.* and *rt. cap.*), where it is capped by the crushed remains of the proembryos and suspensors (Fig. 45, *crushed sus.*). Empty tissue surrounds the embryo, with a plug of the crushed cells of the central cylinder at the base (Fig. 45, *cen. cyl.*). In the embryo the outside walls of the epidermis are thickened, and two small roundish cotyledons show at the base, succeeded by the hypocotyl, in which theplerome cylinder is outlined by resin canals (Fig. 45, *r. c.*), and these occur also in the cotyledons, cortex, and root-cap. The root apex is well differentiated (Fig. 45, *rt. cap.*).

In the fully developed embryo (Fig. 46, *emb.*) the root-cap projects out beyond the prothallus (Fig. 46, *rt. cap.*), breaking through the opening left by the archegonial cavity, and pressing aside the remains of the crushed suspensor tubes (Fig. 46, *crushed sus.*).

The limiting layers of the prothallus show crushing all round the embryo, while the basal plug is still in evidence (Fig. 46, *cen. cyl.*). The rest of the prothallial tissue has undergone little diminution in area and is packed with starch (Fig. 46, *st.*). This fact suggests that the embryo, in the oldest stage available material shows, has not yet reached its full development on the parent plant, though it is unusually well organized, in

comparison with some Angiosperms, at this stage. Lloyd (32) has described vivipary in *P. Makoyi*, Bl., a species referred by Pilger (40, p. 79) to *P. macrophylla*, Don, var. *maki*, Sieb. Nauml, from Japan, grown in the United States. He describes the hypocotyls as always extruding from the ovules, while the latter are still attached to the sporophyte. No histological details are given, so that it is impossible to compare the development of the embryo in each case.

In Fig. 46 all the growth in the embryo in comparison with the previous stage (Fig. 45, *emb.*) seems limited to the hypocotyl, the cotyledons remaining almost stationary in their development.

The structure of the hypocotyl is essentially that of a root. There is a limiting epidermis with small nuclei and no starch contents; this is succeeded by the cortical layers packed with starch and penetrated by resin canals, which are chiefly aggregated towards the periphery, and surrounding the plerome cylinder. The plerome consists of elongated elements with small nuclei and no cell contents. Two procambial strands, of two or three spiral vessels, occur, one on each side of the plerome cylinder (Fig. 46, *procam. st.*), alternating with the two areas of primary bast. The central pith consists of long, narrow, rectangular cells with no contents and several resin canals. Two strands pass into each cotyledon, which arise from the respective poles of protoxylem in the hypocotyl. Resin canals are distributed as in the latter.

Fig. 47 shows an embryo dissected out.

P. neriifolia.

This species in Fiji is of Willow-like habit, and regularly outlines the streams in that country, the branches spreading over the face of the water. The strobili are conspicuous, as the bracts and ovuliferous scale are unusually long in structure, and so stand well above the dark leaves, to which their glaucous bloom forms a pleasing contrast.

It was determined as *P. bracteata*, Bl., by Seeman (48, p. 266), who first collected it in Fiji; but it does not appear to be the *P. bracteata*, Bl., as grown at Buitenzorg and put in *P. neriifolia*, Don, by Pilger (40, p. 80), nor is the Fijian plant quoted in his monograph. The structure of the leaves is quite distinct. In the latter there are two lateral resin canals, in close association with the transfusion tissue, which forms a small group on the outer side of each resin canal; whereas in the former the resin canals are medianly placed, and quite distinct from the two lateral groups of transfusion tissue.

The leaves are not quite as long as in the Javan plant, and are much narrower. The Fijian habitat also, always on the banks of streams, has not been recorded for *P. neriifolia* in any other locality.

The distribution of the latter is from East India, through Indo-China, Malaya, to New Guinea and Fiji. But the species in question from the latter country would be endemic.

The strobili occur in the axils of the upper leaves of the shoots, the peduncle varying in length from 3–5 mm. The bracts are from five to six in number, the lowest pair unmodified and caducous, the upper with the bract bases being exceptionally long and attenuated (Figs. 48 and 49, *br.bs.*); the free laminae, as usual in the order, drying up in maturer stages (Figs. 50 and 51, *lam. brs.*). The upper bracts may be either equal (Figs. 48, 50, and 51) or sub-equal in size (Fig. 49); the arrangement also varies from sub-opposite (Figs. 48–50) to sub-spiral (Figs. 49 and 51).

One (Figs. 48, 49, and 51) or two (Fig. 50) bracts may be fertile, but in the latter case, though opposite, one ovule is always younger than the other (Fig. 50), which shows, as before noted, that the opposite and decussate arrangement is merely apparent, and due to economy of space in the arrangement of the aerial portions of the members of the shoot, an arrangement always liable to modification, but that is not the inherent basis of construction.

Histology. In a microphotograph of a radial longitudinal section of this species (Pl. LIII, Fig. 78) in about the same stage as Pl. LI, Fig. 49 (dividing megaspore), the ovuliferous scale forms with the integument an unusually long micropyle. It is also very elongated in the basal region (Pl. LIII, Fig. 78).

The vascular system is of the usual type, consisting of two inverted bundles as previously described. Secondary branches run half-way down the lamina of the scale (Fig. 78), an unusual development at so young a stage. The secondary branches terminate each in a group of tracheides in the region of the micropyle. Each bundle is accompanied by a resin canal with functioning epithelium.

The *integument* shows the zone of starch and tannin cells with epidermal layer of the same. The hypodermal cells of the tip of the integument have the usual lignified and spiral thickening.

The *nucellus* is limited at the base by the zone of nutrient cells (Fig. 78). A tapetum of several layers surrounds the female gametophyte, which is in the dividing megaspore stage (Fig. 78). Older stages show many cells of the mesophyll tissue of the scale developing as stone cells. The micropyle is attenuated, the integument keeping pace in length with the long lamina of the scale, which possibly homologizes with the length of the foliage leaves in this species. The apex of the nucellus is not produced as a beak, but rather forms a depression. The nutritive zone of basal cells is very large round the nucellus, which is limited on the interior by a well-marked tapetum surrounding a contracted ♀ gametophyte in the fertilization stage.

*Flores feminei foliolis infra receptaculum destituti.**P. saligna*, D. Don.

P. saligna is well grown in several gardens in Cornwall, as *P. chilina*, L. C. Rich. The present material was obtained at Trewidden, Mr. Bolitho's place near Penzance, in March, 1909. The trees were still in their youth form of shrubby growth, fruiting at ten feet. There were very few cones, and they occurred in the axils of the lower leaves of last year's wood, and consisted of very long peduncles and three (Pl. LI, Fig. 52, *br. bs.*) or four (Fig. 53, *br. bs.*) bracts, of which one was fertile. The bract bases were green and somewhat swollen.

In Fig. 53 two bracts are of unequal size and all show a spiral tendency. This spiral tendency is carried still further in *P. spinulosa*, R. Br., judging from Pilger's figures (40, Fig. 15, II-L). In this stage stone-cell formation has invaded the whole integument, which made it impossible to get good microtome series; the female gametophyte, too, was contracted and shrunken. It seems to be the rule that, where there is a difference in the relative size of the bracts of one cone, the fertile one is generally the largest; this enlargement is probably a subsequent development correlated with nutritive requirements.

P. Totara.

Morphology. *P. Totara* is one of the finest denizens of the New Zealand forest, and may be said to be the classical tree of that country. Its dark green foliage, rather pendulous in outline, massed branching habit, and stringy bark strongly recall the Yew, a resemblance accentuated by the similar colour of the berry-like strobili. According to Cheeseman (14, p. 648), the wood is durable and much used for building purposes, and it was the favourite timber of the Maoris in the construction of their houses and war canoes. It is common in forests from the North Cape to the south-west of Otago, up to 2,000 ft.

The youngest material was collected during a two weeks' stay at Te Aroha, in the beginning of November, from a young ♀ tree in the public gardens. The stage of development ranges from the pollination or differentiated megaspore to free cell formation in the prothallus.

A great many of the ovules remained unpollinated, though there were several ♂ trees in their immediate vicinity. These strobili died off by degrees in great quantities, and, though undistinguishable in the living state, they could always be picked out in formalin by their dead appearance.

As far as it is possible to judge by present experience, it seems to be characteristic of the Podocarps, no doubt associated with the reduced

strobili, that the ovules are in much the same stage on the whole tree at one time. Even when last and this year's strobili are found there is little gradation in the stage of either.

Though constantly looked for, gradation in sizes was rarely obtainable on the same tree or even on others in the same locality.

Professor Macfarlane, on a recent visit to this country, mentioned the case of an isolated ♀ tree of *Ginkgo*, growing near Philadelphia, on which very few fruits matured each year. One year he tried the experiment of tying a bunch of ♂ flowers to the branches, with the result that the tree set a large crop of seed. The next year the experiment did not come off; he therefore decided to adhere to the exact date of the first successful result, which was again repeated, and that special date to the day has invariably proved reliable. The male trees were found to never vary in the maturation of the pollen, and by observing that date in the transportation of the ♂ flowers the crop of seeds on the isolated ♀ tree could be controlled.

The experience at Te Aroha suggests a similar condition. Several ♂ trees were quite near and covered with strobili; the one ♀ tree also bore an abundance of young cones in a lower fertile zone of the young shoots in such profusion as to be noticeable, notwithstanding their small size, on account of the glaucous bloom covering the entire strobili. Yet it was surprising how many were not fertilized. The cones would grow vegetatively for a little time and then drop off.

Possibly only those ovules in a physiologically receptive state when the pollen is shed can retain it. Stopes and Fuji (51, p. 10), in *Ginkgo*, note great uniformity in the development of the different ovules of the same tree, or even on different trees, and it has been remarked in the course of this work how uniform the stages are for the different species.

The strobili of *P. Totara* consist of three (Fig. 54, *brs.*) to four (Fig. 55, *brs.*) bracts, which in the pre-pollination stage are quite unmodified (Figs. 54 and 55, *brs.*). Two are usually fertile (Figs. 55, 58, and 59), but, as we have seen before, one ovule is always younger than the other, showing that the apparently opposite and decussate arrangement of the bracts is merely an ontogenic convenience, not related to the actual organization of the plant, and probably induced by the shortness of the axis of the strobilus, to be lost on the elongation of the same, or an increase in the number of the bracts.

When three bracts are present (Figs. 54 and 56) the arrangement is evidently spiral. Pilger does not take into consideration this contingency, where the opposite and decussate theory cannot hold good. For *P. Totara* (40, p. 84) he gives the 'receptaculum' as formed of two or four 'scales'; whereas, in the youngest stages, two bracts were not seen on the present occasion, always three (Figs. 54 and 56) or four (Fig. 55), but the third one

is completely lost sight of in the subsequent swelling of the bract bases. In section, however, the vascular strand is always traceable (Fig. 58, *v. b.*, 3 *br.*).

As growth increases the bract bases begin to swell a little, but the lamina are still distinct (Figs. 56 and 58); by the pre-fertilization stage, however, their identity may be said to be entirely lost (Fig. 59).

Histology. In longitudinal section of the pollination stage the ovuliferous scale has grown well above the bracts (Fig. 57, *o.s.*), and it shows a production of the apex above the insertion of the ovule. The vascular system of two bundles starts in this apex, each from a hypodermal group of tracheides. It spreads ring-like below the insertion of the ovule, but as far as the available material goes no laminal branching occurs (Figs. 57 and 58, *v. b. o. s.*). Resin canals with epithelium accompany the vascular supply on the ventral side, limiting the tissue of the *integument*, in which the nutritive cells are arranged in the normal zone (Fig. 59, *tan.* and *st.c.*).

The hypodermal cells at the micropyle show spiral thickening and elongation (Fig. 57, *a.*). The *nucellus* is roundly pointed, but not beaked; pollen-grains rest on the apex, but no tubes are traceable. Two or three layers of tapetal tissue limit the nucellus in the vicinity on the dividing macrospore (Fig. 57, *tap.*).

In an older stage (Fig. 58, *pro.*) the ♀ prothallus shows free nuclei. In this case the tracheides of the vascular system of the third bract come into the section, though the presence of the former is not otherwise indicated (Fig. 58, *v. b.*, 3 *brs.*).

In older stages again, collected at Auckland in October, the bract bases were already swollen up to their mature size and identical in colour with that of the Yew aril, points alone indicating the laminae (Fig. 59, *br. bs.*).

The cells of the bract bases show an increase in size and number, but not in contents, being evidently filled with a watery cell-sap. They retain their foliar structure; the proliferation of cells taking place in the mesophyll, the arrangement of the cell layers in this tissue is retained (Pl. LIII, Fig. 79).

The ovuliferous scale shows increase in length, and centripetal lignification of the cells of the integument, involving half its tissue, is in progress. A two-layered megaspore membrane surrounds the ♀ prothallus, which is very much contracted. Archegonia can be traced in the apex of the prothallus. Many of the cells show two nuclei, which would point to the maturation of the oosphere (see p. 530). This would agree with the development of the ovular tissues, and the contraction of the prothallus shows that endosperm formation has not yet been initiated.

In this case we see that the swelling and coloration of the bract bases, which are turgid with a sweet cell-sap, are present long before maturity. This development can therefore be of no use to the plant in facilitating distribution by the agency of birds, as stated by Pilger (40, p. 22).

It may possibly have this secondary result, as the berry-like swelling and sweet cell-sap persist to maturity; but such a result can hardly be described as a function, it is in fact incidental. When a modification sets in at so early a stage, and is so gradual in its accomplishment, it shows the initial cause must be more fundamental in character than a merely secondary result would demand, and it is more probably correlated with the function of the nutrition of the young ovule, as previously suggested.

The ground under the tree from which these strobili were collected was strewn with the Yew-like berries, and many were put up in formalin, both from the ground and from the tree, under the impression that they had been shed at maturity, but all were subsequently found to be in the pre-fertilization stage, as far as could be judged from the contracted prothallia.

Oliver, in a paper on the ovules of the older Gymnosperms (37, p. 455), discusses the fact that all the seeds of these plants preserved are in the stage just preceding fertilization, only occasionally being met with in an earlier state. He says:

'In the course of evolution, probably, the time of banding the integument was postponed till embryonic changes had set in, so that well-marked ovular or seed phases became very recognizable; but in the Palaeozoic seeds known to us, such a distinction can hardly be drawn. In referring to them the term *seed* is usually employed, though in recent Gymnosperms the corresponding stage would be called an unfertilized ovule. This usage in terminology has doubtless arisen from the appearance of maturity which their integumentary tissues present, a maturity which seems to preclude all possibility of subsequent expansion.'

The latter sentence might equally well have been written of the same stage in *Podocarpus*. Merely some enlargement in growth, progressive lignification of the tissue of the mesophyll and integument, and the loss of function in the resin canals, which apparently coincides with the cession of further vegetative growth, are the only vegetative features in the embryonic stages in these strobili, the ovuliferous scale being fully developed for protective purposes by the pre-fertilization stage.

Coulter and Chamberlain (18, p. 47) consider it possible that the Palaeozoic seed matured in developing a testa before fertilization, but becoming detached after pollination, developed a proembryo which subsequently aborted. Scott, in reviewing the above work (47, p. 171) in 'Nature', says: 'The interesting question of the constant absence of an embryo in all Palaeozoic seeds hitherto investigated is discussed. This has been regarded as the normal condition, the development of the embryo not having begun until the seeds were shed, and then having passed over at once into germination. The author inclines to the view that all Palaeozoic seeds investigated were abortive, having been shed prematurely. The fact that nearly all the seeds observed were in the same stage of development,

and the usual presence of normal pollen in the pollen chamber, scarcely seem consistent with this view.'

These conditions are also fulfilled in the modern *Podocarps*, as we have seen, as far as the shedding of the seed before or after fertilization, as quoted above. Such shedding may very well be due to altering conditions of temperature or water supply, or to unknown physiological conditions which demand a reduction in the number of fruits the sporophyte can mature. The demands of the purely vegetative tissues of the strobilus on account of the advanced organization of the ovuliferous scale is as great before fertilization as it is after; therefore, once initiated, the embryonic development is practically a fresh charge on the energies of the sporophyte.

P. Hallii.

P. Hallii is a scraggy, untidy looking tree, distributed over New Zealand, and is considered a variety of *P. Totara* by Pilger (40, p. 84), who makes it var. *Hallii*, Pilg. Cheeseman (14, p. 648) keeps it up as a species, and this point of view, which would be supported by any botanist who had seen both species in the field, is also borne out by histological results.

The strobili occur singly in the axils of the lower foliage leaves of lateral shoots and consist of a short peduncle, and in material investigated apparently two bracts, of which one (Pl. LI, Figs. 60, 61, 62, and Pl. LII, Fig. 64) or both may be fertile (Pl. LI, Fig. 63). The bract bases may remain either normal (Figs. 61, 62, and Pl. LII, Fig. 64), or their bases become swollen (Pl. LI, Fig. 60). The ovule is very elongated, and may be as long (Fig. 60), or even longer than the bracts (Pl. LII, Fig. 64), or shorter (Pl. LI, Fig. 61) than the same.

Histology. The material, which was collected in March, shows embryo formation, but the exact stage could not be determined, as the prothallial tissues having dried to a certain extent, the paraffin in consequence could not penetrate sufficiently well for successful sectioning.

The ovuliferous scale shows a very much produced apex, equalling that seen in *P. spicata* (Fig. 62).

The two inverted bundles, running down from the tip, show no lateral branching in the lamina (Fig. 62, *v. b. o. s.*); each sends a phloem strand from the base of the ovule into the nucellus (Fig. 62, *ph. st.*). The resin canals are very large and no longer functional, all epithelium having disappeared.

This condition was also noted by Brooks and Stiles (10, p. 311) in *P. spinulosa*, but to state that they are always functionless, as they infer, is judging cause from effect.

We have seen that in the earlier stages of the ovuliferous scale the resin canals are initiated with the vascular tissue system (Pl. LIII, Fig. 77, *r. c.*), and invariably show a well-marked and active epithelium of thin-walled cells and dense contents (Pl. XLIX, Fig. 8 *c.*). Their constant presence and

distribution (on the phloem or ventral side of the bundles) suggests that they play an important part in the very active metabolism of the ovuliferous scale, which controls the developing ovule. The complete organization of the former in the pre-fertilization stage, when even the lignification processes in the tissue of the same and of the integument have begun, also the metamorphosis of the bract bases, show how vital these rapid metabolic processes must be, as their action is so limited in period.

With the growth of the embryo the activity of the zone of tannin cells at the base of the integument and nucellus seems to cease, as in the first case the walls of the cells lignify, and in the second the entire tissue is digested by the rapidly growing ♀ gametophyte. The prothallus is about two-thirds its mature size at fertilization, and independently elaborates its own starch supplies for the nutrition of the embryo, merely drawing on the sporophyte for crude materials. The conveyance of supplies must be limited, once the nucellar tapetum no longer functions, to the phloem strands, which, as we have seen, penetrate the lignifying tissues (Pl. LIII, Fig. 72) in greater or less degree, through specialized areas. This secondary induration is different in form from that which obtains from about the pollination stage in the hypodermal cells at the apex of the integument. These cells are spirally thickened, the walls being very thick (Pl. LI, Fig. 57 *a*), and limited to a very small area.

The cells of the integument, on the contrary, show ordinary lignification of the walls with centripetal development, as seen in *P. Totara*, where in a young state only the peripheral layers were lignified, which had increased to half the tissue in the pre-fertilization stage, and it is evidently initiated in the zone of the nutrient tannin and starch cells as their available supplies are absorbed and their activity ceases.

In Fig. 62 a longitudinal section of the strobilus of this species shows three bracts, one of the upper pair fertile, and a lower sterile one, the presence of which was quite unnoticeable on examination before selection for embedding, and only revealed in the microtome series. Attention may also be called to the fact that, were the third bract placed decussately to the upper pair, the apex would not come into the radial section figured (Fig. 62, *br.* 3), but only the vascular strand seen, as figured in *P. Totara* (Fig. 58, *tra.* of 3 *v.b.*).

The tissue of the *integument* is entirely indurated and lignified, turning yellow with potash and red in phloroglucin. The nucellar tissue is crushed and empty (Fig. 62, *nuc.*).

The megaspore membrane can still be traced, limiting the ♀ prothallus—indeed it peels off on disarrangement of the tissues; the prothallus cells are packed with starch, with an embryo about half the length of the prothallus in the centre, of which the exact stage could not be distinguished, the tissue having to a certain extent dried up.

P. nivalis.

This species is a much branched erect or prostrate shrub, occurring in sub-alpine localities in New Zealand, from 2,000 to 5,000 ft. During a stay of four weeks at Mt. Cook, in the South Island, a serial collection of strobili was made, the species being very abundant about there. The material is in pollination stage, showing the breaking of nucellar tissue round the megaspore and vacuolization of the latter, and is in usually good condition.

The older shoots of this species seem to innovate, this year's strobili occurring singly in the axils of the lower leaves of this year's shoot (Pl. LII, Fig. 65, *strob.*), whereas last year's, containing young embryos, would be on the next lowest portion, separated by the scars of the bud scales.

The fertile area on the young shoots is as well marked as in *P. Totara* (see p. 552).

The strobili consist of a short peduncle bearing two (Figs. 66 and 67) or three (Figs. 65 and 68) bracts, of which one (Figs. 65-7, 69, 70) or two (Fig. 68) may be fertile. Pilger (40, p. 85) for this species, as for *P. Totara*, gives only two 'scale leaves' with one ovule, but the two ovules were as often seen as not present, as were also the three bracts (Figs. 65 and 68); the presence of the third is sometimes indicated at maturity (Fig. 69), but often all evidence is lost in the basal swelling and fusion.

In *P. nivalis* the bracts, as usual in the Eupodocarps, are unmodified in the earliest stages (Figs. 66 and 67). It is on pollination that the bract bases begin to show distinct modification.

In the oldest or young embryo stage, as in *P. Hallii*, about an equal number of examples were seen with unmodified bracts (Figs. 70 and 71), which in this species are suffused with red from the pollination stages and probably before, but there is no glaucous bloom.

Where the bases do swell up they show the same colour and consistency so familiar to us in the Yew arils, and also characteristic of *P. Totara* and *P. Hallii*; and, similarly, all trace of the third bracts, where present, is lost, the blades being reduced to mere points.

Pl. LIII, Fig. 81 is a photomicrograph of a section taken through the apex of the integument, which is enclosed in the base of the ovuliferous scale. Two bundles are shown in the scale, as yet hardly organized, the ovule being in the homogeneous nucellus stage. The lamina of the fertile bract is seen to the left, and that of the sterile one to the right.

In this species the larger ovules were in the early embryo stage, with no cotyledons. The bract bases, however, were fully coloured and developed, as was the case with *P. Totara* (Pl. LI, Fig. 59) in the pre-fertilization stage, and *P. Hallii* (Fig. 63), in which the embryo was a little more advanced. In other instances the bracts remained unmodified (Pl. LII, Figs. 70 and 71),

as described for *P. Hallii* (Pl. LI, Fig. 61 and Pl. LII, Fig. 64). Sometimes a small dead ovule would be found still attached to the strobilus (Fig. 71).

The development of the species is so similar to *P. Totara* and *P. Hallii* that no longitudinal sections are given. The chief difference is in the micropyle, which is very long, which is also the case with the integument and the apex of the prothallus. The produced conical apex of the ovuliferous scale is intermediate between the two former species. Certainly in their development as in appearance, these three species seem to be very closely allied.

CONCLUSIONS AND SUMMARY.

In the foregoing pages we have seen that much of the debatable structure of the different parts of the fruiting axis in *Podocarpus* is due to interpretation based on the study of secondary modifications alone, which are easily explained by a serial study of the process of development in early stages.

The structure of the different parts of the cone is then homogeneous; therefore it is only by tracing the serial development of the axis as a whole from the bud to the fruit that the progressive sequence of the evolution of the structure and the specific development of its different parts can be offered.

This study at the same time strikingly reveals the relationship of the axis to the strobilus or cone of the Abietineae and its component parts, a relationship previously suggested by Bennett and Brown (2), Sperk (50), and Bertrand (3), and recently supported by Tison, in *Saxegothaea* (57).

These authors all consider the ovuliferous envelope of the Podocarpoideae as analogous with the ovuliferous scale of the Abietineae, which, to quote Bertrand (3), 'from the Abietineae to the Taxineae through *Saxegothaea* and the Podocarps shows a general tendency to surround in a hood-like fashion the ovule or ovules which it carries, fusing more and more till finally it merges in the ovular integument in *Torreya* and *Cephalotaxus*'. Bertrand traces a further reduction in strobilus organization in the fewer number of bracts and increased independence of the ovuliferous scale for protective purposes, through *Microcachrys* and *Dacrydium* until the final reduction is reached in *Podocarpus*.

Tison has confirmed this interpretation for *Saxegothaea*, in which he considers the so-called aril of earlier botanists and the 'epimatium' of Pilger to be the ovuliferous scale of the other Conifers, the summit of which is developed to protect the ovule, the coalescence of the different parts of the female cone being less than in the other genera, where there is less development of the fertile bract above the ovule, whose base is partially protected by the ovuliferous scale. In other species of *Podocarpus* the bracts only develop below the ovule, which is encircled by the ovuliferous scale.

Correlated with the gradual independence in function of the ovuliferous scale, we get a gradual change in the relation of the ovule to the scale.

In the Abietineae two ovules are placed at the base of the scale, one on each side, which is the most economic arrangement where the cone itself is organized for protective purposes. In Araucarineae one ovule is inserted medianly on the scale. In the Podocarpoideae, as Pilger has noted (40, p. 16), we get a gradual pushing up of the ovular rudiment on the 'epimatium' or ovuliferous scale.

In *Saxegothaea* the apex of the ovuliferous scale is a homogeneous membrane, without vascular structure, merely protective in the pollination stages, the ovule being inserted towards the base of the bract and remaining free from the same, except at the base. The two inverted strands which supply the ovule are spoken of by Tison as the ovular supply; they are described as being without resin canals, and insert themselves on the vascular bundle of the bract at the base of the same, with a semi-rotation similar to that obtaining for the bundles of the ovuliferous scale in *Podocarpus* when they insert themselves between the bundles of the strobilus. It is impossible to draw any close comparison between *Saxegothaea* and *Podocarpus* in these respects, as the exact delimitation of the tissues of the ovuliferous scale and bract respectively are not insisted on.

From a cursory examination of *Dacrydium* (on which it is hoped to publish results later) it is possible that in that genus good intermediate series between *Saxegothaea* and *Podocarpus* will be found, showing the retrogression in the development of the fertile bract above the scale, and the increase in the protective function of the latter, which, however, does not fold round the highly inserted ovule, while on the other hand the coalescence of the different parts of the cone is still marked.

In *Podocarpus* we find a similar series, showing the course of reduction in the cone, the actual strobilus organization appearing only in the youngest stages, as subsequently the laminae of the bracts composing the cone do not develop further. The ovuliferous scale takes on an entirely independent organization, analogous to that of the foliage leaves, and completely surrounds and protects the ovule, which, as it grows up, it carries well above the bracts of the strobilus, the insertion of the ovule being towards the apex of the scale. This independent function is correlated with a great reduction in strobilus organization, the fertile bracts decreasing in number until they are limited to one or two in an apical position as the cone decreases in size and protective organization.

In Pilger's excellent monograph of the Taxaceae the Podocarpoideae are classified according to the progressive development of the 'epimatium', which he regards as an accessory organ, a ligula-like excrescence of the 'carpel', through *Microcachrys*, *Saxegothaea*, and *Dacrydium* to *Podocarpus*, in which family this organ reaches its maximum development.

It is interesting to note that this arrangement accords completely with the views of the authors quoted above, and also with the results of the present work on *Podocarpus*, as progressive development of the ovuliferous scale is correlated in each stage with reduction in strobilus formation.

The systematic position therefore remains on Pilger's basis, by merely substituting ovuliferous scale for 'epimatium'.

Morphologically the results may be summarized as follows:

In *Podocarpus*, in the youngest phases, a strobilus formation obtains which is masked by subsequent modification.

An actual series of successive stages in the reduction of the strobilus is apparent in the different sections of the family.

In § DACRYCARPUS the peduncle is clothed with scale leaves, in spiral sequence, which show increase in size just below the strobilus.

The strobilus is reduced to two to five bracts, of which one to three may be fertile.

In these bracts, which are more or less unmodified in the younger stages, the bases show subsequent swelling and coalescence, ultimately changing colour, but the laminae remain green and unaltered.

The lamina of the fertile bract is fused with the ovuliferous scale to the apex of the latter, showing the cohesion between the scale and the supporting bract seen in *Microcachrys* and *Saxegothaea*, as also in *Agathis*, *Araucaria*, and the *Abietineae*.

In § DACRYCARPUS this fusion may be complete, as in *P. dacrydioides*, or sometimes incomplete, as in *P. imbricata*, where the apex of the fertile bract often remains free, and may even exceed that of the scale.

The ovuliferous scale entirely enfolds the ovule, leaving an orifice at the micropylar end where the integument protrudes on pollination; but subsequent growth in the lamina of the scale, and swelling at the base of the same on the ventral surface, cause the micropyle to be pressed against the lower portion of the scale, closing up the orifice.

In § NAGEIA (if *P. vitiensis* can be taken as typical of that section) and § STACHYCARPUS the peduncle (branched in the former) is still clothed with scale leaves, showing increase in size below the strobilus.

The strobilus consists of eight to ten bracts, of which all, or only one or two of the apical ones, are fertile. These bracts are fleshy and strap-like in the youngest stage, and opposite and decussate in arrangement. There is no subsequent swelling of the bases, and the laminae may be shed on or before fertilization, leaving only scars, which show a spiral sequence, due to elongation of the axis.

The lamina of the ovuliferous scale develops quite independently of the lamina of the fertile bract, which enfolds and protects the former in the youngest stages, but either remains undeveloped as a ring at the base, or is subsequently shed.

§ EUPODOCARPUS offers the greatest extreme in the reduction of the strobilus in the genus, from the point of view of number of members, but the cone-like organization is nevertheless obvious in the young stages.

The peduncle is naked, and the bracts of the strobilus may be reduced to two. In some species the two lower retain the strap-like unmodified form we get in § STACHYCARPUS, and are merely protective in the young stages, being subsequently shed as in that section. In *P. spinulosa* (40, p. 77) the bases often swell up like those of the upper bracts. In other species they are finally eliminated altogether.

The upper bracts, of which one or two are fertile, are unmodified and protective in the young stage, but their bases soon swell and become coloured as in § DACRYCARPUS; the laminae, however, do not persist, as in that section, but become entirely merged in the basal swelling, all subsequent development being arrested.

The secondary swelling and coloration of the bract bases in some cases is already present in the pre-fertilization stage; its presence can therefore be of no use to the plant in the dissemination of seeds, as stated by Pilger, but is probably correlated with ovular development by serving as water-storage tissue.

The ovuliferous scale is well protected by the sterile bracts in the young stages, but gradually rises above them until, on pollination, the lamina of the fertile bract alone encircles the base as a ring, remaining stationary in development. The ovuliferous scale takes on not only the whole protective covering of the ovule, but by the early and complete organization of its metabolic activities supplies the material for the development of the ovule as well.

Judging from the stages obtained in the material collected, development occurs in the early spring. In Fiji this season is in August and September, and material collected in those months showed pollination and young embryo stages. In New Zealand at the same season, in September and October in the North Island, *P. ferruginca* and *P. Totara* showed pollination and post-pollination stages and pre-fertilization. In the South Island, at Mount Cook, at an altitude of 2,500 ft., *P. nivalis* showed pollination to young embryo stages in December and January, while further south, at Glade House in March or autumn, *P. Hallii* was found in the embryo stage.

At Buitenzorg, enlarging megaspore and pre-fertilization stages were found associated in December, and on other trees embryos, mature and immature, were also collected.

As is the case with the Abietineae, last year's cones were generally found concurrently on the old wood with those developed on this year's wood above them.

There is a very marked uniformity in the stages of development of the

ovules in the strobili of each period. It is probable that this feature is associated with the great reduction in the number of fertile bracts to each cone. The same fact has been recorded for *Ginkgo*.

HISTOLOGICAL RESULTS.

The ovuliferous scale shows the complete organization of a foliage leaf with epidermis, stomata, and mesophyll tissue. It is provided with a well-developed vascular system with inverted orientation, and accompanied by resin canals.

In § DACRYCARPUS a hypodermal sclerotic layer is present in both the ovuliferous scale and the foliage leaves.

In § STACHYCARPUS, on pollination, groups of stone cells form a regular zone in the mesophyll tissue. In *P. ferruginea* these were also present in the foliage leaves.

The cells of the mesophyll show secondary thickening throughout the group, which is initiated before fertilization.

The vascular system of the ovuliferous scale consists of two bundles (*P. vitiensis* four), each accompanied by a resin canal. These arise each at the extreme apex of the scale in a hypodermal group of tracheides, as is also the case in the foliage leaves. They branch in a ring below the insertion of the ovule, half-way down the scale. From this ring secondary branches may run into the lamina of the scale, so encircling the ovule; these branches stop half-way down the lamina or continue right to the micropyle, and are always terminated by groups of tracheides.

Below the ovule the main bundles separate, and by a gradual semi-rotation the phloem becomes peripherally placed when they insert themselves, one on each side of the vascular strand of the fertile bract, on to the ring of bundles in the strobilus.

Resin canals accompany each bundle on the phloem side. These are very active, with well-developed epithelium, and evidently play an important part in the metabolism of the scale. Their function gradually ceases on the organization of starch formation in the female prothallus. In later embryo stages the epithelium is no longer traceable.

The resin canals limit the tissue of the integument in the plane of the mesophyll tissue of the scale.

The integument shows basal growth, and its small regular cells stand out well from the irregular mesophyll of the scale. Long lignified hypodermal cells are differentiated in the apex, at the micropyle, at pollination, at which stage also a nutritive zone of starch and tannin cells (*cellules tannifères* of Tison) is laid down round the base and sides of the nucellus till the prothallus is fully organized, when, as is the case with the resin canals, the

function of these cells apparently ceases and the walls gradually lignify, areas being left where phloem strands penetrate to the nucellus.

In *P. ferruginea* these tannin cells are organized in regular superposed layers, laterally elongated, which surround the integument.

The nucellus, composed of larger and less compact cells, is also characterized by a smaller zone of tannin cells. Before pollination the apex shows rows of loose stigmatic cells, which catch the pollen-grains. These cells subsequently become crushed on the elongation of the tubes; the latter are often exposed in consequence.

No pollen-grains or cases of penetration by pollen-tubes were observed from any portion of the nucellus other than the stigmatic apex.

In § NAGEIA and § STACHYCARPUS, also some species of § EUPODOCARPUS, the apex of the nucellus is very much elongated.

From the pollination stages starch is present in the cells of the apex in all species, and the walls often show thickening.

A well-differentiated tapetum of several layers is present in all the species examined, the cells with active nuclei and denser contents showing continuous disintegration in the outer layer, from the development of the megaspore to the absorption of the body of the nucellus by the female gametophyte.

Tetrad formation was not seen.

In megaspore formation the nucleus divides, a parietal layer of free nuclei surrounding the central vacuole, which gradually fills up with prothallial tissue. Further stages were not traceable, owing to contraction of tissue, but are evidently paralleled with Coker's results on *P. coriacea* and similar development in the Abietineae.

A megaspore membrane of two layers was observed in all the species surrounding the developing prothallus, which persists till the embryo stages. In *P. polystachya* it was not traceable with certainty in the embryo stage.

The female prothallus at fertilization consists of a central cylinder of small elongated and rectangular cells, and large, mostly binucleate, polygonal cells extending to the periphery, and it is limited by an epidermal layer of small uninucleate cells, with denser contents and active nuclei.

The number of archegonia seen was five to seven.

The archegonia, arranged in one or two groups, are very long and flask-shaped. The neck consists of two to six cells, and they are each surrounded by a single layer of jacket cells.

In one case two archegonia were enclosed in one jacket.

No ventral canal cell was seen.

Sterile prothallia, with a cavity replacing the archegonia, were observed. In one case no tracheides were present, but on two occasions well-developed tracheides were found in the central cylinder of small-celled tissue.

A complex of proembryos with suspensors forms a cavity at the apex of the prothallus. One suspensor develops an embryo which penetrates the central cylinder. Starch formation is initiated in the central cylinder cells immediately below the embryo, and mitotic divisions occur in the cells. The two divisions must follow one another in rapid succession, as four daughter nuclei are generally seen enclosed in the same limiting membrane. These nuclei further divide up to eight, remaining active and normal even when the cells are packed with starch.

The cavity formed by the complex gradually closes up as the embryo increases in size. Resin canals surround theplerome cylinder before the cotyledons are differentiated, and appear in their tissue as soon as the latter develop.

In the mature embryo the root-cap extrudes through the apex of the prothallus.

The cortical tissues of the embryo are packed with starch, but none is seen in the cells of the plerome cylinder.

The structure of the hypocotyl is that of a diarch root, and has two areas of primary bast alternating with two poles of the protoxylem, showing spiral vessels. Two branches from each pole pass to each cotyledon.

Resin canals are present in the root-cap, hypocotyl, and pith of the mature embryo.

The acquisition of a considerable quantity of material in various young stages has rendered it possible for the first time to bring forward a certain amount of evidence in favour of the view that in *Podocarpus* we are dealing with a much modified cone. The cone character is well seen at an early stage, but subsequent developments, including the swelling of the bract bases at the expense of the lamina, or the shedding of the latter and the great development of the ovuliferous scale, together with the reduction in the number of fertile members (usually only one), completely mask the strobilus organization. This view was formulated by Bennett and Brown (2) as early as 1838, and later by Sperk (50) and Bertrand (3), and quite recently by Tison (57), working on *Saxegothaea*. With the exception of Tison these authors were limited to herbarium material.

In conclusion, my thanks are due in New Zealand to Mr. T. F. Cheeseman, Curator of the Auckland Museum, for most useful data on localities and seasonal developments, and also for the inestimable aid rendered by his admirable 'Manual of the New Zealand Flora'; to Mr. F. Grey, of Nelson, for his indefatigable kindness in arranging expeditions in that district, of which his steady botanical exploration has given him an unrivalled knowledge; and to Professor Charles Chilton, of Christchurch, for his kindness in allowing me to avail myself of laboratory facilities at the University to test material obtained.

I must also express my indebtedness to Herr H. J. Wigman, the Director of the Botanic Gardens at Buitenzorg, for material obtained from the gardens, and for facilitating my stay at Tsjibodas; also to Mr. H. N. Ridley, F.R.S., C.M.G., Director of the Botanic Gardens at Singapore; and finally to Professor J. B. Farmer, F.R.S., for his great kindness and the invaluable facilities afforded me at the Royal College of Science during the course of this investigation.

EXPLANATION OF PLATES XLIX-LIII.

Strob., strobilus; *ped.*, peduncle; *s.*, scale; *bud s.*, bud scales; *l.*, leaf; *s.l.*, scale leaves; *br.*, bract; *s. br.*, sterile bract; *f. br.*, fertile bract; *b. br.*, base bract; *lam.*, lamina; *ap. bud.*, apical bud; *ap.*, apex; *o. s.*, ovuliferous scale; *mic.*, micropyle; *i.*, integument; *nuc.*, nucellus; *o.*, ovule; *v. b. f. br.*, vascular bundle, fertile bract; *v. b. o. s.*, vascular bundle, ovuliferous scale; *x.*, xylem; *ph.*, phloem; *ph. str.*, phloem strands; *tr.*, tracheides; *r. c.*, resin canal; *mes.*, mesophyll; *c.*, cells; *stone c.*, stone cells; *st.*, starch; *t.*, tannin; *h. f.*, hypodermal fibres; *e.*, epidermis; *stom.*, stomata; *idio.*, idioblasts; *tis.*, tissue; *lig.*, lignified; *m. m.*, megaspore membrane; *pro.*, prothallus; *meg.*, megaspore; *tap.*, tapetum; *arch.*, archegonia; *in.*, initials; *n.*, nucleus; *e. n.*, egg nucleus; *j. c.*, jacket cells; *n. c.*, neck cells; *p. g.*, pollen-grain; *p. t.*, pollen-tube; *nuc. cap.*, nucellus cap; *pro. emb.*, proembryos; *sus.*, suspensor; *cen. cyl.*, central cylinder; *dig. c.*, digested cells; *cots.*, cotyledons; *pl.*, plerome; *plu.*, plumule; *hyp.*, hypocotyl; *rt. cap.*, root-cap; *pro. cam. str.*, procambium strands; *cor.*, cortex; *stig. ap.*, stigmatic apex; *gen. n.*, generative nucleus; *stalk n.*, stalk nucleus; *tube n.*, tube nucleus; *cup. l.*, cupressoid; *imb.*, imbricate; *epi.*, epithelium.

PLATE XLIX.

Fig. 1. *P. imbricata*. Branch showing strobili in two stages: this year's with unmodified bracts, in early pollination stage; last year's with bract bases swollen at the expense of the lamina, in pre-fertilization stage. Nat. size.

Fig. 2. Strobilus with two bracts, each fertile; bract bases swollen and verruculose; scale leaves subtending strobilus removed. $\times 16$, red. $\frac{1}{2}$.

Fig. 3. Strobilus with two bracts, one fertile; showing the apex of the fertile bract unusually free and prolonged, and larger size of the scale leaves of the peduncle immediately subtending the strobilus. $\times 16$, red. $\frac{1}{2}$.

Fig. 4. Strobilus with four bracts, one fertile, with apex still free, in fertilization stage; the peduncle is covered with imbricating scale leaves, those subtending the strobilus showing less modification as the latter increases in size. $\times 8$, red. $\frac{1}{2}$.

Fig. 5. Sterile strobilus, showing base of ovuliferous scale swollen and verruculose (Singapore). $\times 8$.

Fig. 6. Longitudinal section through ovuliferous scale and ovule in pre-fertilization stage, showing lamina of fertile bract, with normal vascular bundle, fused with the lamina of the scale, with inverted vascular system, both enclosing the ovule; epidermis, hypodermal layer of fibres, and mesophyll with lignified idioblasts are continuous for both; the integumental tissue is limited by the resin canals and shows a zone of nutritive cells, i.e. tannin and starch; lignified cells occur in the apex, at the micropyle; the nucellus shows also a zone of nutritive cells, and starch is deposited in the cells of the apex; a tapetum showing continual breaking down of tissue limits the nucellus on the inside; the female gametophyte is invested by a two-layered megaspore membrane, and shows archegonia; the cells of the prothallus are binucleate. $\times 16$, red. $\frac{1}{2}$.

Fig. 6a. Archegonium with contracted protoplasm and resting egg nucleus, showing neck cells at apex, surrounded by jacket cells. $\times 625$.

Fig. 6b. Two archegonia in one jacket, seen in a prothallus of another species. $\times 625$.

Fig. 6c. Idioblasts in mesophyll tissue.

Fig. 7. Strobilus with two bracts, one fertile, from the subsummit zone of Kinabalu (11,500 ft.), in which the scale leaves do not spread out below the bracts, as in Fijian and Buitenzorg material; pollination stage; the apex of the lamina of the fertile bract projects above the ovuliferous scale. $\times 16$, red. $\frac{1}{2}$.

Fig. 8. Longitudinal section of strobilus in pollination stage or after; the fertile bract shows distinct apex, which becomes obscured as ovule matures; the nucellus is contracted, but pollen-tubes can be traced in the apex. $\times 16$, red. $\frac{1}{2}$.

Fig. 8a. Hypodermal layer of fibres in the lamina of the fertile bract and that of the ovuliferous scale, with epidermis. $\times 625$.

Fig. 8b. Verruculose outgrowths on the swollen bract bases, the epidermis showing tannin contents; no hypodermal layer of fibres. $\times 625$.

Fig. 8c. Resin canal with epithelium of thin-walled cells with active nuclei and darker staining contents, surrounded by cells containing tannin and starch. $\times 625$.

Fig. 9. *P. dacrydioides*. Longitudinal section of pollination stage; tannin and starch cells show at the base of the integument and nucellus, with starch in the apex of the latter, and a well-marked tapetum limiting on the inside; megaspore shows dividing nuclei. $\times 16$, red. $\frac{1}{2}$.

Fig. 10. Peduncle with imbricating scale leaves, terminated by strobilus of three bracts, one fertile, the lamina of which is fused with the ovuliferous scale. $\times 8$.

Fig. 11. Strobilus showing two bracts, one fertile, older stage. $\times 8$.

Fig. 12. Strobilus of three bracts, one fertile. $\times 8$.

Fig. 13. Longitudinal section of above stage: the prothallus is contracted, but shows centripetal filling by free nuclear division. $\times 16$, red. $\frac{1}{2}$.

Fig. 14. *P. vitiensis*, showing position and branching of peduncles, each branch bearing a strobilus with one fertile bract; the ovules are in the fertilization stage, the upper ones on simple peduncles being younger. Nat. size.

Fig. 15. Young strobilus, showing peduncle with imbricating scale leaves; the strobilus is composed of five pairs of bracts, opposite and decussately arranged, with one of the upper pair fertile; the lamina of the fertile bract is free from the ovuliferous scale, which bears an ovule with undifferentiated nucellus. $\times 16$, red. $\frac{1}{2}$.

Fig. 16. Peduncle with eight bracts, of which the upper two are fertile; the ovuliferous scales bearing the ovules have grown far above the lamina of the fertile bracts; these laminae, with those of the sterile bracts, subsequently desiccate and fall off, leaving only the elongated bract bases, as in the last species, which remain unmodified; fertilization stage. $\times 16$, red. $\frac{1}{2}$.

PLATE L.

Fig. 17. Longitudinal section of above stage, showing the growth of the lamina of the ovuliferous scale, that of the fertile bract remaining stationary; the prothallus shows contraction, but archegonia are traceable in its tissue: σ prothallia show above the archegonia, the stage being just prior to fertilization. $\times 16$, red. $\frac{1}{2}$.

Fig. 18. Male prothallus with pollen-tube, which has penetrated the unusually long apex of the nucellus, showing two generative nuclei, with stalk and tube nucleus. $\times 245$.

Fig. 19. *P. spicata*. Bbranch showing strobili in the axils of the foliage leaves. Nat. size.

Fig. 20. Strobilus bearing three fertile tracts, showing bud scales at base, and modified foliage leaves above, which are succeeded by the fertile bracts and an apical bud. $\times 16$, red. $\frac{1}{2}$.

Fig. 21. Strobilus of which the apical bud has been damaged, leaving only a cicatrized scar; this fact has probably stimulated the development of the modified leaves into foliage leaves; one fertile tract on the shoot. $\times 16$, red. $\frac{1}{2}$.

Fig. 22. Longitudinal section of strobilus, showing produced apex of ovuliferous scale. A regular zone of stone cells occurring in groups of two or three is seen in the mesophyll; phloem strands penetrate to the nucellus, and the vascular bundles send secondary branches into the lamina of the scale; the prothallus shows contraction, but free cell-division can be traced. $\times 16$, red. $\frac{1}{2}$.

Fig. 22a. Section through micropyle, showing non-septate closing cells. $\times 625$.

Fig. 23. Stone cells in the mesophyll of the ovuliferous scale. $\times 625$.

Fig. 24. *P. ferruginea*. Strobilus with peduncle in the axil of a foliage leaf; the fertile bract slightly covers the ovuliferous scale; pollination stage. $\times 8$.

Fig. 25. Strobilus in younger stage with scale leaves dissected off the peduncle; the bracts are still folded and protect the ovule enclosed in the scale; the nucellus is undifferentiated. $\times 16$, red. $\frac{1}{2}$.

Fig. 26. Strobilus and peduncle still enclosed in the scale leaves investing the latter. $\times 16$, red. $\frac{1}{2}$.

Fig. 27. Peduncle bearing strobilus composed of six pairs of bracts, of which one of the uppermost pair is fertile; the ovuliferous scale shows above the bract; scale leaves clothe the peduncle. $\times 16$.

Fig. 27a. Ventral view of same, showing micropyle. $\times 16$, red. $\frac{1}{2}$.

Fig. 28. Strobilus with two fertile bracts; ovuliferous scale has grown up above the bracts, of which only the bases persist, the laminae having shrunk to pin points; scars indicate the sterile bracts, of which the laminae have already been shed; pre-fertilization stage. $\times 8$, red. $\frac{1}{2}$.

Fig. 29. Longitudinal section of strobilus slightly older than above stage; phloem strands penetrate to the nucellus from the vascular bundles; the tannin cells of the integument show a symmetrical, laterally elongated arrangement; pollen-tubes have penetrated half-way down the apex of the nucellus, and the very contracted prothallus shows cell-wall formation; a scar is all that remains of the lamina of the fertile bract; in section the arrangement of the bracts in the strobilus is seen to be more spiral than opposite and decussate, as the morphology would suggest. $\times 8$, red. $\frac{1}{2}$.

Fig. 30. *P. elata*. Earliest stage, showing strobilus of four bracts, the lower pair being narrower than the upper, of which one is fertile; all four enclose the ovuliferous scale. Ventral view, the opposite sterile bract having been removed. $\times 16$.

Fig. 30 a. Dorsal view of fertile bract, showing unmodified lamina and base. $\times 16$.

Fig. 31. Older stage, ovuliferous scale showing above the bracts, which are becoming broader and thicker. $\times 16$.

Fig. 31 a. Lateral view, showing both upper bracts, with the lower pair dissected off. $\times 16$.

Fig. 31 b. Ventral view of same, showing micropyle. $\times 16$.

Fig. 32. Strobilus showing lower bracts which remain undifferentiated; the upper pair show shrinking laminae and swollen bases. Pollination stage. $\times 16$.

Fig. 32 a. Ventral view of above, showing sterile bract cut off, to expose micropyle. $\times 16$.

Fig. 33. Strobilus with ovule showing young embryo; the unmodified bracts still persist, the upper bracts show very swollen bases and laminae shrunk to points; the ovuliferous scale extends above the fertile bract. $\times 16$, red. $\frac{1}{2}$.

Fig. 34. Group of tracheides terminating a vascular bundle in the lamina of the ovuliferous scale. $\times 625$.

Fig. 35. *P. polystachya*. Strobilus with ovule, showing embryo; the unmodified lower bracts have been shed and in the upper ones all foliar structure is lost, the lamina being no longer indicated, while the bases are fused in a succulent whole. Nat. size.

Fig. 36. Longitudinal section of prothallus, showing complex of proembryos, one being formed from each archegonium; the suspensor bearing successful embryo is seen penetrating the central cylinder of prothallus, the cells of which are binucleate, and those immediately below the embryo show dense starch contents. $\times 245$.

Fig. 37. Longitudinal section of prothallus, showing embryo increasing in size at the expense of the central cylinder; the remains of the suspensor tubes are still traceable, also the cavity formed by proembryos, with disorganized remains of complex; contraction of tissue is shown at the apex of the prothallus, causing the epidermal layer to fold in and out. $\times 16$.

PLATE LI.

Fig. 38. Longitudinal section of ovule enclosed in the ovuliferous scale, showing stone cells scattered in the mesophyll of the latter, also laminal branching of the vascular bundles; the integument shows lignification of the cell-walls and the nucellus is reduced to the apex, which, still showing starch and pollen-tube, forms a mere cap; the prothallus has grown at the expense of the nucellar tissue, and shows an undifferentiated embryo; the cavity left by the complex of proembryos has almost closed, though still filled with the crushed remains; digested cells surround the embryo, and the crushed and empty tissue of the cells of the central cylinder is being pushed down as a plug by the vertical growth of the embryo. $\times 16$, red. $\frac{1}{2}$.

Fig. 39. Longitudinal section of embryo, showing differentiation of the cotyledons, root apex, and resin canals; the dotted area shows the relative distribution of starch in the prothallus, of which the cells, excluding the peripheral layer, are multinucleate. $\times 8$, red. $\frac{1}{2}$.

Fig. 39 a. Multinucleate cells of the prothallus, packed with starch grains. $\times 625$.

Fig. 39 b. Peripheral layer of the prothallus, with megaspore membrane. $\times 625$.

Fig. 40. Nucleus in prothallial cells, on initiation of division, showing four daughter nuclei still enclosed in the limiting membrane, as seen in Fig. 36, in the cells of the central cylinder, just below embryo. (L. Digby del.)

Fig. 41. Sterile strobilus borne on same tree as the fertile one drawn in Fig. 35. Nat. size.

Fig. 42. Longitudinal section of above. In this prothallus, which contains no starch, tracheides are developed in the central cylinder; a cavity occurs where the archegonia would normally be found. $\times 16$.

Fig. 43. Tracheides as seen in the central cylinder of small-celled tissue of sterile prothallus. $\times 625$.

Fig. 44. *P. bracteata*. Mature strobilus, with swollen bract bases, deep purple in colour (Buitenzorg). Nat. size.

Fig. 45. Longitudinal section of embryo, showing cotyledons, with plerome cylinder and cortical resin canals. $\times 8$, red. $\frac{1}{2}$.

Fig. 46. Longitudinal section through prothallus, showing embryo with extruding root-cap; in the embryo resin canals occur both in the cortex and the pith; procambium strands of spiral vessels mark the plerome cylinder; the cotyledons show similar development, each being served with two vascular strands. $\times 8$, red. $\frac{1}{2}$.

Fig. 47. Embryo dissected out. $\times 8$, red. $\frac{1}{2}$.

Fig. 48. *P. neriifolia*. Strobilus in earliest stage available, with four bracts, one of which is fertile; the lowest pair of unmodified bracts have been cut off, showing two pairs of upper bracts, apparently opposite and decussate (Fiji). $\times 8$, red. $\frac{1}{2}$.

Fig. 49. Later stage, strobilus with three bracts, one of which is fertile, showing approach to spiral arrangement. $\times 8$, red. $\frac{1}{2}$.

Fig. 50. Strobilus of three bracts, of which two are fertile; the caducous lower bracts have already been shed; the upper ones show shrunken laminae and swollen bases. $\times 8$, red. $\frac{1}{2}$.

Fig. 51. Fertilization stage. Nat. size.

Fig. 52. *P. saligna*, showing a strobilus of three bracts, of which one is fertile; the peduncle, in this species, is very elongated. $\times 8$, red. $\frac{1}{2}$.

Fig. 53. Basal portion of a strobilus with four bracts, showing a modification of the decussate arrangement. $\times 8$, red. $\frac{1}{2}$.

Fig. 54. *P. Totara*. Strobilus of three bracts, still undifferentiated, one of which is fertile; ovule in pollination stage. $\times 8$.

Fig. 55. Strobilus of four bracts, two of which are fertile; the oldest ovule shows nuclear division in macrospore. $\times 8$.

Fig. 56. Strobilus with three bracts, of which two are fertile; the oldest ovule shows free cell formation in the prothallus. $\times 8$.

Fig. 57. Longitudinal section of Fig. 55, showing well-differentiated tapetum and enlarging macrospore. $\times 16$, red. $\frac{1}{2}$.

Fig. 58. Longitudinal section of a strobilus with three bracts; in the largest ovule the female gametophyte shows free nuclear division, while the youngest is in the enlarging megaspore stage. $\times 16$, red. $\frac{1}{2}$.

Fig. 59. Strobilus with four bracts, of which two are fertile; the laminae are barely indicated, but the bases have swollen to a large size, and are of a bright red colour; the ovules are in the pre-fertilization stage, the peripheral half of the integument showing lignification of the cells.

Fig. 60. *P. Hallii*. Strobilus with bases of bracts swollen and red in colour, one bract being fertile; the ovule is in young embryo stage. $\times 8$, red. $\frac{1}{2}$.

Fig. 61. Strobilus in which the bract bases have remained unmodified; one bract is fertile, with ovule in young embryo stage. $\times 8$, red. $\frac{1}{2}$.

Fig. 62. Longitudinal section of a strobilus with three unmodified bracts, the upper one fertile; the ovuliferous scale shows stone-cell thickening in the mesophyll and very large resin canals, also phloem strand penetrating the integument; the integument is entirely lignified, with the exception of a few cell layers in proximity to the nucellus, which is mostly digested by the prothallus; the latter is surrounded by a well-developed megaspore membrane and contains a young embryo. $\times 16$, red. $\frac{1}{2}$.

Fig. 63. Strobilus with two fertile bracts. Nat. size.

PLATE LII.

Fig. 64. Strobilus with bract bases unmodified and shorter than the ovule.

Fig. 65. *P. nivalis*, showing a strobilus with three bracts, still undifferentiated, one of the lower bracts being fertile; the strobilus is in the axil of a foliage leaf of the axis. $\times 8$.

Fig. 66. Strobilus with two undifferentiated bracts, one of which is fertile; the ovule is in the pollination stage. $\times 8$.

Fig. 67. Strobilus with two bracts, one of which is fertile; enlarging macrospore stage. $\times 8$.

Fig. 68. Strobilus with three bracts, two of which are fertile; macrospore stage with dividing nuclei. $\times 8$.

Fig. 69. Strobilus with three bracts, one of which is fertile; the lamina of the bracts are reduced to points, while the bases are much swollen and of a bright red colour; young embryo stage. $\times 8$, red. $\frac{1}{2}$.

Fig. 70. Strobilus with two bracts, both unmodified; ovule in young embryo stage. $\times 8$, red. $\frac{1}{2}$.

Fig. 71. Strobilus with three bracts; the lamina of one bract with an undeveloped ovule is dead. $\times 8$, red. $\frac{1}{2}$.

PLATE LIII.

Sections cut $2-3\ \mu$ on a Minot microtome.

Fig. 72. *P. vitiensis*. Transverse section through an ovule in the pollination stage, taken below the base of the nucellus, where the four bundles of the scale break up into branches which run down the lamina of the same (Fig. 17). In this case eight branches can be counted; the integument shows a thick ring of tannin and starch cells, the walls of which are becoming lignified. This ring is seen penetrated in two places by phloem strands from the vascular system (Fig. 17). The tannin cells surrounding the base of the nucellus are seen in the integument, which is limited by an epidermal layer of tannin cells. Similar cells mark the peripheral layer of the nucellus, which is bounded on the inside by the tapetum in which lies the dividing macrospore. $\times 24$.

Fig. 73. Transverse section, same series, taken through the micropyle and the base of the ovuliferous scale, just above the apex of the nucellus where the four bundles have again approximated. $\times 25$.

Fig. 74. *P. spicata*. Longitudinal section of nucellus only, showing the well-marked tapetum, megaspore membrane, and free cell formation in the prothallus. $\times 120$.

Fig. 75. Longitudinal section of ovule, showing zone of stone cells (torn) in the ovuliferous scale, with the zone of tannin and starch cells lining the integument and the nucellus. The cells at the apex of the nucellus contain starch and show some pollen-tubes; on the inside the nucellus is limited by the tapetum. The prothallus is very much contracted, but the megaspore membrane can be traced folding in and out with the prothallial tissue, which shows cell-wall formation. $\times 45$.

Fig. 76. *P. ferruginea*, longitudinal section of young strobilus in the stage of Fig. 25. It shows an undifferentiated nucellus with basal cell growth and a limiting layer of tannin cells to the nucellus and the free portion of the integument; in the ovuliferous scale the tannin cells at this stage are limited to the epidermis and two or three hypodermal layers. $\times 27$.

Fig. 77. Transverse section through the nucellus, integument, and bract bases of the same stage. The two vascular bundles are seen with the xylems converging, whereas in the apex of the scale the phloems face each other. This rotation finally leads to a normal orientation as the bundle slips into its place in the ring of leaf-traces in the strobilus. $\times 42$.

Fig. 78. *P. neriifolia*. Longitudinal section of strobilus in pollination stage (Fig. 49), showing a very attenuated ovuliferous scale; a well-marked tapetum is seen in the nucellus, enclosing the enlarging megaspore. $\times 7$.

Fig. 79. *P. elata*. Longitudinal section of strobilus with undifferentiated nucellus (Fig. 31), showing modified bracts with swollen bases, proliferation of mesophyll tissue; also the independence of the vascular system of the fertile scale and the sterile bract at the base of the strobilus, indicated by the two resin canals far apart. $\times 26$.

Fig. 80. Transverse section of strobilus in above stage, taken at the apex of the nucellus, showing lamina of the fertile bract. Slightly oblique. $\times 40$.

Fig. 81. *P. nivalis*. Transverse section of an ovuliferous scale taken across the micropyle, showing the foliar structure of the scale. $\times 45$.

The Histology of the Sieve Tubes of *Pteridium aquilinum*, with some Notes on *Marsilia quadrifolia* and *Lygodium diaphanum*.

BY

E. M. MARGARET HUMÉ,

Bathurst Student of Newnham College, Cambridge.

With Plates LIV and LV.

NO re-examination of the sieve tubes of any Vascular Cryptogam has been made since more accurate methods of histological investigation have been introduced. It seemed therefore desirable to make an examination which would render possible a comparison between the sieve tubes of some Vascular Cryptogam and those of certain Angiosperms¹ and of *Pinus*,² as worked out by A. W. Hill, and of *Macrocystis* and *Laminaria*,³ as worked out by M. G. Thoday (Sykes).

HISTORICAL.

De Bary,⁴ in his 'Comparative Anatomy of Phanerogams and Ferns', seems to have been the first to recognize the parietal layer of protoplasm which forms the characteristic lining of the sieve tubes of Vascular Cryptogams. He also noticed that the refringent granules contained in the protoplasm were aggregated against the sieve plates, and figures⁵ a connexion between granules of adjacent sieve tubes, across the pit-closing membrane. De Janckzewski⁶ also mentions the presence of the refringent granules, as do most persistently all writers upon the subject. He mentions that starch is very rarely present in the sieve tubes of either Vascular Cryptogams or Monocotyledons; the latter, he says, also possess the refringent granules. He recognized that portions of the pit-closing membrane in *Pteridium aquilinum* give the same reactions as the callus of Angiosperms, but he regarded it as quite exceptional among Vascular Cryptogams, and held that their sieve plates are really unperforated.

Russow⁷ confirmed de Janckzewski's observation of the presence of refringent granules in Monocotyledons. His examination of Vascular Crypto-

⁷ Russow ('82), p. 207.

gams was not very extensive, but he observed the presence of callus in most Ferns, with the exception of the Marattiaceae and Ophioglossaceae, and noticed that the refringent granules adhere to the free ends of the callus rods. He came to the conclusion that the sieve plates are perforated, but does not seem to have been able to demonstrate both callus rods and connexions at the same time.

Poirault,¹ in the course of his extensive researches into the structure of Vascular Cryptogams, also came to the conclusion that the sieve plates must be perforated by connecting threads, but he too was unable to prove it; neither could he determine whether the paired callus plugs, on either side of the sieve plate, were or were not continuous with one another across the middle lamella.

The question has remained in this uncertain condition ever since, as far as the Vascular Cryptogams are concerned. The only additional observations worthy of note are due to Boodle,² who, using Grüber's azoblue as a callus reagent, showed the widespread presence of callus among the Ferns, with the exception of the Schizaeaceae, Hymenophyllaceae, and, as he at first thought, of the Gleicheniaceae. Examination of material of the rhizome of *Gleichenia pectinata*, which had not been allowed to come into contact with spirit, revealed the presence of callus,³ and suggested the probability of its presence in the other two orders as well, if suitable material and methods could be found to demonstrate it. Boodle⁴ mentions that the refringent granules are 'often distinctly grouped on the sieve plate'. The question of the perforation of the sieve plates was not attacked by him, but the callus is described as a rod running through the wall, and having expanded heads. He also notes the presence of callus in the pits between sieve tubes and phloem parenchyma cells.

In *Pinus*⁵ and the Angiosperms,⁶ A. W. Hill has traced the development of the connexions between adjoining sieve plates. He has shown that, in their earliest condition, these appear as delicate protoplasmic threads, with a darkly staining node. Later, probably by the action of ferments working along them, the threads become converted into thicker slime strings, while, at the same time, the cellulose of the cell-wall immediately surrounding the slime string is altered into callus. Several slime strings may be contained in the same callus rod, as in *Pinus*, or each string may have its own callus rod (*Vitis*). It is only the cellulose portion of the cell-wall which becomes converted into callus; hence the callus does not form a continuous rod right across the pit-closing membrane, but is interrupted at the middle lamella. Here, however, the ferments also bring about some change, and immediately round each median protoplasmic node the pectic

² Boodle ('01), pp. 395-9.

⁴ Boodle, loc. cit., p. 397.

⁵ Hill ('08).

substances of the middle lamella become altered, so that they stain darkly with protoplasmic dyes. The portion of the middle lamella which is thus altered separates the callus rod into two halves, and is called the median nodule. The slime strings may be further bored out until they become very thick, and meanwhile the median nodule is apparently dissolved away and callus deposited as a tubular lining right across the pit-closing membrane. In *Wistaria* the wall between adjoining slime strings may be completely dissolved away, and several small strings may coalesce to form one large one. In *Vitis* the original slime strings remain independent. Callus is present on the sieve tube side of the pits connecting sieve tubes and bast parenchyma cells. The sieve tubes of *Vitis* function from year to year, and become plugged during the winter with callus, which is dissolved away in the following spring when the phloem resumes its activity.

In the light of the foregoing facts, an examination of the sieve tubes of *Pteridium aquilinum* was undertaken in order to determine whether the protoplasm of adjacent sieve tubes is, or is not, continuous across the sieve plate, and if it is so, what relation such a connexion bears to the distribution of the callus. It was also hoped, if possible, to throw some light upon the nature of the refringent granules. *Pteridium aquilinum* was chosen for the purpose, because it possesses exceptionally large sieve tubes; for the same reason *Marsilia quadrifolia* was also selected. In the latter case everything seems to indicate that the development of the sieve tubes closely resembles that of *Pteridium*, but the actual sequence of development was not worked out. The absence of secondary thickening in Ferns makes the accurate seriation of the various developmental stages of the sieve tubes a rather tedious business, as a number of blocks have to be cut, and after preparation the stages contained in them are often found to be only duplicates of those already obtained. The development was worked out in the rhizome, as it contains all the older stages as well as the young ones.

METHODS OF RESEARCH.

The methods used were, in the main, those introduced by W. Gardiner¹ and adapted by A. W. Hill² and M. G. Thoday.³

A dilute solution of iodine in potassium iodide was used for fixation, and swelling was effected by treatment, for two or three weeks, with a much stronger solution of iodine. Kolossow's mixture was used for mordanting, and for staining safranin and London blue. Excess of safranin was washed out in dilute glycerine, and the washing-out process is continued in the London blue.⁴ In cases where staining with safranin was insufficient the sections

¹ Gardiner ('97), p. 100; ('98), p. 504.

² Hill ('01, '08).

³ Thoday (Sykes) ('08, '11).

⁴ For the use of this stain as a callus reagent and for washing out safranin from cell-walls, see Sykes ('08), p. 299.

were remordanted in dilute iron alum and stained in water blue made up with aniline.¹

The material of *Marsilia quadrifolia* and *Lygodium dichotomum* was obtained from the University Botanic Garden, by the kindness of the Curator; that of *Pteridium aquilinum* was collected in Gamlingay Wood.

DISTRIBUTION AND GENERAL CHARACTERS OF THE SIEVE TUBES.

Both in *Marsilia* and in *Pteridium* the sieve tubes are characterized, as has already been stated, by their remarkable size (Pl. LV, Fig. 32).

In *Pteridium* they occur as a complete ring surrounding the xylem in each of the vascular strands of the rhizome (Pl. LV, Figs. 31 and 32). The vascular strands are flattened dorsiventrally, corresponding to the horizontal position of the rhizome, and it is on the dorsal and ventral sides of these strands that the phloem attains its greatest development. Laterally it is much thinner, the phloem elements being very small and scarcely distinguishable from the protophloem. The ring of large sieve tubes is very regular, and is not usually more than one cell thick, so that each sieve tube abuts on another on either side of it, but centrifugally and centripetally it abuts upon phloem parenchyma, protophloem, or pericycle (Pl. LV, Figs. 31 and 32). The sieve plates of the lateral walls, therefore, occur almost invariably upon the radial walls, i.e. between two sieve tubes, and being in *Pteridium* of frequent occurrence, they form a very perfect, continuous conducting channel round each of the vascular strands. The importance of this will be realized when it is recalled that the roots occur all along the ventral side of the rhizome, while a single frond is given off laterally each year; there is no aggregation of roots and leaves at a definite node, as will be described in *Marsilia*.

The protophloem (Pl. LV, Fig. 29) occurs as an almost continuous ring of very small and, in the mature state, thick-walled elements, situated just outside the ring of large sieve tubes. Irregularly distributed, and abutting on the tangential walls of the sieve tubes, are the phloem parenchyma cells (Pl. LV, Fig. 31), which are elongated, with dense contents and a large elongated nucleus. Pits can be seen in the walls between sieve tubes and phloem parenchyma cells (Pl. LV, Figs. 30 and 32). The pericycle is generally one cell thick, and the cells are very obviously sister cells of the endodermis. Pits are particularly abundant on the tangential walls between pericyclic and endodermal cells. As regards the general characters of the mature sieve tubes, they are large, very thick-walled elements, with a thin parietal layer of protoplasm containing refringent granules. The lumen of the cell appears empty in cross section, but no doubt, in life, the contents

¹ Hill ('08).

are a watery fluid. The terminal walls of the sieve tubes are generally very much inclined (Pl. LIV, Fig. 26), so much so that in longitudinal section they are often indistinguishable from the lateral walls. Both in the terminal (Pl. LIV, Fig. 13) and in the lateral (Pl. LIV, Fig. 14) walls large thin areas occur; these are the sieve plates. They are generally more numerous on the terminal walls, but no definite rule can be laid down, and it is almost impossible to distinguish with absolute certainty between a lateral wall with numerous large plates and a terminal wall with few small ones; the two classes merge into one another, and a separation of the two types is not founded on any fundamental difference in their structure. In a transverse section terminal plates can often be distinguished by the fact that they may run right across the diameter of what would otherwise be a single circular sieve tube, dividing it into two elements, each having a half-moon-shaped cross section (Pl. LIV, Fig. 26). The distinction of sieve areas into sieve fields and sieve plates, employed by Hill in describing the Phanerogams, will not be of value here, since there is no sharp differentiation of the two types. The development of sieve plates on the terminal walls is sometimes very extensive indeed, the major part of the wall being thin, and the thickened portion consisting only of bars of cellulose running transversely from side to side of the wall; such a wall is very reminiscent of that of a tracheide.

In *Marsilia* the general relations do not differ very materially; the stele is a solenostele in which the sieve tubes form two fairly regular concentric rings, or rather two pairs of arcs, for laterally phloem development is feeble as in *Pteridium*. The sieve tubes have somewhat thicker walls than those of *Pteridium*, but in general appearance they resemble them very markedly. The development of sieve plates on the lateral walls of the internodes is not so extensive as in *Pteridium*, and gives more the impression of scattered pits. At the nodes, however, the lateral sieve plates seem to be developed fully. This is interesting in view of the fact that roots are developed at the nodes only in *Marsilia quadrifolia*, roots, petiole, and sporocarp all growing out at the same level round the procumbent rhizome. There is, therefore, a special demand for conduction around the stem at the nodes, while the internodes are comparatively passive in this respect. Russow¹ asserts that terminal walls in the sieve tubes occur, as a rule, only at the nodes, the tube running unbroken from node to node, but this statement has not been found to be correct. Terminal walls are not very frequent in the internodes, but they do occur. They are often considerably inclined, which may have caused Russow to overlook them; and they bear numerous sieve plates; in other details the phloem of *Marsilia quadrifolia* does not differ materially from that of *Pteridium*.

¹ Russow ('72), p. 5.

HISTOLOGY.

In the earliest stages of development of the sieve tubes of *Pteridium aquilinum*, the same difficulties of observation were experienced as seem to have been encountered by A. W. Hill. The walls of the sieve tubes, at an early age, are thin (Pl. LV, Fig. 29), and it is not until they have undergone quite a marked increase in thickness that it becomes possible to demonstrate the presence of threads traversing the walls. The contents of the sieve tubes are at first quite considerable, consisting of rather darkly staining protoplasm, which tends to contract very easily with any reagents and, in transverse section, often falls out altogether. Such behaviour would probably rupture the connecting threads, but even in cases where the contents are still present and are little or not at all contracted, no certain indications can be seen of any connexions. As the diameter of the sieve tube increases the protoplasm becomes more and more drawn out into a thin layer, lining the walls, to which it is very closely applied. The walls are by this time considerably thickened, the areas of the sieve plates are mapped out, and in particularly favourable cases, delicate protoplasmic threads may be seen crossing the membrane (Pl. LIV, Fig. 1). At the middle lamella they show a rather more darkly staining protoplasmic node. The recognition of the protoplasmic threads before the appearance of callus is extremely difficult in the large sieve tubes, but it is easier in the elements of the protophloem. These elements become very much thickened, and show deep pits with long drawn-out pit fillings. Callus often cannot be detected at all; in fact it would appear as if the protophloem elements were not much used by the plant, and retain their juvenile characters right through life (Pl. LIV, Figs. 2 and 3). The connecting threads in the sieve plate are not as a rule aggregated into groups, but are dotted about singly all over the sieve plate. Up to, and even after, the first appearance of callus the refringent granules so often described appear to be small and distributed through the sieve tube, though mainly collected about the sieve plates (Pl. LIV, Fig. 1). It cannot be said with absolute certainty that, at this stage, they bear a definite relation to the threads, since they often appear to have no connexion with them; how far this can be attributed to disturbance brought about by cutting, however, it is not very easy to say.

The callus appears first as a shallow basin about the head of each thread (Pl. LIV, Fig. 4); callus formation seems generally to take place simultaneously on both sides of the pit-closing membrane, though some instances¹ were observed in which it was advanced further on one side than on the other (Pl. LIV, Fig. 4). Callus formation advances from either side towards the middle lamella, but stops short at it, while a corresponding

¹ Cf. Sykes ('08), Pl. XIX, Fig. 15; and Hill ('08), Pl. XVII, Fig. 24.

alteration of the substance of the middle lamella between the callus plugs takes place. This change in the middle lamella causes it to have the property of staining with protoplasmic dyes, and after treatment with safranin the altered places are very conspicuous as red dots (Pl. LIV, Figs. 5 and 6). The threads stain more darkly at this stage, but are still very slender, so that they are not very conspicuous; before treatment with London blue they can generally be traced fairly easily, but after the callus has been stained, the deep blue colour is often sufficient to obliterate the outline of the slime strings altogether (Pl. LIV, Fig. 4). Each slime string possesses its own distinct pair of callus basins (Pl. LIV, Fig. 9), though when two slime strings are sufficiently near together their callus basins may touch one another, and give the appearance of more than one string contained in a single mass of callus (Pl. LIV, Fig. 6). Soon after this stage has been reached, it is quite apparent that the arrangement of the refringent granules bears a very definite relation to that of the slime strings and callus basins (Pl. LIV, Fig. 12). The granules are larger than in the earlier stages, and their appearance suggests that they are more of the nature of mucilaginous droplets than of granules. A refringent granule is attached to each end of the slime string (Pl. LIV, Figs. 12 and 17), and in a section of a sieve plate each slime string has the appearance of a hatpin with a knob at each end. Whether, however, the callus is of a sticky nature and causes the granules to adhere, or whether they are actually connected with the slime strings, could not be determined. In a surface view of a sieve plate the refringent granules, which stain darkly with safranin, make the callus basins invisible (Pl. LIV, Figs. 13 and 14), though on focusing carefully the granules take a mauve tinge, due to the blue of the callus below them; in sections of this stage, stained in London blue only, there can be seen successively, on focusing downwards, the clear outline of the upper refringent granule, then a blue spot (the callus rod), and lastly the outline of the lower refringent granule. In sections stained with both London blue and safranin the callus can only be seen here and there in surface view as a blue spot, where the refringent granule above it has been dislodged (Pl. LIV, Figs. 15 and 16); in such cases the median nodule can be focused as a red spot in the midst of the blue (Pl. LIV, Fig. 15). The median nodule is also visible as a dark spot on focusing down through the granules (Pl. LIV, Fig. 15). The granules seem to grow larger after their attachment to the ends of the slime strings becomes apparent (Pl. LIV, Fig. 16). When this stage becomes visible the callus basins begin to be dissolved away (Pl. LIV, Figs. 18 and 19), possibly through the action of the granules, which sink down into the cavity left by the disappearance of the callus. The median nodule, also, next becomes entirely dissolved away, so that there is now a thick slime string (Pl. LIV, Figs. 18-26) stretching uninterruptedly across the pit-closing membrane, and derived apparently, in part at least, from the refringent granules or mucilaginous

droplets of each end of the slime string. The solution of the callus does not always go on quite at the same rate all over the same sieve plate, so that various stages of the sinking in of the granules may be observed. Sometimes the sinking in has not proceeded quite at the same rate (Pl. LIV, Fig. 19) on both sides of the plate; and sometimes the granule becomes dislodged by cutting after it has sunk in some distance, and the deep pit into which it had sunk then becomes visible (Pl. LIV, Fig. 24); the pit thus left empty has noticeably the same shape and size as the callus basin from which it was derived. Whether the callus always becomes completely dissolved away, or whether a thin shell or tubule is sometimes left, is not quite certain. Certainly stages were often seen in which no remaining trace of callus could be detected, but others were also observed in which a very faint blue tubule could be seen before the slime string was stained in safranin. Probably the solution is ultimately completed, and as far as could be seen no redeposition of callus ever takes place. Portions of the rhizome, which must have been many years old, were examined and the sieve tubes were found to be still functional; thick slime strings, such as those described above, generally perforated the sieve plates; in a few places traces of callus were observed still, but there is little doubt that these represent paths, which, for some reason or another, have not functioned very extensively. The whole aspect of the sieve plates suggests most strongly that it is as the result of use that much of the foregoing process of evolution is gone through. Thus the most rapidly developed slime strings represent the most frequented paths, and in support of this view it may be mentioned that in the terminal plates, which necessarily see the most service, the development is most rapid.

In the pits connecting sieve tubes with phloem parenchyma cells (Pl. LIV, Figs. 27 and 28), callus was never observed,¹ even in elements in which it was fully developed in the sieve plate. The pits are simple depressions of considerable depth, usually containing a single connecting thread. The wall of the sieve tube being a great deal thicker than that of the adjoining parenchyma cell, the middle lamella is asymmetrically placed, lying very much nearer to the lumen of the parenchyma cell than to that of the sieve tube. The connecting thread can be seen as a granular protoplasmic filament running to the middle lamella, where there is a dark dot—the median node. The wall between the lumen of the parenchyma cell and the middle lamella is so extremely thin that the detection of any pit or thread on that side is very difficult, but in some cases they can be seen to exist. It would seem, therefore, as if there is no boring out of the thread even on the sieve tube side, such as Hill² has described for *Pinus* and the Angiosperms, and his view that the ferment action is initiated

¹ Contrast Hill ('01), Pl. XXXIII, Fig. 23, and pp. 600-2, and Hill ('08), Pl. XVIII, Figs. 50, 51, 52, and pp. 278-80.

² Hill ('08), p. 281.

within each sieve tube, and necessarily works outward in all directions towards the middle lamella, would hardly be supported by the facts in *Pteridium*. Of course it may be that callus does occur very transiently in these pits at some stage, examples of which have not been hit upon. This seems hardly probable, as, did it occur, the most likely place would be in sieve tubes where the sieve plates show the presence of callus; but in these no callus was found in the pits in question. If the slime strings become bored out by use, by the travelling of ferments and other substances along them, it seems strange that the same process should not take place in the case of threads leading into the phloem parenchyma cells, which have every appearance of being in a state of activity.

Accumulations of callus (Pl. LIV, Figs. 10 and 11) were occasionally observed, but their presence could not be connected with any particular stage in development, nor was their distribution at all regular; possibly their formation is attributable to some pathological condition in the particular elements in which they were found. Callus formation is generally entirely limited to the paired basins connected with each slime string. Material was gathered in December and examined for accumulations of callus, blocking the sieve tubes during the winter rest, but no evidence of anything of the kind could be seen. Sections were examined, from the apex of the rhizome backwards to regions as much as five years old (the giving off of a frond being taken as an annual event), and in no part was a development of callus beyond the ordinary detected. It does not seem therefore as if any blocking of the sieve tubes during winter takes place.

MARSILIA QUADRIFOLIA.

No systematic examination of *Marsilia* was made, as has been stated already, but the stage at which callus is developed was detected, and everything indicated that the mucilaginous droplets behave in the same way as in *Pteridium*. The lateral plates in the internodes are few and small, often taking the form of isolated threads in pits; they seem to be but little used, as even in sections of comparatively older material their threads appear to be granular, protoplasmic, and unaffected by ferments.

Some material of *Lygodium dichotomum* was also examined, especially in order to investigate the presence or absence of callus, in view of Boodle's inability to demonstrate it in the Schizaeaceae.¹ None could be detected, but, as the material available was all of nearly the same age, this was not surprising. Preparations stained with safranin were not made, so that no definite statements can be made as to the perforation of the sieve plates, but the aspect of the unstained sieve tubes suggested that they did not differ materially from those of *Marsilia* and *Pteridium*.

¹ Boodle ('01), p. 396.

CONCLUSIONS.

According to de Janckzewski, as summarized by Russow,¹ the sieve tubes of Vascular Cryptogams differ from those of Phanerogams in their shape, in the absence of callus, and in the fact that the pores of the sieve plate are always closed. Russow was able to show that Cryptogams are not characterized by the absence of callus from their sieve tubes, and the foregoing account shows that the pores are not closed, but are as open as they are in Phanerogams; and that the process of development is similar in many ways. The outstanding differences therefore are in shape and contents; the sieve tubes of Vascular Cryptogams are larger and thicker walled and contain refringent granules.

The size of the sieve tubes and the thickness of their walls in Vascular Cryptogams are, it would seem, very likely dependent on the fact that, owing to the absence of secondary thickening, they have to function for a long time, in some cases for as much as twenty years, while in some Dicotyledons and Gymnosperms they are renewed each year. In some Phanerogams (as in *Vitis*), it is true that they do function for more than one year, after being blocked with callus in the winter. *Vitis*, being a climber, perhaps needs more than the average amount of phloem, and therefore makes use of more than the current year's growth of phloem. It was suggested to the writer that the absence of blocking by callus in winter in *Pteridium* might be due to the fact that the rhizome is an underground organ, and is therefore not so severely affected by the frost as an aerial one would be. With a view to determining whether this theory is borne out by the state of affairs in other underground organs, a rapid examination was made of winter material of the roots and stem of *Vitis vinifera*. The sieve tubes of the stem showed the great pads of callus blocking the sieve plates which Hill has described,² but in the roots no such pads could be found, and the sieve tubes showed masses of slime pressed against the sieve plate, the pores of which were clearly traversed by the slime strings. Little doubt, therefore, seems to exist that the sieve tubes of *Pteridium* remain unblocked by callus in winter because the rhizome is a completely subterranean organ and is, on that account, not subjected to the severities of weather to which an aerial organ would be exposed during the winter.

The facts ascertained concerning the finer histological details of the sieve tubes of *Pteridium aquilinum* correspond closely with Hill's observations on *Pinus* and the Angiosperms. The presence of the protoplasmic threads in the early stages, and the way in which they are bored out to form slime-strings associated with callus, are all materially the same. The salient differences are the ultimate total disappearance of the callus while the sieve

¹ Russow ('82), p. 208.

² Hill ('08), pp. 275-6, and Pl. XVIII, Figs. 41 and 54.

tube is still functional, and the presence and behaviour of the mucilaginous droplets, which still remain somewhat of an enigma. The fact that the droplets or granules occur in Monocotyledons also, and that in the early stages of the development of the sieve tubes in Vascular Cryptogams they cannot be distinguished in the granular mass of protoplasm forming the contents of the sieve tubes, seems to suggest that their manifestation may be connected in some way with the prolonged functioning of the sieve tubes. Their general behaviour and appearance suggest that they are viscous drops of slime akin to the substance of the slime strings, but whether they really function in the formation of the slime string, or whether they merely sink mechanically into the pits left by the solution of the callus, cannot be affirmed absolutely; their final fate would certainly appear to be incorporation in the substance of the slime string. It is possible that they are attached to it *ab initio*, and are at first very small, and that afterwards they gradually swell until their relationship to it is easily discernible. In that case they would seem to be simply the swollen heads of the slime strings. The separate individuality of the mucilaginous droplets would naturally become more clear as the parietal layer of protoplasm becomes thinner, consequent upon the increase in size of the sieve tube.

The constant connexion of the droplets with the sieve plate was noticed by both Russow¹ and de Bary,² and the latter figures the droplets as connected with one another by threads crossing the sieve plate.

With regard to the callus, it cannot be disputed that there is no very great development of callus in Vascular Cryptogams. In the life-history of each sieve tube, however, in *Pteridium*, at any rate, there is a stage at which callus is quite abundant and easily detected. An observer, examining material in the stages before callus formation or after its dissolution, would be disposed to say that callus was absent, and this no doubt led to the contradictory statements that were for a long time made upon the subject. The stage in which callus is present does not seem to last very long; the amount of the rhizome of *Pteridium* in which this stage is to be found would therefore be comparatively small in relation to the total mass, and the chance of the region containing callus being overlooked would be considerable. The same is true of *Marsilia quadrifolia*; many sections were examined, and the callus stages were only present in a few. No stages with callus were found in *Lygodium dichotomum*, but the material examined was all derived from petioles of approximately the same age, so that the absence of callus was not surprising; examination of a sufficient quantity of material of varying ages would very likely reveal it. Boodle records his inability to detect callus in the Schizaeaceae, attributable probably to the same cause, as the general appearance of the sieve tubes in *Lygodium*, though they are

¹ Russow ('82), p. 209.

² De Bary ('84), Fig. 79 B.

smaller, does not suggest that their development is likely to differ fundamentally from that in *Pteridium*.

The short duration of the stage in which callus can be detected, in the sieve tubes of those Vascular Cryptogams examined, confirms the view advanced by other authors,¹ that callus can be formed as an early stage in the solution of the cellulose of the wall. The existence of callus in various states of aggregation or hydration is mentioned by Mangin² and M. G. Thoday;³ these different states perhaps represent different stages of solution. Deposition of callus directly from the protoplasm does not seem to occur in *Pteridium*, unless the exceptional cases figured in Pl. LIV (Figs. 10 and 11) originated in that way.

SUMMARY.

1. The distribution of the sieve tubes and sieve plates in *Pteridium aquilinum* provides for conduction all round the vascular strand, both in the node and internode. In *Marsilia quadrifolia*, conduction around the stem is especially provided for in the nodes, but in the internodes there is very little provision for it. The variations in the distribution of the sieve plates in the two types are connected with the association together of the leaf, roots, and sporocarp at the node in *Marsilia*, while in *Pteridium* the roots have no regular distribution in relation to node and internode.

2. The sieve plates in *Pteridium aquilinum* are traversed at the earliest stage by delicate protoplasmic threads, each with a median protoplasmic node.

3. Callus is developed as a pair of basins in connexion with each individual thread, and the middle lamella between the callus basins becomes altered to form the median nodule.

4. The protoplasmic thread begins at the same time to be bored out to form a slime string, and at this stage the refringent granules or mucilaginous droplets can be seen to be arranged regularly, one at each free end of each slime string.

5. The callus next becomes dissolved away, and the mucilaginous droplets sink down into the cavities thus left.

6. Finally, the median nodule becomes dissolved away, and a homogeneous thick slime string is produced, derived partially, as far as can be seen, from the paired mucilaginous droplets.

7. The sieve tubes function for years, but no callus seems to be deposited in winter to block them. This is very probably because the rhizome of *Pteridium* is a subterranean organ. Winter material of the roots and stems of *Vitis vinifera* showed callus blocking the sieve tubes in the stem, but not in the root.

¹ Oliver ('87), p. 112; Hill ('01), pp. 597-600; Hill ('08), p. 278; Thoday ('11), p. 673.

² Mangin ('92), p. 263.

³ Thoday ('11), p. 315.

8. Connexions between sieve tubes and phloem parenchyma cells are frequent, but no callus was ever detected in connexion with them.

9. From a limited examination, the impression was received that the development of the sieve tubes in *Lygodium dichotomum* and *Marsilia quadrifolia* resembles that in *Pteridium aquilinum*.

My thanks are due to Mrs. Thoday, to whom I am deeply indebted for her never-failing kindness and counsel, and for an initiation into histological methods of research.

EXPLANATION OF PLATES LIV AND LV.

Illustrating Miss Hume's paper on the Sieve Tubes of *Pteridium aquilinum*.

PLATE LIV.

Lenses used were Swift's $\frac{1}{8}$ 'apochromatic' objective, with 6, 8, and 12 Zeiss's compensating oculars. Staining was with safranin and London blue except where otherwise stated. The blue colour in the figures represents callus. The figures throughout are of *Pteridium aquilinum*.

Fig. 1. Longitudinal section of portion of sieve plate, abutting on parenchyma cells on the right of the figure, on another sieve tube on the left. Protoplasmic threads, showing a median node

traverse the lateral sieve plates. A certain amount of granular protoplasm lines the sieve tube and is aggregated at the sieve plate. $\times 650$.

Fig. 2. A group of protophloem elements in longitudinal section. The contents are comparatively dense, especially in the pits. The middle lamella is not visible, and only one of the protoplasmic threads shows a median node. $\times 650$.

Fig. 3. Longitudinal section of two protophloem elements connected by protoplasmic threads. Middle lamella and median nodes are faintly visible. $\times 730$.

Fig. 4. Transverse section of two adjoining sieve tubes. Aggregation of the granules is more marked and callus formation has commenced on both sides of the plate, but has advanced somewhat further on one side than on the other. Alteration of the middle lamella to form the median node has begun, and the staining of the threads is darker. $\times 600$.

Fig. 5. Transverse section. A very common aspect of stages containing callus, in which only the median node and the paired callus basins can be seen. The layer of protoplasm covering the plate is thicker but less granular than usual. $\times 1,000$.

Fig. 6. Transverse section, showing groups of paired callus basins with their median nodules in the same stage as Fig. 5. The large empty lumen and parietal layer of protoplasm of the sieve tubes and the dense contents of the abutting phloem parenchyma cells are shown. $\times 550$.

Fig. 7. Longitudinal section, showing lateral sieve plates of radial wall in surface view. Stained with London blue only so that the callus basins alone are shown as blue dots. (Semi-diagrammatic.)

Fig. 8. Longitudinal section, showing a much inclined terminal wall in surface view. Cf. Fig. 7; the sieve plates are larger and much more numerous than in a radial wall. Stained with London blue only. (Semi-diagrammatic.)

Fig. 9. Longitudinal section of a sieve tube wall bearing numerous sieve plates. Callus basins and median nodules have been developed and the protoplasmic threads are undergoing conversion into the more darkly staining slime strings. Granules in some cases show attachment to slime strings. $\times 650$.

Fig. 10. Longitudinal section, showing a much inclined terminal wall in surface view. An exceptional case in which there is a considerable development of callus over the surface of the plate. The granules show a regular arrangement in relation to the ends of the slime strings. $\times 700$.

Fig. 11. Transverse section of group of abutting sieve tubes, showing accumulations of callus on two lateral sieve plates. $\times 480$.

Fig. 12. Longitudinal section of a lateral wall with numerous sieve plates; a slightly more advanced stage than Fig. 9. The slime strings are thicker, and the relation of the granules to the slime strings is more definite. Solution of the callus has commenced, and its outline has become less sharp. $\times 650$.

Fig. 13. Surface view of a large inclined terminal plate. The sieve plates are very numerous and show the distribution of the refringent granules all over them, each granule concealing a slime string beneath it. $\times 750$.

Fig. 14. Surface view of radial wall. The sieve plates are smaller and much less numerous. Refringent granules as in Fig. 13. $\times 600$.

Fig. 15. Surface view of two sieve plates in optical section. The refringent granules conceal the underlying callus and slime strings, except in one or two cases where the granule has been dislodged and the callus has become visible. The median node is focused as a dark dot in the midst of the callus basins and is also visible through one or two of the granules. $\times 800$.

Fig. 16. Two sieve plates in surface view. The granules have increased in size. One granule dislodged, showing corresponding underlying callus basin. $\times 800$.

Fig. 17. Longitudinal section of a stage corresponding to surface view in Fig. 16. Paired callus basins, median nodules, and refringent granules, some of which have been dislodged. $\times 800$.

Fig. 18. Transverse section of adjoining sieve tubes with lateral plate between them. Three slime strings, considerably thickened, with granules attached, cross the sieve plate. The callus is partially dissolved away, leaving only a thin tubule; the median node is still present. $\times 600$.

Fig. 19. Longitudinal section of single sieve plate. Callus, with slime strings not much thickened, but with granules attached on one side of the plate. Callus dissolved away on the other side, one granule sinking in and another detached not far off. $\times 800$.

Fig. 20. Longitudinal section of three slime strings, the top one cut obliquely; the callus is

completely dissolved. The paired granules of the middle slime string have sunk in unequally. The paired granules of the bottom one are connected by a thick slime string and the median nodule is still visible. $\times 1,000$.

Fig. 21. A longitudinal section showing four slime strings. The granules have sunk more deeply in and almost abut upon one another. $\times 1,000$.

Fig. 22. Longitudinal section of a single slime string. The granules connected by a short thick slime string. $\times 1,000$.

Fig. 23. Longitudinal section of a single slime string. Two granules in contact across the middle lamella. $\times 1,000$.

Fig. 24. Longitudinal section of a single slime string. The granule on one side has sunk in almost to the middle lamella. The granule of the other side has become dislodged in cutting and is lying near. The secondary pit formed by the solution of the callus and from which the granule has been dislodged is visible. The sieve plate is one containing only the single slime string illustrated, and the thickened portions of the wall limiting the sieve plate are visible behind the granules. $\times 1,000$.

Fig. 25. Transverse section of two sieve tubes with a lateral plate connecting them. Thick slime strings with median nodules and paired granules. $\times 420$.

Fig. 26. Transverse section, showing an inclined terminal wall crossing the lumen of the large sieve tube and dividing it into two separate elements. The granules are in various stages of sinking in and the slime strings are thick. Owing to the fact that the wall is inclined, many of the slime strings being cut obliquely are incomplete, and others have had their granules detached. $\times 600$.

Figs. 27 and 28. Transverse sections of a portion of a sieve tube abutting upon phloem parenchyma cells. The pits each contain one, or more rarely two, protoplasmic threads. The median nodule is visible as a dark spot. The wall of the sieve tube is much thicker than that of the phloem parenchyma cell, so that the portion of the thread traversing the wall of the latter is very short and only just recognizable. $\times 600$.

PLATE LV.

C = cortex; *E* = endodermis; *P* = pericycle; *PPh* = protophloem; *Ph* = phloem;
PPr = phloem parenchyma; *X* = xylem.

Fig. 29. Transverse section of young rhizome. The sieve tubes (*Ph*) are unthickened and the contents have fallen out. The protophloem elements are considerably thickened, and many of them still retain their contents, but no connecting threads are visible. $\times 470$.

Fig. 30. Transverse section of rhizome, old. A group of sieve tubes with lateral sieve plates connecting them. Traversing the sieve plates, the slime strings can be seen indistinctly. The refringent granules are visible as dark dots embedded in the walls in connexion with each slime string, especially on the largest plate of the largest sieve tube *A*; the pits connecting a sieve tube with a phloem parenchyma cell can be distinguished. $\times c. 500$.

Fig. 31. Transverse section of portion of mature rhizome. The distribution of the sieve tubes as a peripheral ring of elements, connected with one another by sieve plates on the radial walls, is shown. The position of the sieve plates is indicated, slightly diagrammatically, by the blue colour of callus. Protophloem is almost absent from this section. $\times 450$.

Fig. 32. Transverse section of portion of rhizome, old. The peripheral row of sieve tubes skirting the xylem is shown. The sieve plates on the radial walls are large, and in places the granules and slime strings can be seen. $\times c. 500$.

The Production of Hairs on the Stems and Petioles of *Tropaeolum peregrinum*, L.

BY

ARTHUR W. HILL, F.L.S.

With Plate LVI and seven Figures in the Text.

THE common Canary-creeper or 'Canariensis'¹ of gardens is generally assumed to be a typically glabrous plant, and an examination of specimens grown in the British Isles or of material collected in South America preserved in herbaria fully bears out this assumption. Occasionally, however, it may be noticed that plants growing under favourable conditions show a very few hairs on young stems or petioles, but where they are growing normally and luxuriantly no traces of hairs can be seen, and the plants are absolutely glabrous.

In the summer of 1910, I noticed that some small plants of *Tropaeolum peregrinum*, growing in my garden, which had received injury to the leaf laminae, had developed a few hairs, and from this observation it seemed desirable to try and find out the cause of the production of hairs, and to ascertain the conditions under which it may be artificially induced. In the first case in which hairiness was noticed, snails were found to have eaten the laminae of the leaves more or less completely, leaving the young plants with only stems and bare petioles.

When making experiments the laminae were removed from healthy plants, and after an interval of a few days hairs were quite conspicuously developed on the young portions of the stem and on the young petioles. Experiments have been repeated during the past summer with greater care. Seedlings were grown until they had developed about ten leaves, and all the laminae were then removed; as each new leaf began to develop, its lamina was also removed, so that, except for the green stems and petioles, the plants were deprived of their main organs for assimilation and transpiration. Some of these plants so mutilated have been grown in the open, and some under a bell-jar in a moist atmosphere. It was found in August last (Aug. 19) that such plants developed hairs in the open in about four or five days, but

¹ *Tropaeolum canariense*, Hort. *T. aduncum*, Sm. = *T. peregrinum*, L.

in September, both in the open and under the bell-jar, hairs were noticed on the formerly glabrous plants in three days' time (laminae removed 12 o'clock, Sept. 12, 1911, examined Sept. 14, 1911, and a few developing laminae removed, no hairs seen; Sept. 15, 1911, scattered hairs especially on younger parts. Rain fell on the night of 13th and air cool). Again, in October, the experiment was repeated during cold, dull, foggy weather (Oct. 14-16), and a plant under a bell-jar deprived of all its laminae developed a fairly dense felt of hairs on the younger parts in a space of three days. A similar plant in the open developed hairs, but to a less extent. Control plants with the laminae undisturbed, grown both in the open and under a bell-jar, showed no trace of hairs. It was noticed, however, that under a bell-jar a very few hairs were developed occasionally if the plant had been covered for about two weeks. The plants which had been stripped of their laminae were continued in this condition by removal of all developing leaves for about ten days, with the result that quite a dense felt of hairs was developed, clearly visible to the naked eye. In the case of the plants under a bell-jar the hairs were much longer than those of plants in the open, and hairs measured from 0.5-1 mm. in length. If, after this copious development of hairs has proceeded for some days, the plant is again allowed to grow normally and the laminae are not removed, the production of hairs gradually diminishes, and in a short time ceases, with the result that the stems and petioles are again as glabrous as when the experiment was started. The hairy condition can be again induced in the growing portions by removal of the laminae, and the glabrous by their retention, so that by the alternate removal and retention of the laminae the hairy or glabrous condition may be produced. Should, however, the leaves which are allowed to form after a glabrous period be malformed and remain more or less aborted, the stem and petioles will still retain their hairy character.

On a plant which had been kept defoliated for some weeks under a bell-jar out of doors, it was noticed that hairs had developed on the mid-ribs and under sides of the young leaves which were allowed to form at the end of October.

The hairs in *T. peregrinum* are unicellular, the outgrowth of a single epidermal cell. In a transverse section of the stem of a glabrous plant all the epidermal cells appear to be identical in character, and no cells can be distinguished as potential hair cells. When, however, hairs are about to be developed, certain epidermal cells become filled with dense granular contents, and such cells, at a slightly later stage, form small protruding papillae which will grow out to form the long unicellular hairs.

The full-grown hair has thin walls, and contains a copious supply of granular vacuolated protoplasm with a conspicuous nucleus suspended either near the base or towards the middle of the hair. The apex of the hair is rounded and slightly swollen, which makes it appear somewhat glandular,

but this appearance is only due to the refractive character of the protoplasm at the tip of the hair.

The hair cells are seen to occupy a position comparable to that of the stomata in relation to the ordinary epidermal cells of the stem when a surface view or longitudinal section of the stem is examined. The epidermal cells are elongated, while the cell from which a hair arises is almost circular in outline. No such small cells could be seen except when a hair was either in process of formation or had already been formed. It would seem, there-

TEXT-FIG. 1. A small piece of stem showing hairs.

TEXT-FIG. 2. An epidermal cell, destined to become a hair, with dense granular contents.

TEXT-FIG. 3. A slightly later stage, the cell forming a papilla.

TEXT-FIG. 4. A fully developed hair with nucleus suspended near the base.

TEXT-FIG. 5. Surface view of an old piece of epidermis showing a small hair cell in optical section.

TEXT-FIG. 6. A stoma in optical section to compare with Fig. 5.

TEXT-FIG. 7. A young hair of *Tropaeolum majus*.

fore, that the stimulus caused by the removal of the laminae induced division in some of the epidermal cells, and that one of the products of the division gives rise to a hair, while the other elongates to form an ordinary epidermal cell. Such cell-division appears to take place near the apex of the stem when the tissues are still quite young, but it is also clear that hair mother-cells may be cut off from epidermal cells in older portions, as it has been noticed that the longer the plant is deprived of its laminae the denser the hairs become throughout the whole portion of the stem which is still capable of growth.

As far as I am aware very little has been done in the way of attempts

to produce a hairy or glabrous condition, though characters of hairiness or the reverse are known to be variable¹ among plants according to circumstances.

Vesque² discusses the development of hairs, and agrees with the theories of Kraus and Mer that the formation of hairs is due to the excess of nutritive matters and to the arrest in growth of the organs which carry them. He adds, 'Des plantes différentes sont plus ou moins propres à développer des poils sous l'influence du milieu. Tandis que certaines espèces deviennent velues au point d'être méconnaissables, je n'ai jamais réussi à faire développer un seul poil sur une plante réellement glabre, sur le pois, par exemple.'

Vesque would possibly not consider *Tropaeolum peregrinum* to be a truly glabrous plant, and it is unfortunate that his paper was not brought to my notice until it was too late to make similar experiments on peas to those made on the Canary-creeper.

It is of interest to notice that the allied species, *Tropaeolum majus*, the common 'nasturtium' of gardens, is always hairy on the under surfaces of the leaves, and when grown under unfavourable conditions the starved plants tend to show an extension of the hairs down the short petioles. But when the plants receive favourable treatment the petioles become elongated and glabrous. The hairs, however, in *T. majus*, which are normal organs of the plant, differ from the straight unicellular hairs of *T. peregrinum* in being multicellular and curved. The hairs which arise from single epidermal cells may consist of from three to several cells, the terminal cell being usually the longest.

The cause of hair production in *T. peregrinum* may perhaps be due to the excess of water supplied to the plant in its abnormal condition, and to the sudden arrest of growth owing to the removal of the large evaporating and growing surface represented by the laminae. It was not obvious that the hairs performed any marked function connected with transpiration, though it may well be that they represent the plant's efforts to provide a substitute for the large transpiring surfaces which it has lost.

EXPLANATION OF PLATE LVI.

A photograph of the upper part of a plant deprived of its laminae and showing a considerable development of epidermal hairs. Slightly enlarged.

HILL — TROPAEOLUM.

Anatomy of *Gnetum africanum*.¹

BY

AUGUSTA V. DUTHIE.

With Plates LVII-LIX.

THE following account of the anatomy of *Gnetum africanum* is based on material collected by Professor H. H. W. Pearson in Montobello, on April 7, 1909. My thanks are due to Professor Pearson for handing over the material to me for investigation, and for much helpful advice with regard to the work.

In view of the systematic position of *Gnetum* and the difficulty of obtaining suitable material for investigation, it seemed worth while to place on record the facts ascertained with regard to the anatomy.

BRIEF REVIEW OF THE MORE IMPORTANT PUBLISHED WORK ON GNETUM ANATOMY.

Griffith's 'Remarks on *Gnetum*', which appeared in the Linnean Society's Transactions of 1859, contains a few references to the anatomy of the genus. Professor Bower in 1882 published an account of the germination and seedling structure of *G. Gnemon*, while the seedlings of *G. scandens* and *G. moluccense* have been investigated recently by Hill and de Fraine. A few references to the anatomy of *G. Gnemon*, *G. scandens*, and *G. Thoa* occur in de Bary's 'Comparative Anatomy of Phanerogams and Ferns'. Strasburger, in 1872, investigated the course of the bundles in leaf and stem, and the vascular supply of the axillary buds in several species of *Gnetum*. In 1894 Boodle and Worsdell published a paper on the 'Comparative Anatomy of the Casuarineae, with special reference to the Gnetaceae and Cupuliferae'. The species of *Gnetum* examined were—*G. Gnemon*, *G. paniculatum*, *G. scandens*, *G. neglectum*, and *G. Thoa*.

EXTERNAL CHARACTERS.

The genus *Gnetum* comprises between 20 and 30 species of tropical trees and climbers, two of which—*G. africanum* and *G. Buchholzianum*—are natives of the African continent. *G. africanum* was first discovered

¹ Percy Sladen Memorial Expedition in South-West Africa, 1908-9, Report No. 20.

by Welwitsch in the Cazengo district of Central Angola in 1858, and was described by him in the Linnean Transactions of 1869. The species is a climber with long slender stems which are swollen and jointed at the nodes; the much elongated internodes are sometimes more than 15 cm. long. The plant exhibits marked heterophylly. In the material examined the lateral branches spring from the axils of short, opposite scale leaves; while the expanded foliage leaves produce only abortive buds in their axils. On superficial examination the scale leaves resemble the persistent bases of the petioles of foliage leaves, and were apparently mistaken for such by Welwitsch.¹ No root material was available.

STEM.

The oldest material examined shows a stem 5 mm. in diameter, its surface covered with a thin layer of cork. The younger internodes are marked with numerous, irregularly arranged dots and striations of a dark brown colour, while the youngest branches are smooth and green. The secondary thickening is perfectly normal; there is no trace of the successively renewed thickening rings which are present in *G. scandens*² and *G. Thoa*. It is possible that this abnormality may occur in older stems than those investigated. The number of vascular bundles seen in transverse section of the axis varies considerably; from 12 to 20 were observed in the internodes examined.

Xylem. The wedge-shaped xylem-masses are separated by conspicuous medullary rays (Pl. LVII, Fig. 1). The first-formed elements of the protoxylem have loosely coiled, spiral thickenings occasionally combined with annular markings. Those formed later have very close spiral or reticulate thickenings and often communicate by means of a row of large pits on the oblique walls. Reticulately thickened tracheides are specially abundant in the region of the node. Boodle and Worsdell³ have pointed out that in *Gnetum* the vessels first formed by the cambium have usually several perforations in their end walls, resembling in this respect the well-known vessels of *Ephedra*. In several cases two rows of large, circular, bordered pits were seen in the sloping end of a reticulate nodal tracheide of *G. africanum*, and one of the vessels was found to possess two rows of perforations on the oblique wall, as described by the above authors in the node of *G. paniculatum*. In general, however, only a single row of perforations occurs in these first-formed vessels. Transitional stages between pitted tracheides with a row of large, closed, bordered pits on their terminal wall, and true vessels were observed, the central pits of the oblique walls being perforated, those at the ends closed. Transitional stages between vessels with several circular perforations and those with a single long narrow one

¹ Welwitsch (9).

² De Bary (3).

³ Boodle and Worsdell (1).

were also noticed (Pl. LVIII, Fig. 8, *a-d*). The later formed vessels usually have inclined end walls with a single oval or circular perforation (Fig. 8, *e-f*). In one case two large circular openings were observed. In transverse sections the remains of the oblique septa of the vessels with their perforated bordered pits are often seen (Pl. LVII, Fig. 1). Associated with the true vessels of the secondary xylem are numerous gymnospermous tracheides. The thickness of the walls and the size and shape of the bordered pits in both vessels and tracheides vary considerably. In addition to the tracheal elements large numbers of elongated cells with protoplasmic contents and simple pits occur in the secondary xylem. They do not contain starch, but occasionally numerous minute crystals of calcium oxalate are found in them. Near the cambium these parenchymatous cells are usually seen to be arranged in regular rows continuous with the albuminous cells in the phloem (Pl. LVIII, Figs. 9, 12); in the older wood they are scattered, apparently owing to the enlargement of the vessels. Occasionally, the lumina of the vessels were found to be blocked with resinous substances.

Phloem. The boundary between the xylem and phloem masses of the vascular bundles, as seen in transverse section of the younger internodes, has the shape of an arc whose concave side is directed outwards. In older internodes this appearance is generally lost. The phloem elements are extremely regular;¹ but when sections are placed in water, considerable swelling and distortion occurs. No hard bast elements are present. The large sieve tubes are arranged in radial rows (Figs. 9, 10, 12). Compound sieve plates occur in large numbers on the very oblique end walls, but are less numerous on the vertical walls (Figs. 13 and 14). On staining with iodine after heating in glycerine, minute starch grains may be seen in the albuminous contents of many of the sieve tubes. Considerable callus formation covers the older sieve plates (Figs. 15, 17, 18). These callus pads stained readily with water blue, Russow's callus reagent, and corallin soda, but were unaffected even after prolonged staining with aqueous solutions of aniline blue and eosin. Particularly good results were obtained with water blue.

The albuminous cells are also arranged radially, and, as was remarked above, they are generally continuous with the elongated parenchymatous cells of the xylem (Fig. 12). In longitudinal section they are seen to be long and narrow, with dense proteid contents and well-defined, often elongated, nuclei (Fig. 14). Their end walls are at first transverse, but later become oblique. Numerous minute crystals of calcium oxalate are often collected at one end of these cells, and small starch grains are occasionally present. A doubling of the radial rows of albuminous cells and sieve tubes often takes place. In the older phloem, owing to the displacement of the elements, the albuminous cells come to lie at the corners of the sieve tubes

¹ Boodle and Worsdell (1).

and the likeness to companion cells is then very marked (Fig. 12). At the periphery of the bundle lies the crushed mass of protophloem. In tangential sections through the phloem of older stems, fusiform rays are often seen. These vary much in size, some of them being only one cell wide and from one to three cells high; others are several cells wide and higher in proportion (Figs. 11, 16). These rays are specially numerous near the nodes of old stems. The cells are thin-walled, with protoplasmic contents, and are packed with minute crystals of calcium oxalate. A few starch grains are occasionally present. Intermediate stages were observed between the smaller rays and albuminous cells with crystallogenous contents (Fig. 16).

Pith. The pith consists of elongated cylindrical cells with pitted walls which are conspicuously lignified in the region of the vascular ring. In most of the older internodes the central thinner-walled cells have been disorganized (Pl. LVII, Figs. 1, 4), though this is not always the case. The older stems have the pith cells packed with rounded starch grains; these are entirely absent from the pith of the younger internodes. In the pith region below the growing point, and in the pith of the nodes, large numbers of crystals of calcium oxalate were found. Running longitudinally through the pith are latex tubes similar to those of the cortex which will be described below. In the pith of the node large numbers of branched, lignified, fibrous cells occur (Fig. 5). Similar sparingly branched lignified elements are very occasionally found in the pith of the internode.

Primary Medullary Rays. As is well known, the primary medullary rays are very conspicuous, and extend from pith to cortex, gradually broadening outwards (Fig. 1). Their width varies considerably in different internodes. These rays are composed of parenchymatous cells which are often radially elongated. Many of the cells are lignified and provided with simple pits; others are packed with calcium oxalate crystals and crystal sand. The amount of lignification of the ray varies. In young stems most of the ray cells are lignified; all have conspicuous protoplasmic contents, and some are packed with crystals. Between the phloem masses large thin-walled crystallogenous cells are very numerous. In older internodes a very large number of thin-walled crystallogenous cells occur, and in the wider parts of the ray there are stone cells with lignified, pitted, and conspicuously striated walls (Fig. 1). These sclerosed cells are very numerous in the ray parenchyma between the masses of bast. Starch was found to be absent from the rays of the young internodes, but is present in considerable quantities in those of older stems. The crystals in the ray cells are usually rhombic in surface view and vary greatly in size (Pl. LIX, Fig. 30), many of them being extremely minute. They resemble closely those found in the crystal sacs of phloem and cortex. In tangential section the rays are often seen to be broken up into partial rays by vascular tissue (Pl. LVII, Fig. 2). Single bridging xylem elements were frequently observed (Figs. 2, 3). In one

section a large pitted vessel was seen bridging a ray, and in a few cases bridging phloem elements were also noted.

Cortex. The ground tissue lying next to the phloem masses consists, in young stems, of thin-walled parenchymatous cells through which a few latex tubes and fibres are scattered. In older stems an irregular ring of large parenchymatous cells becomes strongly lignified, forming the conspicuous sclerenchymatous zone (Fig. 1 and Pl. LVIII, Fig. 9). The walls of these stone cells are stratified and pitted, and resemble the sclerotic elements of the old medullary rays. The fibres are elongated and unbranched, with cellulose walls and pointed ends. They are very numerous in the outer cortex, but are occasionally found inside the zone of stone cells. The white lustrous thickening layer is often found to have separated from the primary wall (Pl. LIX, Fig. 27). The marked contraction which sometimes occurs may have been caused by the alcohol in which the material was preserved. The cell lumina of many of the fibres are almost entirely obliterated; the walls of some show well-marked stratification (Fig. 27). In the cortex of the node, stellate fibrous cells also occur (Pl. LVII, Fig. 5), but they are extremely rare in the internode. In the younger internodes the parenchyma of the cortex, especially near the epidermis, contains numerous chloroplasts. A considerable quantity of storage starch is present in the cortex of older stems, and is very abundant in the parenchyma between the zone of stone cells and the phloem masses. Crystallogenous cells, similar to those of the rays, also occur in the cortex.

Latex Tubes. Among the most striking elements of the cortex are unbranched secretory tubes similar to those found in the pith and leaf-stalk. These laticiferous vessels of *Gnetum africanum* do not differ from those of *Gnetum Gnemon* described by Bower.¹ Their origin from vertical rows of elongated parenchymatous cells was observed in microtome sections of the young stem below the apical cone. Two or three nuclei were observed in several of these cells. Occasionally short, lateral protrusions of these vertical tubes were found forcing themselves between the neighbouring cells. The coagulated, albuminous contents turn a golden yellow on treatment with iodine. On placing longitudinal sections of the stem in strong sulphuric acid, the cellulose walls are dissolved and the strands of coagulated latex show up very distinctly. After prolonged treatment with alkanet tincture the contents of the tubes turn a reddish brown.

Epidermis of Stem. The epidermal cells of the young internodes are papillate, with much thickened outer wall and well-defined cuticle. The wall thickening in older internodes often projects irregularly into the cell cavity. The stomata are arranged in vertical rows and sunk below the level of the epidermis (Pl. LIX, Fig. 23). Their structure resembles that of the leaf stomata which will be described below.

¹ Bower (2).

Cork. The formation of cork in the internodes of *G. africanum* was found to be very irregular. The phellogen originates in circumscribed areas of the stem epidermis (the dots and striations mentioned above) and then spreads peripherally (Pl. LVIII, Fig. 21). It is not unusual to find part of an internode covered with 8–10 layers of cork and the rest with no sign of phellogen formation. This is probably connected with the climbing habit of the species. Some of the older internodes are surrounded by a thin and regular mantle of cork whose surface shows many minute cracks. In several of the stems examined, however, periderm formation cuts deeper and deeper into the cortex at certain points, and thus cortical fibres and secretory tubes come to be embedded in the outer cork. Occasionally, groups of fibres are completely isolated by cork cells (Pl. LVII, Fig. 4). In longitudinal sections these cork rings are found to be connected with the peripheral layer of cork. Similar cork rings surrounding a core of fibres were found in *G. scandens* and *G. Buchholzianum*. Layers of thick-walled phelloderma cells containing numerous crystals are sometimes found inside the phellogen. In several internodes the ground tissue cells inside the sclerenchymatous zone were found to have undergone division, often to such an extent that part of the zone of stone cells was ruptured and pushed out to the periphery of the stem, while large parenchymatous cells next to the phloem masses had become sclerosed. If an anomalous zone of xylem and phloem occurs in this species, the cambium must arise in this secondary tissue inside the zone of sclerenchyma (Pl. LVIII, Figs. 19, 20). A curious feature of some of the sections examined was the mucilaginous disorganization of groups of parenchymatous cells in the region of the protophloem masses (Fig. 20).

Stem Apex. According to Stapf,¹ Dingler² made the surprising statement that he had traced the growth of the stem apex of *Ephedra* to a 4-sided apical cell. Microtome sections were cut through the apical cone of branches of *G. africanum*, but in every case a small-celled meristem was found.

LEAF.

As was mentioned above, *G. africanum* possesses pairs of scale leaves in addition to the expanded foliage leaves. In transverse sections of the node below the swollen bases of the foliage leaves, eight bundles are seen to leave the stele, four passing into the base of each leaf. The two median leaf-traces are the first to separate from the vascular ring (Pl. LVII, Fig. 5). Sections through the bases of the pair of scale leaves immediately below the female cone showed the same bundle supply. On tracing the bundles through the scale leaf they were seen to fuse laterally, so that near the apex the separate strands could no longer be distinguished. A small twig which possessed six pairs of scale leaves was also examined. The vascular supply resembled that described above. Undeveloped buds were

¹ Stapf (7).

² Dingler (4).

found in the axils of these leaves. Sections were also cut through old nodes with opposite lateral branches in the axils of the scale leaves. Again eight bundles leave the stele as in the cases already described. These bundles branch in passing through the cortex,¹ the median leaf-traces often bifurcating before the lateral are quite clear of the vascular ring. A number of these branches enter the axillary bud, while others pass into the leaves. The material available did not admit of all the details of the leaf and axillary branch supply being made out, but in the sections examined a brush of xylem elements appears to pass up into the free part of each scale leaf.

Petiole. The short petiole of the foliage leaf is slightly furrowed above and convex beneath. Numerous latex tubes and fibres traverse the petiole and pass into the midrib. A few lignified spicular cells are also present. The four leaf-trace bundles remain distinct through the entire length of the petiole. A considerable amount of secondary tissue is formed by the cambium of each of these bundles.

Lamina. The four bundles of the petiole enter the base of the lamina and fuse laterally in pairs about one-fourth of the way up the midrib. Complete fusion occurs at some little distance above this point. The cambium of the midrib forms a considerable amount of secondary xylem and phloem. As is well known, the reticulate venation of the *Gnetum* leaf is of the normal dicotyledonous type (Figs. 6, 7). The leaf lamina, though fairly thin, is extremely tough. Below the cuticularized upper epidermis lies a single row of short palisade cells. The many-armed, spongy mesophyll occupies a considerable part of the substance of the leaf. The sclerenchymatous framework of the lamina consists of branched acicular cells and elongated fibres. The former have lignified, finely striated walls, occasionally perforated by simple pits. They are stellately branched and differ from the spicular cells of *Welwitschia* in the absence of an outer crystal-bearing layer of cellulose from their walls (Pl. LIX, Fig. 29). They occur for the most part in the stellate parenchyma close to the lower epidermis, the more prominent arms usually lying in the plane of the lamina. The fibres, which are far more numerous, are of enormous length. Their cellulose walls are so strongly thickened that in places the cell lumen is almost entirely obliterated. On isolating these fibres after maceration the ends are frequently found to be shortly and unequally branched. Similar branches occasionally occur at other points, but are seldom of great length (Figs. 28, 31). A bundle of these fibres strengthens the leaf margin and prevents tearing. These marginal fibres resemble those of the axis in being much straighter than the fibres described above and entirely unbranched.

The ordinary epidermal cells of both surfaces have strongly undulated walls (Pl. LVIII, Fig. 22), but opposite the larger veins they are narrower and more regular in outline. Nodose thickenings of the walls are fairly common.

¹ Strasburger (8).

The epidermis is provided with a well-marked cuticle which shows up distinctly on treatment with alkanet root or a fresh solution of chlorophyll.

The stomata are small, numerous, and arranged irregularly over the whole of the under surface with the exception of the veins and veinlets. A few are also present on the upper surface over the midrib.¹ They occur on the scale leaves as well as on the foliage leaves. Each stoma is accompanied by two subsidiary cells lying parallel to the pore (Fig. 22), but the material did not admit of the determination of the origin of the subsidiary cells. Several cases of 'twin stomata' were observed. In the leaf the stomata are about on a level with the subsidiary cells (Pl. LIX, Fig. 24), but in the young stems the stomata, which are here placed parallel to the longitudinal axis, are considerably sunken (Fig. 23). Seen from above the stoma often bears a striking resemblance to the under surface of a cowrie shell (Pl. LVIII, Fig. 22). The outer wall of each guard cell is provided with a lignified flap marked by delicate striations (Fig. 22). The guard cells, as seen in longitudinal section, are enlarged at the ends and somewhat contracted in the middle (Pl. LIX, Fig. 25). They contain large quantities of starch. As in most investigated Gymnosperms, ridge-like protuberances of the membrane are absent.

SUMMARY.

Gnetum africanum is heterophyllous, producing pairs of scale leaves which subtend the lateral branches, and foliage leaves with abortive buds in their axils. The stems examined showed normal secondary thickening.

The number of vascular bundles seen in transverse section of the axis varies considerably.

The first-formed vessels have several perforations on their sloping end walls, and transitional stages were found between these and the later-formed vessels with a single circular perforation. As is usual in climbers, the vessels of the secondary wood are of considerable size.

The phloem tissue is composed of regular rows of sieve tubes alternating with rows of elongated albuminous cells. Numerous compound sieve plates occur on the oblique end walls and also on the lateral walls of the sieve tubes. Considerable callus formation takes place.

In addition to the conspicuous primary medullary rays, smaller fusiform rays packed with calcium oxalate crystals are sometimes found. Transitional forms between the latter and the elongated albuminous cells of the phloem occur. Rhombic crystals of calcium oxalate, which vary greatly in size, are present in large numbers in certain cells of the xylem, phloem, medullary rays, cortex, and phelloderma, also in the pith of the nodes.

Sclerenchymatous elements of various forms occur in the stem. Stone cells with lignified and pitted walls form a conspicuous zone outside the

¹ Griffiths (5).

vascular bundles, and also occur in the broader parts of old medullary rays. Branched acicular cells with lignified and finely striated walls occur in the pith and cortex of the nodes. Elongated fibres with enormously thickened cellulose walls are present in large numbers in the cortex.

Latex vessels with cellulose walls and dense albuminous contents occur in pith and cortex, also in petiole and lamina of the foliage leaf.

Cork formation is exceedingly irregular. The phellogen originates in circumscribed areas of the epidermis and spreads peripherally. It is not unusual to find periderm formation cutting deep into the cortex at certain points, and occasionally groups of fibres are completely isolated by cork cells. Division of the ground tissue cells within the sclerenchymatous zone was observed.

The stem apex was found to possess a small-celled meristem.

Four bundles pass into the base of each foliage leaf, the median leaf-traces being the first to leave the vascular ring. The bundles which supply the scale leaves subtending the lateral shoots branch on passing through the cortex, a number of the bundles passing into the axillary shoots.

The reticulate venation is of the usual Dicotyledonous type.

A single layer of short, palisade cells occurs below the upper epidermis. The spongy parenchyma consists of many-armed, loosely packed cells.

Fibres and branched acicular cells are present in large numbers in the mesophyll of the leaf.

The stomata are arranged irregularly over the under surface of the lamina with the exception of the veins and veinlets. They also occur on the upper surface over the midrib, and are about on a level with the surrounding epidermal cells. The outer wall of each guard cell is provided with a lignified flap. The stomata of the young stems are sunken below the level of the epidermis.

On the Microsporangium and Microspore of *Gnetum*, with some Notes on the Structure of the Inflorescence.¹

BY

H. H. W. PEARSON, Sc.D., F.L.S.,

Harry Bolus Professor of Botany in the South African College.

With Plates LX and LXI and six Figures in the Text.

THE study of the life-history of *Gnetum* has been attended by considerable difficulty; the results hitherto obtained are incomplete and not entirely harmonious. This is due mainly to the lack of adequate material for investigation. The localities in which most of the known species occur are not easy of access. The characters of the inflorescence are such as to preclude the possibility of obtaining a long series of stages at one gathering. In the female inflorescence in particular, the range of development defined by the youngest and the oldest flowers is a small one, and at any one time the flowers of all the inflorescences of a particular plant represent but a short series of stages. This is in striking contrast to the spike of *Welwitschia*, for example, in which, for a period measured by weeks, a large number of flowers developing in strictly acropetal succession furnish a crowded series ranging perhaps from the stage of the macrospore mother-cell to that of the advanced proembryo. In the female inflorescence of *Gnetum* a further difficulty arises from the fact that in many species (*G. africanum*, *G. Buchholzianum*, *G. scandens*, &c.), a large proportion of the ovules become arrested early in their history; this may be due to an obvious disease, as in *G. scandens*,² or to more obscure causes, among which may perhaps be reckoned an insufficiency of available food. There are therefore good grounds for Lotsy's conclusion that it is 'absolutely necessary to be a resident in the tropics if one wants to obtain a pretty complete series, and even then it is slow and difficult work'.³ Failing this we must resort to the less satisfactory process of piecing together the isolated facts established by various investigators working by different methods, at different times, on different species.

¹ Report of the Percy Sladen Memorial Expedition in South-West Africa, 1908-9, No. 15. This expedition was assisted by a grant from the Royal Society.

² Lotsy ('99), p. 47; ('03), p. 397.

³ Lotsy ('99), p. 47.

Among the objects of the Percy Sladen Memorial Expedition of 1908-9 was that of obtaining material for the study of the life-history of *G. africanum*. This species was collected at Montobello in the Cazengo district of Angola, by Mr. J. Gossweiler, F.L.S. and the writer, in April, 1909. The ovules then obtained have yielded information regarding the condition of the embryo-sac and its contents both before and after fertilization, but they have not made it possible to describe completely the origin and development of the endosperm. It is hoped that, by the kindness of Mr. Gossweiler, a further supply of ovular material will be available in the course of a few months. Meanwhile, the following facts established for the male inflorescence and flower are placed on record.

As far as was possible with the information then available, the visit to Central Angola was timed to coincide with the later stages of ovular development, and it was hardly expected that young male inflorescences would be seen. While ovules were obtained in abundance only four male spikes were found; these have yielded all the stages shown in Pls. LX, LXI, Figs. 5-20. A further supply was gathered in the same locality by Mr. Gossweiler in January, 1910; these were preserved in alcohol and have been used in the investigation of the grosser morphological characters now to be described. Herr G. Zenker has most kindly sent me material of the male inflorescences of *G. Buchholzianum* from the Kameruns. A comparison of the internal morphology of these with that of *G. africanum* has led to very interesting conclusions regarding the degree of affinity between the African species and the important differences which separate them from the Indo-Malayan forms which have been studied. I am further greatly indebted to Mr. I. H. Burkill, Professor Gammie, and Mr. W. Talbot, C.M.G., for supplies of material of *G. scandens*.

The structure of the male inflorescence and the development of the parts of the flower of various species of *Gnetum* have been described by Griffith, Strasburger, Karsten, and Lotsy. Their results are scattered and some of them are in danger of being overlooked; it may therefore serve a useful purpose to summarize them briefly.

Griffith¹ describes the inflorescence in a few species. In *G. Bruno-nianum* he notes the presence of two sterile bracts on the peduncle. The bracts subtending the flowers are connate at the base and form an obsolete involucre ring; in its axil are a single ring of female flowers and many male flowers developing basipetally ('pluriseriatis, superioribus primo evolutis'). The female flower consists of a central fleshy ovate body which 'appears to be a naked ovule'. 'The nature and structure of the two envelopes indicate them to be perianthial.' Articulate hairs occur between the flowers. In a climbing species whose specific name is not given, he observes the presence of two vascular bundles in the axis of the male flower:

¹ Griffith ('54).

'Diandrum esse conjicio, filamenta vasorum fasciculi 2 laterales adsunt, nec centrales ut in filamentis monandris et anthera vere didyma e loculis 2 omnino discretis.'

Strasburger¹ gives a detailed account of the male inflorescence of *G. Brunonianum*. The cupule subtending each nodal ring of flowers represents two fused bracts. The internodes are short (l. c., Taf. xxi, Figs. 1 and 2). In each ring the uppermost flowers are female (incomplete); below these there may be as many as sixty male flowers. The basipetal order of development of the flowers in each node is indicated in Figs. 2 and 5 (l. c.). Each flower is surrounded by a number of filamentous hairs. The two anthers stand laterally on the summit of the axis, the two perianth leaves being placed antero-posteriorly. In the axis of the inflorescence the bundles are arranged in a ring from which the numerous leaf-traces arise; these pass out direct to the leaf-cupule; before entering the latter they give off branches which proceed upwards and outwards to supply the flowers. These latter form a somewhat indefinite ring lying outside the main cylinder and within the circle of leaf-traces. This median ring gives rise to small complexes of four or more bundles, each of which passes out to a flower. The complexes which supply the female (incomplete) flowers consist of somewhat larger bundles and their grouping occurs somewhat earlier than in the case of those which pass into the male. The spike commonly ends in a single terminal incomplete female flower. The two bundles in the axis of the male flower terminate each as a group of spiral elements immediately beneath the anthers. The perianth differs from that of *Ephedra* in that each of its two constituent leaves is traversed by 1-3 vascular bundles; these are reduced to a few spiral elements, but can nevertheless be followed to the upper edge of the leaf. The arrangement of the bundles thus described and figured² corresponds closely with that found in *G. scandens* (cf. Text-fig. 2). The anthers dehisce by transverse slits; the structure of the anther wall is similar to that of *Ephedra*. The pollen is oval, often almost round; the exine bears no protuberances, but contains definite thin areas or pores. The same author³ later states, on the authority of Karsten, that there is no prothallial cell in the pollen-grain and that shortly before the opening of the anther there are present, in some two, in others three, nuclei.

Karsten⁴ in 1892 made some reference to the germination of the pollen-grain, but did not deal with the earlier stages until a year later.⁵ He then described the development of the anther and microspore from the study of material representing six Malayan species. The youngest node in the inflorescence bears no flowers. There are about nine incomplete female flowers at the top of each axillary ring. The male flowers are much

¹ Strasburger, E. ('72).

³ Strasburger ('80).

² Strasburger, l. c., Taf. xxi, Figs. 5 and 14.

⁴ Karsten ('92).

⁵ Karsten ('93).

crowded; they are arranged in about eleven regular parastichies, each containing five to seven flowers. These relations obtain in *G. Gnemon*, *G. latifolium*, *G. neglectum*, and *G. funiculare*. In *G. Rumphianum* the number of flowers in each parastichy is smaller. The hairs arise from single superficial cells between the insertions of the flowers; they are particularly abundant between the female flowers and the male which stand immediately beneath them. The axis of the male flower bears two anthers, except in *G. Rumphianum*, in which there is only one. Of the two perianth leaves the upper arises earlier than the lower and overlaps it in aestivation. In the young anther there are two hypodermal tapetal layers clearly derived by periclinal division from a single layer.¹ After the cessation of division in the sporogenous cells, the walls separating them become indistinct and finally invisible. The body of the sporangium then consists of 'lediglich freie Zellen ohne Cellulosewände mit je einem Kerne'; this is surrounded by the two- (sometimes three-) layered tapetum and the epidermis. These 'freie Zellen' are the pollen-mother-cells. A contracted condition of the nuclear thread precedes the first division, which is rarely seen; it is followed immediately by a second division resulting in the presence of four free microspore nuclei in each mother-cell. At maturity the pollen-sac wall consists of a single layer of cells. The cells bordering the transverse line of dehiscence are either smaller or larger than the rest, and their contiguous walls are so rounded off that the area of contact is small. The presence of pores in the exine, as described by Strasburger, is denied; its surface is covered by delicate warty protuberances. Microspores in various stages of germination are found in the same sporangium. The first nuclear division in the microspore was not seen. One of the nuclei of the binucleate spore divides, the spindle in this case being very difficult to see. No more than three nuclei were seen in the pollen-grains; in this condition they appear to be mature. On germination the pollen-grain contains only two nuclei. No distinct generative cell can be seen in the pollen-grain, but it appears in the pollen-tube.

Lotsy² finds three free nuclei in the pollen-grain of *G. Gnemon* before its transference to the ovule. He regards one as vegetative, two as generative. He confirms the statement of Karsten that a generative cell occurs in the pollen-tube of *G. mollucanum*.

Coulter³ found twelve chromosomes in the heterotypic and homotypic divisions in the pollen-mother-cell of *Gnetum Gnemon*.

Gnetum africanum is a climbing species occurring spasmodically in the dense forests of Central Angola, Gaboon, and the Kameruns. Its recorded localities in Angola are about 150 km. from the coast; they are

¹ Karsten, l. c., Taf. viii, Fig. 14.

² Lotsy ('99).

³ Coulter ('08).

situated at an elevation of about 2,000–2,500 ft. among the hills which separate the low-lying coast-belt from the edge of the central African plateau. *G. Buchholzianum*, also a climber, is known from a few localities in the Kameruns (Abo, Yaunde, Johann-Albrechtshöhe). No other species are at present known to occur in Africa. *G. scandens* is a widely distributed Asiatic species; it extends eastwards from the Bombay Presidency through Sikkim, Assam, the Khasia Hills, Chittagong, Burma, Andaman Islands, and the Malay Peninsula to China.

According to Welwitsch, *G. africanum*¹ is dioecious. The male inflorescence is a slender structure, varying in length from 2 to 2½ inches; the internodes are about 4 mm. long (Pl. LX, Fig. 1, *b*). The apical node bears no flowers (Text-fig. 5). The axis terminates in an elongated, blunt segment which at its base is closely invested by the leaf-cupule.

In *G. Buchholzianum* the male inflorescence in the main features of its form and structure resembles that of *G. africanum*. In the former the average length of the internodes is probably slightly less, and its surface is more strongly curved than in the latter (cf. Pl. LX, Figs. 1, *b*, and 1, *c*). The curvature of the surface of the internode of *G. Buchholzianum* (Pl. LX, Fig. 1, *d*) appears to be a constant character by which the species can at once be distinguished from *G. africanum*. In both, the peduncle bears a pair² of reduced connate leaves with strongly acute apices; these are situated usually about ½ in. below the first flower-bearing node. The peduncle above and below the insertion of this pair of bracts is approximately circular in section. The cupular leaf-sheath subtending each flower-ring is equally developed all round its edge except the lowest one or two, in which, sometimes in *G. africanum*, commonly in *G. Buchholzianum*, the margin is prolonged into two equal or somewhat unequal teeth which are decussate with those of the sterile peduncular whorl.

The form of the inflorescence of *G. scandens* differs in some important respects from that of the African species. The upper portion of the peduncle is flattened in a plane perpendicular to that of the insertion of the pair of peduncular bracts (Pl. LX, Fig. 1, *a*). The floriferous part of the axis is shorter; its nodes are closely crowded—in these characters contrasting very markedly with the greatly elongated axis of the female inflorescence;³ its apical segment is very short. Certain structural differences, to be described below, between *G. scandens* and the African species are even more striking. The characteristic features which distinguish *G. scandens* from the latter are found also in other Indo-Malayan species, and it may be that they are common to all the species of this geographical region.

¹ Welwitsch ('71).

² Engler ('08) states that there are usually three leaves in this whorl. This is not the case in the material under investigation.

³ According to Cooke ('07), the fruiting inflorescence may be as much as 10 in. long.

In *G. scandens* the uppermost flowers in each ring,¹ as in *G. Brunonianum* and other Indo-Malayan species, are female (incomplete). The occurrence of female flowers in this position seems to be extremely rare in the African species. A single example has been observed in *G. africanum*, and in this case the upper circle of the ring showed only one female flower.²

In the young spikes the flowers are completely concealed by the bract-cupule, the edge of which is closely applied to the projecting base of the next younger cupule in *G. scandens*, or to the base of the succeeding internode in the African species. The appearance of the anthers at the surface before they dehisce is due primarily to the elongation of the floral

axis, in consequence of which the imbricating leaves of the perianth are pushed apart and the edge of the cupule is forced outwards. It is probable that at the same time there occurs a slight intercalary elongation of the axis of the inflorescence. In *G. Brunonianum*, to which *G. scandens* possesses so high a degree of structural resemblance, the apex of the male spike is commonly occupied by a single female flower.³ A similar case has not been observed in *G. scandens*, nor in either of the African species.

In *G. africanum* and *G. Buchholzianum*, the peduncle immediately below the pair of sterile bracts contains twelve to fifteen bundles in the ring. Four traces of single or double origin arising from these pass into each leaf (Text-fig. 1); the two

TEXT-FIG. 1. Diagram of transverse section of peduncle of male spike of *G. africanum*, just below insertion of pair of reduced sterile leaves (cf. Fig. 1, b.s.). l.b. = leaf-base; l.t. = leaf-trace. $\times 28$.

median pass out direct and in advance of the other two, which, arising from the sides of the ring, pursue a curved path in the cortex through nearly a quarter of a circle. In *G. scandens* each of the corresponding pairs of bracts receives seven traces, of which the median leaves the ring first; the rest follow in pairs, each succeeding pair being separated by a wider angle from the median. In all three species the ring above the insertion of the sterile bracts contains from twelve to fourteen

¹ In *G. scandens* the two uppermost nodes bear male flowers only; and occasionally the lowest node is barren and bears only hairs.

² This was seen in a hand-section. It is therefore possible that more than one female flower may have been present.

³ Strasburger ('72).

bundles. These relations correspond fairly closely with those described by Strasburger¹ for *G. Brunonianum*.

In the axis of the inflorescence the bundles of the ring may be somewhat more numerous. A branch from each passes out at each floriferous node to the leaf-cupule. On its way through the cortex it bifurcates once at least in a horizontal plane; on entering the cupule it undergoes further forking so that numerous small bundles pass up towards the free edge of the cupule. From each leaf-trace just before it enters the cupule in *G. scandens*, there arises an inverted strand which ascends until it becomes

TEXT-FIG. 2. Diagram of longitudinal section through node and internode of male spike of *G. scandens*, to show course of vascular bundles. *v.b.* = bundles of the ring; *l.c.* = leaf-cupule; *f.c.* = flower bundle-complex; *f.t.* = flower-trace. $\times 15$.

lost in a complex network from the nodes of which the bundles supplying the flowers are derived (Text-fig. 2).² These branches from the leaf-traces furnish the whole of the vascular supply to the flowers in *G. scandens*, as is also the case in *G. Brunonianum*.³

In both the African species the origin of the vascular network from which the flower-strands are derived is less simple. In these there is an outer series of normally orientated bundles arising from the leaf-traces at some distance from their origin from the ring-bundles, and proceeding upwards to the level of the lowest flowers, where they enter the network

¹ Strasburger ('72).

² Cf. Strasburger ('72), Taf. xxi, Fig. 5.

³ Strasburger, l. c.

from the nodes of which the flower-traces are derived. The bundles of this outer series are apparently homologous with the outer series of the female spike in *G. scandens*¹ and *G. africanum*,² and, in that case, are not represented

TEXT-FIG. 3. Longitudinal section through two nodes and an internode of *G. Buchholzianum* (one half only shown; the letters *p.c.* stand in the pith cavity). *i.t.* = internodal flower-trace; *m.c.* = mucilage cavity in the leaf cupule. Other lettering as in preceding figures. $\times 15$.

in the male spike of the former species (Text-fig. 2). In addition to the outer series there is in the male spike of *G. africanum* and of *G. Buchholzianum*, an inner series of flower-traces, inversely orientated through the whole or the greater part of their course. Arising either from the leaf-traces in close proximity to their insertion on their parent-bundles, or directly from the parent-bundles themselves, either at some point within the node or in the lower half of the next higher internode, they pass upwards within the cortex for a longer or shorter distance before turning sharply downwards to join the floral complex at the level of the uppermost flowers of the node (Text-fig. 3, *i.t.*). After separating from the leaf-traces or ring-bundles the ascending traces frequently run up so close to the ring-bundles that their phloem groups fuse; a transverse section through such a combination shows a more or less complete amphivasal structure.

Quite exceptionally such a case as that shown in Text-fig. 4 is found. Here the main trunk of the leaf-trace leaves the ring-bundle at the

¹ Thoday ('11), Text-fig. 2, OB.

² l. c., Text-fig. 3, OB.

top of the node; the descending bundle (of the inner series) arises from it close to its point of origin, and the outer flower-trace is given off on its way down to the leaf. This is probably to be regarded as a case in which the main trunk of the leaf-trace has remained adnate to the ring-bundle through the length of the node. And it is not improbable that in the more normal case shown in Text-fig. 3, the bundles of the inner series really arise from the leaf-traces or from the ring-bundles in the neighbourhood of the point of departure of the leaf-traces, and are adnate to the latter until they reach the level of the top of the node or some higher point in the lower half of the next internode.

The inner series of bundles now described for the male spikes of *G. africanum* and *G. Buchholzianum* are without doubt to be regarded as the homologues of the inner series of the female spike of *G. africanum*,¹ which they resemble in their origin, their course, and their orientation, and also of the inner series of the female spike,² and probably the single series in the male spike of *G. scandens* (Text-fig. 2), which are orientated in the same manner. The 'augmenting' bundles which appear to be a constant feature of the more advanced female spike in *G. scandens* and *G. africanum*³ are not found in the male spike of these species nor of *G. Buchholzianum*.

TEXT-FIG. 4. Longitudinal section through a node and parts of two internodes of *G. africanum* (an exceptional case). Lettering as in preceding figures. $\times 15$.

The course of these ascending, later descending, bundles of the inner series in the male and female spikes of *G. africanum* and in the male of *G. Buchholzianum* bears a resemblance to that of the sporangiophore trace in *Palaeostachya vera*.⁴ This arises from the ring immediately above the bract-bundle,⁵ and it 'does not separate from the main bundle until it has ascended through almost exactly half the internode'. It then becomes reflexed as in the African *Gneta*. In the case of *Palaeostachya* there are grounds for the opinion that the course of the sporangiophore trace is to some extent determined by the distribution of sclerized tissue. In *Gnetum*

¹ l. c., Text-fig. 3, BIV.

³ Hickling ('07).

⁴ l. c., Text-fig. 2, BIV.

⁵ l. c., Text-fig. 1.

no such explanation is possible, for although the ground tissue contains a great development of sclerenchyma, its elements are for the most part isolated and its distribution is quite independent of the arrangement of the bundles (Text-fig. 4). It is stated that one of the outstanding differences between *Calamostachys* and *Palaeostachya* is the absence of any considerable reflection of the sporangiophore trace in the former. Hickling's conclusion that the two forms need not be remotely separated on this account receives some support from the fact that we have in *Gnetum* an even greater difference of a like character between living species of the same genus.

From the nodes of the network formed by the branching and anastomosis of the traces described above, short branches arise and proceed directly outwards towards the insertions of the flowers. These are more or less concentric or distinctly collateral; in the latter case the phloem may be situated on either the upper or the lower side of the xylem.¹ Each of

TEXT-FIG. 5. Longitudinal section through apex of inflorescence of *G. scandens*. $\times 15$.

these upon entering the floral axis gives off two branches in a vertical plane which pass, the one into the upper, the other into the lower, perianth leaf of the male flower (Text-fig. 3); the main trunk almost immediately forks in a horizontal plane and becomes resolved into two xylem-traces (Pl. LX, Fig. 3), which pass up the axis of the flower and end blindly, one beneath each anther, as described by Strasburger.

In still another character of the male spike, the African species differ from *G. scandens* and from other Indo-Malayan species whose structure has been investigated. In *G. scandens* the bundles of the leaf-cupule lie not far beneath the upper epidermis, with which they are united by continuous tissue. In both the African species a large mucilage canal intervenes between the leaf-bundle and the upper epidermis² (cf. Text-figs. 3 and 4; Pl. LX, Fig. 2). This canal is continuous all round the cupule. The early stages of its development have not been seen, but it is clearly lysigenous in origin. Its roof usually consists merely of the epidermal cells, to which, however, the remains of underlying tissue are frequently attached. Its occurrence is not limited to the flower-bearing nodes, for it attains complete development in the youngest node, which bears no flowers (Text-fig. 6). In the African species also the pith tissue of the older internodes of the inflorescence is always disorganized and its cavity filled with a mass of mucilage. In herbarium specimens the internodes are shrunk to such an extent that they have the form of stout threads connecting the nodes, which

¹ Cf. Thoday ('11), p. 1106.

² l. c., p. 1104.

by comparison appear to be greatly swollen. This disorganization of the axial parenchyma is absent from all the material of *G. scandens* that is available for examination. It appears, therefore, that the tendency to undergo mucilaginous degeneration is much greater in the African species than in others that have been studied. But a somewhat similar disintegration of the tissue of the leaf-base in contact with the axillary bud occurs in the seedling of *G. Gucon*.¹

Apart from the remarkable behaviour of the vascular strands supplying the flowers in the African species the most peculiar feature of the male spike is the basipetal development of the flowers in each ring; this character is common to all three species, and, so far as is known, no species has been described in which it does not occur. In *G. scandens* the bundles which supply the flowers arise as branches from the leaf-traces just before these enter the leaf. Such an origin of the vascular supply of an axillary bud seems to be somewhat rare among the cases investigated,² but it occurs in *G. africanum*.³ The stem of this species is heterophyllous. So far as is shown by the material available, branches never arise from the axils of the ordinary foliage-leaves, but are subtended by reduced leaves which bear a close resemblance to the sterile leaves on the peduncle; their leaf-traces, from which those of their axillary branches arise, are as small and frequently almost as

TEXT-FIG. 6. Longitudinal section through apex of male inflorescence of *G. africanum*. *Scl.* = sclerenchyma. $\times 28$.

numerous as those which pass into the cupules of the inflorescence. The narrow space between the reduced leaf and its axillary shoot is occupied by a dense growth of hairs similar in form and origin to those which occur among the flowers of each ring. The flower-ring as a whole is, therefore, undoubtedly axillary in position. But the basipetal order of development of its members is not paralleled in the vegetative organs. A few examples of supra-axillary shoots have

¹ Bower ('82), p. 283; Pl. XXV, Fig. 19.

² The two bundles from the axillary branch unite at once with two of the leaf-traces in *Clematis* (de Bary ('84), p. 244).

³ Material of the vegetative parts of *G. scandens* is not available.

been seen, but the succession of these is strictly acropetal. It appears that the basipetal development of lateral organs is very frequently, if not always, associated with arrested apical growth.¹ In the *Gnetum* male inflorescence the same association is found, for although the rings follow one another in acropetal succession, the growth of the axis is definite. The number of rings in each spike is almost constant within narrow limits, 14–17 in *G. scandens*, 8–10 in *G. africanum*, 7–9 in *G. Buchholzianum*; exceptionally the axis becomes arrested early, and the rings produced are fewer—two in one example of *G. Buchholzianum*. But whether the number of floral rings is normal or less, the axis at length terminates in a segment which differs from those beneath it. This last segment bears no flower-primordia, and the bundles which should supply the flowers are not represented even by procambial strands (Text-figs. 5 and 6). Such a segment as this puts an end to the normal apical development of the axis as effectively as if it were a flower. And in *G. Brunonianum* 'der Scheitel der Inflorescenzaxe gipfelt auch hier häufig, wie in den rein weiblichen Inflorescenzen, in einer einzigen weiblichen Blüthe'.² The axis then is of limited growth. This being the case, and since the inflorescence may consist of as few as two flowering nodes and a terminal segment (which in some cases is an ovule with appendages), it is conceivable that the ancestral type of inflorescence was an axis bearing a single lateral ring of male flowers, and a terminal female flower. In any case it seems at present impossible to refer the male spike of *Gnetum* and either the spike or flower of *Welwitschia* to a common type that is not very remote from both.

The structural characters of the male spike in which *G. scandens* and other Indo-Malayan species differ from the African species may be summarized thus:

*Indo-Malayan species.*³

Internodes suppressed.

A ring of imperfect female flowers at the top of every node except one or two nearest the apex.

No mucilage canal in the cupule.

Vascular complex supplying the flowers derived entirely from a single series of strands ascending from the leaf-traces.

African species.

Internodes longer than nodes.

In nearly all cases female flowers entirely absent.⁴

Large mucilage canal continuous round the cupule between upper epidermis and vascular bundle.

Vascular complex supplying the flowers derived from a double set of strands, one as in *G. scandens*, the other descending from the top of the node or from the internode above.

¹ Goebel ('00, '05.)

³ Hitherto described.

² Strasburger ('72), p. 158.

⁴ A single exception seen in *G. africanum*.

Until more complete information as to the structure of the axis of the spike in other species and in earlier stages of development is available, it is useless to seek for an explanation of the remarkable differences now shown to exist between *G. scandens* and some of its allies on the one hand, and the African species on the other. It is, however, worthy of emphasis that the most remarkable fact established in this investigation—viz. the presence of a series of strands descending to the nodal flower-complex—is associated with elongated internodes. It would be of great interest to know whether this association is constant. The structural differences found between the male and the female axes of the same species are such as might be anticipated in view of the much longer duration of the female spike and the greater demands made upon its vascular system. Speaking generally, these are (1) a tendency to lignification of the medullary tissues of the female and to mucilaginous degeneration of the same tissues in the male; (2) the appearance of adventitious bundles 'augmenting' the inner series, and of transfusion tracheides associated with the cupular traces in the female and their absence from the male.

The similarity of structure of the male spikes of the two African species, and the differences which separate them from those of the Indo-Malayan species whose anatomy is known, are of phylogenetic interest. If the internal characters of the female spike of *G. Buchholzianum* bear a close resemblance to those of *G. africanum*, as may be expected, the near affinity of these two will be more firmly established. But while nothing is known of the internal structure of the vegetative and reproductive organs of any of the eleven American species, nor of the majority of those which occur in the Indo-Malayan region, no definite conclusions can be drawn as to the phylogenetic position of the African species with regard to the rest of the genus.

The hairs which occur among the flowers are usually of the character which has been described by previous writers. Occasionally, however, they assume the form of cell-plates, which are of interest owing to their resemblance to ramenta (Fig. 4). In the younger inflorescences the cells of the hairs contain starch.

In the youngest flowers available the anther wall consists of an epidermis and two layers of tapetum (Fig. 5); these latter are clearly derived by tangential divisions from an initial layer.¹ As development proceeds the outer of these becomes exhausted and flattened, while the cells of the inner undergo considerable enlargement (Fig. 6), and at length many of them become binucleate (Fig. 9). These stages are closely matched both in *Ephedra*² and in *Welwitschia*.³ By the time that the pollen-grains have reached the 3-nucleate condition, the outer tapetal cells are hardly recognizable, and those of the inner layer have preserved nothing of their

¹ Karsten ('93), Taf. viii, Fig. 14.

² Land ('04), Figs. 5-7, 14.

³ Pearson ('06), Fig. 4; ('09), Fig. 2.

original structure save a shrunken, delicate, and interrupted outline (Fig. 7). The cells of the epidermis which now constitute the anther wall are somewhat radially elongated, the outer wall being slightly thickened and cutinized. Running vertically from the summit of the anther for some distance down each side is a double row of cells smaller than the rest, and whose walls, at this stage, are less thickened. These are doubtless the rows described by Karsten between which dehiscence occurs. In all cases in *G. africanum* they are smaller¹ than the rest of the cells of the wall.

The anthers, of which in all three species under investigation there are two on each flower-axis, are normally quite free from one another. Rarely, however, they cohere in the lower half. One case has been seen in which the septum separating them for more than two-thirds of their height was reduced to a cell-wall.

In the stage of Fig. 5 the walls of the sporogenous cells are delicate, but in no way difficult to observe. Later, as the nuclei approach the condition known as synapsis, and while the tissue connexions are still maintained, the cell-walls become extremely thin and indistinct (Fig. 8). At this time the walls stain very faintly in Delafield's haematoxylin or *Lichtgrün*; but in unstained or badly stained preparations they are practically invisible. This must be the stage described by Karsten in *G. Gnemon* in which the sporogenous mass is said to consist of 'lediglich freie Zellen ohne Cellulosewände'.² During synapsis, when perhaps the wall is more difficult to distinguish than at any other time, the most careful observation of good preparations is necessary to convince one that Karsten's description does not apply to *G. africanum*. Here, however, there is no doubt that throughout this and the stages which immediately follow it, a wall is always present. After synapsis it undergoes a gradual thickening, but it does not become conspicuous until the condition of the 'equatorial plate' is approached. The supply of material has not been sufficient for a detailed investigation of this remarkable behaviour of the wall of the mother-cell. There can, however, be no doubt that the substance of the wall on both sides of the middle lamella is actually removed, for the reticulum of the cytoplasm can be seen to be in contact with the delicate separating membrane (Fig. 8). A similar series of changes has not been described for *Ephedra* nor for *Welwitschia*.

Soon after the distinct reappearance of the wall it undergoes a considerable degree of mucilaginous thickening, which, in early stages, is marked by the irregularity of its distribution (Fig. 9). At this stage many of the cells are partially separated from their neighbours (Fig. 9), though their isolation is not usually complete until after the conclusion of the heterotypic division (Fig. 10). When the mother-cells are quite free from one another the wall is thickened all round, but not uniformly so (Figs. 11-15). The

¹ Cf. Karsten ('93).

² Karsten ('93), p. 345.

number of chromosomes appearing in the heterotypic division is probably twelve, as stated by Coulter for *G. Gnemon*.¹ No cell-plate is recognizable in the course of this division.

The homotypic division usually occurs after the isolation of the mother-cells. The two spindles sometimes lie approximately parallel to one another (Fig. 11); in other cases they are inclined at any angle up to 90° (Fig. 12). Stages intermediate between these and that of Fig. 13 have not been seen. In the last figure, spindle-fibres are still visible, and although two of the three cell-plates are not continuous with the wall of the mother-cell (probably on account of contraction in preparation), there can be no doubt that the mother-cell becomes four-chambered in the same way as in *Pinus*.² The chambers are frequently all traversed by the same section; such an arrangement would follow the nuclear division shown in Fig. 11. The walls separating the microspores remain thin (Fig. 14) until these acquire their own cell-walls. Eventually they become almost as thick as the outer wall of the mother-cell (Fig. 15). There is nothing to suggest that the thickening is a second wall and not merely an addition to the primary cell-wall or a uniform swelling of its substance. As a rule it appears perfectly homogeneous in optical section. It stains faintly in Delafield's haematoxylin, but it can hardly consist of unaltered cellulose.³ Apparently ruptured mother-cells from which one or more of the microspores have escaped have been met with. But the setting free of the microspores appears to be more generally due to a gradual solution of the wall of the mother-cell, which loses its definite outline and becomes almost invisible while the microspores are still held in position. This suggests that the thickening of the wall, at least in part, and its final disorganization, are the result of mucilaginous degeneration. This chambering of the mother-cell occurs also in *G. scandens*, but it has not been described for *Ephedra*, nor for *Welwitschia*, nor for any other species of *Gnetum*.

Before the disorganization of the mother-cell wall is complete, the wall of the microspore commences to thicken, and exine and intine are quickly organized. As stated by Karsten, in opposition to Strasburger, the exine contains no distinct pores, but is covered by minute, somewhat irregular protuberances (Figs. 16-20). Also, as in the species studied by Karsten, the microspores in a particular sporangium are not all in the same stage of germination at the same time. A greater degree of uniformity prevails in the stages preceding the organization of the microspore, but even here the development does not proceed *pari passu* in the two sporangia of the same flower.

The germination of the microspore commences after it has been set free from the mother-cell. The spindle in the first mitosis is exceedingly

¹ Coulter ('08).

² Ferguson ('04), p. 35, Pl. IV, Fig. 45.

³ Cf. Ferguson ('04), pp. 35, 36.

delicate (Fig. 17); an evanescent cell-plate is formed; the two resulting nuclei lie quite free in the cytoplasm (Fig. 18). One of the two quickly divides again, the spindle being perhaps less indistinct than in the preceding division. An evanescent cell-plate is formed in this case also (Fig. 19). After the completion of this division, the cytoplasm contains three free nuclei, of which two are usually a little larger than the third. They are most frequently arranged as shown in Fig. 20, but sometimes they lie in a row one above the other. This is the most advanced condition that has been found, and in anthers which are already protruding beyond the edge of the cupule all the pollen-grains are in this state. This is true also for *G. Buchholzianum*. There can be little doubt that these are adult pollen-grains, a conclusion which is in agreement with Karsten's account. As is pointed out above, Karsten states that at the time of germination the pollen-grain contains only two free nuclei. One of the three must therefore disappear; presumably this is the one which does not participate in the second mitosis, and which is to be regarded as 'prothallial' in character and homologous with one of the three free nuclei in the mature pollen-grain of *Welwitschia*.¹ The other two nuclei are probably the one a tube nucleus, the second a generative nucleus.² No indication of the organization of a generative 'cell' has been observed. If such a cell is developed later, as is probable,³ then in the germination of the microspore and the structure of the adult pollen-grain *Gnetum* differs in no important respect from *Welwitschia*. Between *Gnetum* and *Ephedra*, on the other hand, there is a wide gap.

SUMMARY.

1. *G. scandens*, *G. africanum*, and *G. Buchholzianum* have been investigated. The study of the microsporangium and microspore has been mainly carried out on inflorescences of *G. africanum*.

2. The male inflorescence is definite; it bears a number of axillary rings of basipetally developed flowers.

3. Other characters of the inflorescences are summarized on p. 614.

4. The structure of the anther wall and the tapetum is similar to that described by Karsten.

5. The pollen mother-cells are not free naked cells during the early stages of their development. But immediately before and after the condition of the nucleus known as synapsis, the cell-wall is extremely delicate and difficult to observe.

6. Later the wall thickens irregularly and the mother-cells are not usually free from one another until the homotypic division is completed.

7. The reduced number of chromosomes is probably twelve.

¹ Pearson ('06), Pl. XVIII, Figs. 13-16.

² Cf. Lotsy ('99), p. 94.

³ Karsten ('93); Lotsy, l. c.

8. The nuclei formed in the heterotypic division are free.
9. The spindles in the homotypic division are arranged either bilaterally or tetrahedrally.
10. Cell-plates appear after the homotypic division, dividing the cavity of the mother-cell into four loculi, each containing one microspore.
11. While the wall of the microspore is being laid down, the septa of the mother-cell become almost as thick as its outer wall. Before the microspores are set free, exine and intine are differentiated.
12. The outer wall and septa of the mother-cell are probably mucilaginous in character. They usually disappear gradually as if in process of solution.
13. The microspore nucleus undergoes mitosis; one of the two daughter nuclei divides again. There result three free nuclei which may show a radial or a linear arrangement.
14. This appears to be the condition of the pollen when dehiscence of the anther occurs.
15. The three nuclei are probably to be identified as one prothallial, one vegetative (tube), and one generative.
16. The germination of the microspore and the structure of the pollen-grain point to a much closer degree of affinity with *Welwitschia* than with *Ephedra*.

NOTE ON THE INFLORESCENCE AXIS IN GNETUM.—Professor Pearson's investigation of the male inflorescence has made it advisable to add some comment to the short description of the male axis in *G. scandens* made on p. 1106 of my recent paper (Annals, 1911), and Professor Pearson has kindly allowed me to add a note here. On comparison with his full account I find that my description of the male cone, which was based on a small quantity of material and given only for the purposes of comparison, refers to a case which in one respect is not normal. It was stated that the bundle supply of the male floral complex originates in practically the same way as that supplying the ovule. It is now clear that in the male inflorescence axis all the bundles supplying the flowers correspond normally with the *inner* inverse series alone of the female flower, and it is not normal to find any of the bundles of the male floral complex inserted further out on the bract-bundles in a position corresponding to the *outer* series supplying the ovule. This difference between the male and female axes did not become evident to me till I saw Professor Pearson's paper (and consequently made a re-examination of my material), owing to the fact that I first examined an exceptional case in which a few of the lowest floral bundles were inserted in this position.

A comparison between the female cones of the two species investigated by Professor Pearson and myself throws some light on the great difference in the vascular system of the male axes, i. e. the presence of 'descending' bundles in the one species and their absence in the other. This is not accompanied by as great a difference in the female axes, traces of a descending system being present in the female axis of *G. scandens* (ibid., p. 1106). It appears to me probable that the greater or less development of the descending system of bundles in the inflorescence axes of this genus is conditioned by the length of the internode and position of insertion of the flowers characteristic in the species, and by the stage of development of the particular strobilus in question. I have already stated in my paper that in the young cone axis of *G. scandens* no descending bundles were present, but that as the ovules increased in size new bundles were laid down, some of which, on entering the stem, instead of turning downwards to join the crowded ovular bundles at their insertion on the bract-bundles, ran upwards to join the main bundles.

In the axis of *G. Africanum* the descending series was far better developed, even in the young cone, and the greater the age of the cone the greater the development and complication of this series. These facts are probably due to the relatively short internode in *G. Africanum*, and the consequent crowding of the cupules and flowers in this species. In *G. scandens* the young female flowers are at first situated closely in the axil of the cupule, but are afterwards carried out on a stalk so that they are never inserted by a very broad surface, and above their level of insertion there is a long stretch of bare internode beneath the cupule at the base of the next node. But in *G. Africanum* the ovules, sessile at all stages, are inserted by their whole base on the stem, above the cupule, and as the ovules develop and their base widens, they take up an ever-increasing part of the short internode. Thus it is obviously much more convenient for the later formed vascular bundles in the upper part of the ovule to be inserted on the main bundles higher up in the node or even in the internode above, than to run downwards towards the already complicated mass of

vascular tissue at the base of the node : on entering the stem they therefore continue their course through the cortex towards the main bundles, forming the 'descending' series.

In *G. Gnemon* and *G. funiculare*, two other species which I have recently examined, both of which have long internodes and sessile ovules, there is hardly any trace of the descending series, except that in the older ovules a few bundles are found to originate from the main bundles a little above the origin of the bract bundles and to run downwards from these to join the mass of vascular tissue which supplies both bract and flowers.

M. G. THODAY (SYKES).

MANCHESTER, Jan. 1912.

NOTE.

TELOSYNAPSIS AND PARASYNAPSIS.—There exists at the present time a considerable amount of confusion as to the actual nature of the controversial points which cluster, or are supposed to cluster, around the manner of pairing of the somatic chromosomes at meiosis, whereby the well-known heterotype chromosomes are produced. This confusion is due in great part to the attempts which have been made to crystallize the essential differences between two divergent schools of interpretation by the introduction of the terms *Telosynapsis* and *Parasynapsis* respectively.

But it must have become evident to every one at all conversant with the current work on mitosis, that however appropriate these terms may be to express a special mode of chromosome union, they have now become rather misleading to any one not familiar with the details of cytological advance within the last few years. The fact is, that by emphasizing a point of comparative unimportance, they have led to a misconception on the part of many people, as to the really fundamental differences which still divide the two schools of investigators.

Montgomery in America, and Farmer and Moore in England, working independently on very different material, came to the conclusion that the heterotype chromosome arose as the result of an end-to-end union—or a lack of disjunction—of a pair of somatic chromosomes. These paired chromosomes are arranged more or less in the form of an open loop, the sides of which they constitute. The familiar figures observed at diakinesis, and at still earlier stages, depend on the various ways in which the limbs of a loop behave as they approximate towards, or coil round, each other.

In formulating this explanation, the investigators above named were mainly influenced by the very common occurrence of loop-like figures at an earlier stage, which were also traced through succeeding phases; the turn of the loop was supposed to coincide with the point of union between the two somatic chromosomes.

The closer approximation of the sides of a loop was believed by the English authors to take effect at the stage called 'second contraction', a stage which, where it was discerned, appeared to be one of very short duration, and consequently is easily missed. It is obvious, however, that there is no essential difference between a lateral approximation achieved by the twisting together of the sides of such a loop, and an approximation produced by the coming together in pairs of chromosomes hitherto disunited, nor is it a matter of any importance whether the approximation occurs at a somewhat earlier or later period in mitosis.

The really vital question at issue between the two schools does not, as a matter of fact, consist in *Telosynapsis* *v.* *Parasynapsis* as etymologically understood, *but upon the interpretation to be placed on the much earlier stages of prophase* in the heterotype mitosis.

Investigators, represented in the first instance by Grégoire and his pupils, who hold the 'Parasynaptist' view, believe that the early so-called *longitudinal fission of the chromosomes* marks the union of the pairs of somatic chromosomes. Furthermore, they attach no importance to *second contraction*, which is interpreted by their oppo-

nents as concerned in bringing about this union. The 'Telosynaptists', on the other hand, regard this early longitudinal fission as a reality, and as indicating *precisely the same fission as is responsible for the bipartition of the chromosomes of a normal premeiotic or postmeiotic nuclear division.*

I endeavoured to put forward the main features of the whole position as plainly as I could in 1905 :

'Thus the essential peculiarities of the meiotic¹ phase can be explained as follows: They are due to the coherence in pairs of premeiotic chromosomes and to the intercalation of a special form of chromosome-distribution during the course of what would not differ materially from an ordinary premeiotic mitosis. In the first of the two divisions, a distribution of entire premeiotic chromosomes is secured, and thus the number of these bodies is really halved. In the second division, the longitudinal division begun, but temporarily arrested, in the preceding prophase takes effect.'

I have never receded from this position, because it has always appeared to me that, in spite of the many differences in detail exhibited during meiosis in the various members of the animal and vegetable kingdoms, this interpretation harmonizes best with the observed facts, and also with what we have ascertained as the result of comparisons with the other mitoses in the same organisms. It has also materially gained in strength of late years, since improved technique has made it evident that in *somatic* mitoses the chromosomes are actually longitudinally split during the late telophase of the *preceding* division, and that in the succeeding early prophase each differentiating chromosome can be distinctly recognized as already consisting of two longitudinally arranged halves. This duality commonly becomes apparently, but only apparently, lost during the following period of rapid growth and change of form before the chromosome becomes arrayed, along with its fellows, in the equatorial plate. At this latter stage, as every one knows, the split appears, or rather reappears, and results in the separation of the respective pairs of daughter chromosomes. The proof that features precisely similar in this respect are present in the *postmeiotic* as well as in the premeiotic mitoses (first given by Dr. H. Fraser) effectively disposes of the suggestion that this 'early fission' might represent an abortive 'pairing of homologous chromosomes' in the vegetative mitosis. Furthermore, the results obtained by Miss Digby and others, showing that the 'early fission' at the heterotype mitosis is exactly similar to the 'early fission' of the preceding archesporial divisions, render it extremely improbable that a fundamentally different interpretation is to be placed on the two cases.

I have tried in this brief note to point out as clearly as possible what are the really outstanding differences which at the present time constitute the main points at issue between the 'Telosynaptists' and the 'Parasynaptists', inasmuch as they have been greatly obscured by the rather unfortunate names under which the divergent views are now so commonly classified.

Structure and Development of the Ovule of *Bowenia spectabilis*.¹

BY

E. M. KERSHAW, M.Sc.

Assistant Lecturer in Botany, Manchester University.

With Plate LXI and sixteen Figures in the Text.

THIS investigation was undertaken in the hope that it might increase our knowledge of Cycads, and also give further information on points of interest in connexion with the study of fossil seeds, more especially with regard to the development and fate of the pollen-chamber. No detailed account of the ovule of *Bowenia* has yet been published, and it seems desirable that every genus of such a limited and ancient family as the Cycads should be investigated.

The greater part of the material was obtained some years ago by Professor Lang from the plants of *Bowenia* growing in the Royal Botanic Gardens, Kew. All this material was unpollinated, but it supplied an almost complete series of stages from an ovule with only the megaspore cell developed to one almost ready for pollination. The rest of the Kew material consisted of aborting ovules of two sizes, the smaller about the size of a wheat grain, the larger the size of a small hazel nut. Although these were abnormal they afforded much useful information. This material was supplemented by a batch of old pollinated ovules (Fig. 9, Pl. LXI, actual size), collected from the Botanic Gardens, Tokyo, by Dr. M. C. Stopes, to whom I am indebted for the material. While the series is thus an incomplete one, a good general idea of the changes in form and structure of the ovule can be obtained from it. Much of the development shows close agreement with that described by various authors² for other genera, but the chief stages will be briefly described, since they help to fill in some of the gaps in the various accounts. They also contribute to the data necessary for a comparative review³ of our knowledge of the ovule of Cycads, which it is hoped

¹ A preliminary account of this investigation was read before Section K of the British Association, Portsmouth, 1911.

[Annals of Botany, Vol. XXVI No. CIII. July, 1912.]

to attempt at some future date. The present paper will be mainly descriptive, with an indication of the direction in which the facts for *Bowenia* would seem to point in a discussion of the general phylogenetic problem.

DESCRIPTION OF OVULES.

The megasporophylls form a compact strobilus and have a well-defined stalk which expands into a peltate head with a flat or slightly ridged apex (Fig. 9, Pl. LXI). The peltate head is elongated horizontally, and an ovule is borne on the under side of each of the horizontal extensions. The general features of the series of ovules to be described are shown in Text-figs. 1-4 and 14-16, which are outline camera lucida drawings. The main features of the ovules of various ages will be described in order.

(a) UNPOLLINATED OVULES.

The youngest ovule obtained (Text-fig. 1) appears as a small swelling of the under side of the sporophyll, with very little constriction at the point of attachment, for no distinct stalk is yet differentiated.

The nucellus is surrounded by the single, differentiated integument a division line being formed by rows of flattened cells which extend from the base of the ovule to the epidermis. A slight cleft in this region of the epidermis indicates the beginning of growth of the free parts of nucellus and integument.¹ The tissue of the nucellus consists of longitudinal rows of cells traceable to the flat apex and evidently produced by periclinal divisions of the epidermis. In the centre of the nucellar tissue there is a rounded mass of cells with rather denser contents than the surrounding cells. Further growth is indicated in this tissue, for many of the cells show signs of a coming division. This is the sporogenous tissue which later becomes more conspicuous and, by analogy with other Cycads² in which the earlier development has been worked out, may have formed by the division of the original archesporial cell.

Situated usually slightly above the centre in the sporogenous tissue is a conspicuous cell, 0.04 mm. long, larger and with a rather thicker wall than the surrounding cells (Fig. 1, Pl. LXI). This is the mother-cell of the embryo-sac. The protoplasm of the cell is unvacuolated and the large central nucleus has a distinct nucleolus. Ovules of approximately the same age show a rather later condition of the nucleus of the megaspore mother-cell (Fig. 2, Pl. LXI). This seems very like the synopsis condition in preparation for the coming reduction division. The chromatin matter is contracted in a mass to one side and the rest of the enlarged nuclear area is clear. Since, however, the material was only roughly fixed in 70 per cent. spirit it was not suitable for cytological work. The vascular bundles which

¹ Cf. Lang, loc. cit., Fig. 2, Pl. XVII.

² F. G. Smith: Development of Strobilus of *Zamia*. Bot. Gaz., vol. 1, 1910.

are to supply the ovule can be seen as procambial strands in the sporophyll. The changes which take place in the ovule as growth proceeds can easily be followed in the slightly older ovules. All the parts become larger and more differentiated, but the most marked change is that which occurs at the apex of the ovule in the free parts of nucellus and integument. In the ovule just described the nucellus had a broad flat top, almost on a level with the slightly rounded top of the integument and only separated from it by a slight cleft (Text-fig. 1). From this time onwards the parts of the integument and nucellus above the cleft show marked growth. The epidermal cells actively divide by periclinal walls and gradually build up the free areas of nucellus and integument. As the nucellus grows its sides gradually

TEXT-FIGS. 1-4. Series of median longitudinal sections of ovules of various ages. $\times 12$.

become sloping, while the top remains flat, so that the whole of the free part resembles a truncated cone (Text-fig. 2). The integument keeps pace in the growth and follows closely the sloping surface of the nucellus, the apex of which gradually becomes more pointed (Text-fig. 3). The nucellus for some time grows at the same rate as the integument, and the two are therefore of about the same height, but at the stage seen in Text-fig. 3 the integument has begun to outgrow it. From this time onwards the free ends of the integument grow more rapidly than the nucellus, and the micropyle between becomes gradually narrower.

A very similar method of growth of nucellus and integument was described in *Stangeria*, and photographs 2, 7, and 12, Pl. XVII¹ compare very closely with Text-figs. 1-3 of this paper.

¹ Lang, loc. cit.

Shortly after the beginning of active independent growth of nucellus and integument, the megaspore mother-cell begins to increase in size, and the reduction divisions occur. These have not been observed, but the result, a row of three cells, is shown in Fig. 3, Pl. LXI, which is taken from an ovule slightly younger than the one represented in Text-fig. 2. The upper two cells are smaller and their nuclei less dense than the lowest one, which becomes the embryo-sac. The same development of the embryo-sac is described in *Ceratosamia*¹ and in *Stangeria*.² From this time a marked increase in size of the embryo-sac is noticed, and the sister cells show signs of disorganization (Fig. 4, Pl. LXI). The nucleus of the embryo-sac divides

TEXT-FIG. 5. Portion of longitudinal section of ovule represented in Text-fig. 3, showing sporogenous tissue surrounding the embryo-sac. *e.* = embryo-sac; *d.s.* = degenerating sporogenous cells; *s.* = active sporogenous tissue; *f.* = flattened cells of nucellus, bordering on the integument. $\times 300$.

into two, which are shown in Fig. 5, Pl. LXI, with the disorganized sister cells above. Other sections obtained show the result of a second division, an embryo-sac with four free nuclei.

Free nuclear division proceeds and the embryo-sac gradually enlarges, but the protoplasmic contents do not increase at an equal rate, and hence it appears for a long time as a hollow sac with a thin lining of protoplasm in which lie the free dividing nuclei (Fig. 6, Pl. LXI).

The growth of the embryo-sac is accompanied by growth of the surrounding sporogenous tissue. Many of these cells are actively dividing

¹ Treub, loc. cit., 1885.

² Lang, loc. cit.

and appear more densely granular than the surrounding nucellar cells. This tissue appears to act as a nutritive tissue or tapetum. All the evidence points to the tapetum being a modification of the sporogenous tissue as in *Stangeria*.

In rather later stages of the ovule, crushed and disorganized cells of the tissue lie immediately around the embryo-sac (Text-fig. 5). The nutrient which they contained has evidently been absorbed by its encroachment. In this same ovule, which is of the size indicated in Text-fig. 3, the outermost cells of the sporogenous tissue show signs of active division. It is evident that for some time the increase by division of the outer sporogenous cells keeps pace with the destruction of the innermost cells by the embryo-sac, and the result is that the embryo-sac is surrounded until a much later stage by a layer of nutritive tissue. Cf. Text-fig. 5, and Fig. 5, Pl. LXI.

The last of the series of normal, unpollinated ovules is much larger than the previous stages described, and shows marked advances in the structure and differentiation of the various parts. One of these ovules is seen in median longitudinal section in Text-fig. 4, which shows the general relation of parts. The free part of the nucellus is a large dome-shaped mass (Fig. 7, Pl. LXI), surrounded by the integument, which is 0.6 mm. thick, and shows signs of differentiation into the three characteristic layers. The micropylar tube is wide and contains mucilage, the function of which is probably to assist later in catching the pollen-grains. The embryo-sac is so large that it almost fills the lower part of the nucellus.

The chief interest of an ovule of this age is that it shows the first indication of the formation of the pollen-chamber (Fig. 7, Pl. LXI). Running down the centre of the nucellus from the tip to a short distance above the level at which it fuses with the integument, a length of 1 mm., is a strand of cells. These are conspicuous since they are elongated in the vertical direction, while the cells immediately around them are slightly elongated in the horizontal direction and thus appear to radiate from the central strand. Also the surrounding cells have denser contents, larger nuclei, and appear in a more active state of growth than the central cells. Warming¹ figured cells of this nature in the nucellus of *Zamia*, and described them as a kind of conducting tissue. A similar tissue was also figured by Brongniart² in *Cardiocrarpus angustodensis*, also by Stopes³ in *Cycas Rumphii*. Although there is at this stage no sign of breaking down of tissue, it is evident that this central strand indicates the area which will ultimately dissolve in the formation of the pollen-chamber. The embryo-sac has grown with the rest of the ovule, being 1.8 mm. long by 1.2 mm. wide. It still appears essentially as in the last stage, a hollow sac with a thin lining of protoplasm containing nuclei, some of which are undergoing division, but with no sign of

walls between them. The megaspore membrane forms a conspicuous covering, but is thin in comparison with that of other Cycads, and shows no differentiation into layers as described for some genera, e. g. *Cycas revoluta*.¹ In the oldest ovule examined the megaspore membrane is thin and undifferentiated. If, as Thomson suggests, a thick megaspore membrane is to be regarded as a sign of primitiveness, then in that respect *Bowenia* as compared with other Cycads must be regarded as well advanced. The sporogenous tissue which formed so large a mass round the embryo sac of the younger ovule has almost entirely gone. It has evidently failed to keep pace with the advancing embryo-sac, and appears as one or two layers of granular, compact cells at the outside and a few broken and disorganized cells lying loosely around the megaspore membrane (Fig. 8, Pl. LXI). There is no sign of any active formation of new cells. Evidently at a slightly earlier stage the formation of new cells ceased, then, as is shown in Fig. 8, Pl. LXI, the cells of the tissue separated from one another, gradually dissolved, and were absorbed by the encroaching embryo-sac; cf. *Zamia*.² In rather later stages, when the prothallus tissue fills the embryo-sac, the whole of the nutritive tissue has disappeared. The length of time which this tissue persists and its appearance during the last stages varies in different genera. In an ovule of *Stangeria*, with the pollen-chamber beginning to form and the embryo-sac completely filled by the prothallus tissue, the sporogenous tissue is shown³ to still persist in the form of a single layer of much enlarged cells with smaller crushed cells on their inner side. These are the remains of a tissue which earlier appeared as a compact surrounding mass very similar to that in the young stages of *Bowenia*. The embryo-sac gradually absorbed the sporogenous cells around it, except the outermost layer, which enlarged to form the definite layer which Lang termed a tapetum. How long this layer persists cannot at present be stated. Lang was unable to follow it, for in the fertilized seeds which he had all traces had disappeared. A further supply of *Stangeria* material which I have examined confirms Lang's description, but does not help in this point. In an ovule of *Dioon*⁴ with prothallus and pollen-chamber development a definite 'jacket layer' is present round the prothallus, and this acts as a tapetum. It thus appears from the present facts that the sporogenous tissue of *Stangeria* and *Dioon* persists much longer than in either *Bowenia* or *Zamia*.⁵

The integument of the ovule at this stage shows indications of the three layers characteristic of Cycads. The cells destined to form the stone layer are smaller than those forming the fleshy parts, though they

⁵ Smith, loc. cit.

have yet unthickened walls. They extend from the base of the ovule up into the micropylar region (Text-fig. 4). There is a definite and regular epidermis of small rectangular cells limiting the outer fleshy layer in which tannin sacs and mucilage ducts are beginning to appear. The inner fleshy layer is composed of rectangular parenchymatous cells which are indistinguishable from the adjoining cells of the nucellus.

THE VASCULAR SUPPLY OF THE OVULE.

In an ovule of this age it is easy to trace the vascular supply. Longitudinal and transverse sections of the ovule on the sporophyll can be cut before the sclerization of the stone layer. The bundles are, however, not fully developed, and the detailed description of them will be given later in connexion with the oldest ovule. Two series of vascular bundles are present in the ovule. The outer series consists of from 7 to 9 bundles which extend from the base into the micropylar region and only rarely branch. The inner series consists of 12-14 bundles at the base of the ovules. They branch frequently on their way up the ovule and number about 40 at their termination, which is usually just below the point at which nucellus and integument become free (Text-fig. 6). These bundles lie apparently on the border line between nucellus and integument. In some cases, however, which will be described later, there is reason to think that this inner vascular supply is nucellar. The whole of this vascular system is supplied by branches from one of the foliar bundles of the sporophyll (Text-fig. 7). The bundles of the sporophyll which serve the sporangia are markedly large, with a few elements of centripetal xylem; cf. Worsdell.¹ The position and branching of the bundles can be made out by comparing Text-fig. 7 and the series 8-12. In the stalk of the sporophyll the foliar bundle *A* divided into two branches, *a* and *b*—the former being the outermost. The branch *a* divides into *a*¹ and *a*² (dotted line) long before reaching the ovule, and these two branches serve mainly the part of the ovule nearest to the sporophyll. One branch supplies the anterior and the other the posterior region of this part, and each sends branches to both inner and outer series. The branch *b*, after dividing from *a*, runs down for some distance in the sporophyll before turning in the direction of the ovule. It then forks and one branch, *fb*¹, remains in the sporophyll, while *b* turns towards the base of the ovule. Before actually entering the ovule it gives off a second foliar branch, *fb*². The branch *b* supplies the part of the ovule distal to the stalk of the sporophyll, and sends branches to both the inner and outer series.

(b) OLD POLLINATED OVULES.

The last of the normal ovules investigated were much larger than those previously described, and were in addition pollinated. The material con-

¹ Worsdell: Vascular Structure of Sporophylls of Cycadaceae. Ann. of Bot., vol. xii, 1898.

sisted of about a dozen sporophylls, each with a pair of ovules, one of which is represented in natural size in Fig. 9. Very frequently one of the pair of ovules was malformed and had a very twisted, shrunken appearance, but was otherwise quite healthy. The prothallus and archegonia of such an ovule were normal. Possibly the distortion was the beginning of a late abortion, caused by the great pressure exerted on the ovules during the growth of the cone. The normal ovules are about 2 cm. long and 1.8 cm. across. They are distinctly oval in shape with a prominently pointed micropylar tube. The surface of the ovule is smooth and covered with brown flecks due to the tannin sacs beneath the epidermis.

The general relation of parts of such an ovule is seen in diagrammatic view in Text-fig. 13. The three layers of the integument are differentiated, the stone layer being represented by the closely dotted layer.

TEXT-FIG. 6. Diagrammatic transverse sections of the ovule, showing the vascular supply. (1) The base of the ovule. (2) Just below the point at which nucellus and integument become free.

TEXT-FIG. 7. Longitudinal section of sporophyll, showing vascular supply to the attached ovule.—Explanation in Text-figs. 8-12.

The outer and inner series of vascular bundles are well developed. The free part of nucellus and integument is only a small portion of the whole ovule. In the pollen-chamber there are developing pollen-grains whose rooting ends have penetrated the tissues of the nucellus. The prothallus is of large size, usually about 1.8 cm. in length, and has a ring of 5-7 archegonia at the apex.

An examination of the integument shows it to be thin compared with that of other Cycadean ovules of a similar age. The outer flesh forms more than half of the whole thickness, 1.4 mm. Indeed at the end of the micropyle almost the whole of the tissue is outer flesh. This layer of the integument is bounded by a regular layer of small epidermal cells with strongly cuticularized outer walls. The rest of the tissue consists

TEXT-FIGS. 8-12. A series of transverse sections through the sporophyll, showing the vascular supply to the attached ovule.

of large parenchymatous cells containing starch. The innermost cells are completely filled with large starch grains, while in the cells further out the number and size of the starch grains gradually diminish. Those near the epidermis contain only a few small grains. Amongst the outermost cells of this layer there are scattered tannin sacs, which begin to form in a single cell; then frequently an aggregation of such cells leads to the formation of one large sac. Deeper seated in this layer is a ring of large mucilage ducts, about 1.5 mm. in diameter. The main ducts are vertically placed, and from them there are branches and anastomoses in a lateral direction. The outer series of vascular bundles lie among the innermost cells of this layer, separated from the stone layer by about two rows of cells.

The bundles of this series are collateral and have a large amount of centripetal xylem (Fig. 10, Pl. LXI). The centrifugal xylem consists of fairly regular rows of tracheides proceeding from the protoxylem; the phloem elements follow on in equally regular rows towards the outside, where there are a few crushed protophloem elements. The centripetal xylem is about equal in amount to the centrifugal, but the elements are rather larger in size. They lead directly from the protoxylem, and the elements spread towards the inner part of the integument. There is a definite sheath of parenchymatous cells surrounding the bundle. This structure is similar to that described in *Encephalartos* by Stopes,¹ and is a much simpler type of bundle than that which is described by the same author in some species of *Cycas*.

The stone layer, which is yet only partially sclerized, extends from the base of the ovule, where it stretches completely across (Text-fig. 13),² and is penetrated by the inner series of vascular bundles, to about half-way up the micropylar beak. It is of almost uniform thickness, 0.3 mm., except in the basal region, where there is a slight increase. There is no indication of a differentiation of the stone layer into distinct parts as is the case in many *Cycads*.³ The tissue consists of cells slightly elongated vertically, which in the basal region interlace with each other, forming what would be a very resistant tissue when the cell-wall had hardened. Sclerification has as yet only taken place in the micropylar region and about half-way down the free part of the integument (Fig. 11, Pl. LXI). The process apparently begins in the innermost cells of the layer, which have very thick walls with slit-like pits, and gradually spreads outwards. There is a sharp line of demarcation between the outermost sclerized cells and the adjoining cells of the outer flesh, which contain starch. An interesting feature of the micropylar region of the ovule is the occurrence of a second ring of sclerized cells almost bordering on the micropylar tube and extending up about half its length (Fig. 11, Pl. LXI).

¹ Stopes, loc. cit.

² Cf. *Dioon*, where there is a gap in the basal region of the stone layer.

³ *Dioon*—Chamberlain, loc. cit. *Cycas Beddomii*—Stopes, loc. cit.

The cells forming this ring are long and narrow and obliquely placed, making an acute angle with the micropylar tube. The position of these cells shows them to be part of the inner fleshy layer of the integument, but they are very closely related to the stone layer. In some parts they are actually in contact with the sclerized cells of the stone layer, and in other parts the separating parenchymatous cells themselves show signs of sclerification beginning. It seems probable that in an older ovule the whole of this basal region of the micropyle would be one sclerized mass of cells. There seems to be no exact parallel to this condition among living Cycads or fossil seeds. The upper part of the micropylar tube is now closed, and can scarcely be seen in a transverse section. Lower down the tube becomes slightly wider, and the long pointed beak of the nucellus extends up into it. The separating line between inner flesh and stone layer is difficult to make out in the parts where the latter is not sclerized, also there is no obvious line of division between nucellus and inner flesh. The cells of both consist of rather elongated parenchymatous cells with scattered tannin sacs. The inner series of vascular bundles lie in this region and follows an imaginary line dividing nucellus and integument, and obtained by continuing the slit between their free portions towards the base. In many of the ovules the bundles terminate just below the division into free nucellus and integument. In several of those examined, however, the bundles of this inner series were found to extend for a short distance into the free part of the nucellus (Fig. 12, Pl. LXI). From the earliest stages of the ovule where the bundles were beginning to develop it could be seen that they were not integumental, as has been recently generally assumed for Cycads. From the later stages examined it seems that one would be justified in stating that in the case of *Bowenia* there are strong reasons for assuming the inner vascular supply to be nucellar. A transverse section of a bundle of the inner series in the lower part of the ovule is seen in Fig. 13, Pl. LXI. The bundles differed much from those of the outer series. The protoxylem is mesarch, and the greatest development of wood is in the centripetal direction with only a few tracheides of centrifugal direction. The phloem is small in amount and difficult to identify. The possible elements seem to be arranged all round the xylem. As compared with the outer collateral bundles, the inner ones have an almost concentric appearance. As the bundles branch and pass upward through the integument they gradually lose their mesarch appearance. The protoxylem is no longer recognizable, and the bundle consists of a flattened mass of short thick tracheides without phloem. These bundles are very numerous and close together in the upper part of the ovule (Text-fig. 6).

The free area of the nucellus is a comparatively small part 1.4 mm. in length which caps the top of the prothallus. It is limited by a regular epidermis with cuticularized outer walls and terminates in a long beak-like

part 0.4 mm. long, fitting closely into the micropylar tube (Fig. 11, Pl. LXI). This part is shrivelled and black in colour, as are also a few of the outer cells of the lower, expanded part of the nucellus. Below the beak-like portion the tissue of the nucellus is hollowed out and forms a large chamber, which in some ovules extended completely through the nucellus, and so was in direct communication with the prothallus. In others the lower part of the nucellus was intact and no such communication had been established (Fig. 14, Pl. LXI). In this large lower cavity numerous pollen-grains were growing, sometimes as many as twenty in one ovule, and all at approximately the same stage of development (Fig. 15, Pl. LXI). In *Zamia*, on the contrary, pollen-grains at almost all stages of development may be found in one nucellus. The pollen-grains have produced long, unbranched, rooting ends which have penetrated the wall of the cavity and into the nucellar tissue (Fig. 14, Pl. LXI). They run out horizontally from the cavity, and before reaching the surface turn downwards and run just below the epidermis. At the end of each root-like growth is the tube nucleus. When viewed from above the tubes appear as dark lines radiating from a central point. The end of the tube in the cavity is much swollen and contains the developing fertilizing apparatus. It consists of two prothallial cells and a large terminal generative cell (Fig. 15, Pl. LXI). The first prothallial cell is next to the pollen-grain coat. It has a fairly large nucleus and its wall bulges considerably into the second prothallial cell, whose nucleus is thus pushed to one side, and the two thus give the appearance of one cell within another. At the end of the second prothallial cell is the large generative cell, which contains a nucleus 0.03 mm. in diameter (Fig. 16, Pl. LXI). The chromatin of the nucleus is arranged in a definite network, and there is a nucleolus 0.015 mm. in diameter. Situated at opposite ends of the nucleus, generally opposite to an indentation in its margin, are the two blepharoplasts. They are homogeneous bodies with numerous fine radiations arising from them on all sides. When stained with Heidenhain's haematoxylin blepharoplasts and radiations take an intense black. In some cases the pair lie in the plane of the long axis of the pollen-tube, in other cases in a plane at right angles to it.

This is the only stage in the development of the fertilizing apparatus that has been obtained, but the whole structure is so similar to that which has been described for *Zamia*¹ and *Dioon*² that it is evident that development has taken place in the same way as in those where the divisions have been followed.

The female prothallus appears as a white glistening mass with a ring of five to seven archegonia opening into an archegonial chamber, which is

¹ Webber : Spermatogenesis and fecundation of *Zamia*. U. S. Dept. Agric. Bull., Bur. Plant Ind., vol. ii, 1901.

² Chamberlain : Spermatogenesis in *Dioon edule*. Bot. Gaz., vol. xlvii, 1909.

very shallow compared with that in ovules of *Cycas* and *Dioon* (Text-fig. 13). The prothallus is surrounded by the megaspore membrane, which adheres closely to the nucellar tissue rather than to the prothallus. This membrane is still very thin, showing little increase in thickness, if any, from that of the younger ovule. The prothallus tissue consists mainly of large cells with two or three rows of smaller cells at the exterior. In the neighbourhood of the archegonia also the cells are small. They have thin walls and nuclei and no visible stored food material. In the specimens investigated the protoplasm had shrunk considerably from the walls. The archegonium is about 1.7 mm. long and surrounded by a conspicuous jacket layer. It has a pair of arched neck cells above, which are evidently formed by a transverse division of a single cell (Fig. 17, Pl. LXI). The contents of the archegonium consist of foam-like vacuolated protoplasm, with a single nucleus 0.02 mm. in diameter at the apex (Fig. 18, Pl. LXI). The nucleus has an irregular outline and contains numerous masses of chromatin, and various sized granules of a staining substance are scattered around the nucleus in the protoplasm. In Fig. 18, Pl. LXI, two large masses of this substance are seen. It seems very probable that these granules are similar to those described by Ikeno¹ as proteid granules. The central cell of the archegonium is surrounded by a thick 'egg membrane' in which there are pits of various sizes (Fig. 19, Pl. LXI). Through the pits haustoria-like processes of the 'egg' protrude towards the surrounding cells of the jacket layer, the protoplasm of which is very dense and often contains, in addition to the large nucleus, several granules of a substance which stained like chromatin. It has been asserted by several investigators that a thin wall closes the pits of the thick egg membrane. No such closing membrane to the pit can be seen in these ovules with the highest magnification. The preservation of the material may account for this; or it may be, as Chamberlain¹ suggested, that the pit membrane which probably exists in the younger stages is ruptured by the haustoria as they grow out towards the jacket cells.

(c) ABNORMAL OVULES.

The two stages of abnormal ovules were of use in showing intermediate steps in development, especially as regards the pollen-chamber, between those already dealt with. The main features of these ovules will be described before discussing the development and morphology of the pollen-chamber in *Cycads*.

The younger ovules were about 4 mm. long. A vertical section of one of them is represented in outline in Text-fig. 14. In all ovules of this age the pollen-chamber was completely formed, and many of them contained a prothallus with several archegonia; but in all cases it had shrunk, sometimes considerably, from the megaspore membrane. Some of the ovules

¹ Ikeno: *Cycas revoluta*. Jahrb. wissensch. Bot., vol. xxxii, 1898.

TEXT-FIG. 14. Outline drawing of median longitudinal section of young abnormal ovule. $\times 12$.

TEXT-FIGS. 15 and 16. Outline camera lucida drawings of median longitudinal sections of old abnormal ovules. $\times 10$. *p.c.* = pollen-chamber; *p.* = upgrowth of prothallus into nucellus tissue; *n.* = free part of nucellus; *o.* = outer flesh of integument; *n.i.s.* = fused layers of nucellus, inner flesh, and stone layer; *a.b.* = outer integumental vascular bundle.

contained no prothallus, for the development of the embryo-sac had evidently been checked. In these cases layers of cells with the appearance of cork have developed in the interior layers of the integument, apparently to cut off the aborting region.

The specimens have a thin integument with, however, a well-developed vascular supply, so that the abnormality does not seem to have been caused by lack of nourishment as in some cases recorded.

The cells of the prothallus are of uniform size, and from their arrangement it seems probable that the tissue has been formed by divisions of a peripheral layer of cells which gradually fill up the hollow cavity centripetally. The apex of the prothallus between the archegonia is elevated, and although the tissue has shrunk away, a complete impression of its shape is seen in the nucellar tissue with which it was in contact. The condition of the nucellar cells in this region indicates that there must have been very close contact between the two. An upward growth of the prothallus at an early stage of development of the archegonia seems constant in Cycads; cf. Coulter and Chamberlain.¹ Later, the region of active growth is removed to a ring of tissue outside the archegonia, and by rapid cell formation the summit of the prothallus becomes sunk in the 'archegonial chamber'. The archegonium is surrounded by a jacket layer and has a pair of flat neck cells (Fig. 20, Pl. LXI). The central cell contains relatively little vacuolate protoplasm with a central nucleus; but with as yet no differentiated egg membrane.

The pollen-chamber in these ovules is a large cavity open to the micropyle above and to the prothallus below (Fig. 21, Pl. LXI). Comparison with pollinated ovules suggests that in a normal ovule of this age the passage would not be completely formed. It seems advisable to call the whole cavity the pollen-chamber and to distinguish it into the *upper pollen-chamber* and *lower pollen-chamber*; such a division seems functionally a natural one. The *upper pollen-chamber* is the narrower part of the cavity in the pointed tip of the nucellus, which extends for some distance up the micropylar tube. Its walls are thin and hardened and taper off to a fine point. The *lower pollen-chamber* is the large cavity in the wider part of the nucellus beneath the tip.

The older abnormal ovules are about 8 mm. long and therefore twice the size of those described above. Two of them are represented in outline in Text-figs. 15 and 16. The integument and nucellus are normally developed and the two parts of the pollen-chamber are seen. The walls of the upper cavity are hard and cutinized and give it the appearance of a dark, pointed cap, similar to that seen in the old pollinated ovule. The lower pollen-chamber is abnormal in its relation to the prothallus, which is of exceptional appearance, often being completely twisted out of shape. The form and

¹ Coulter and Chamberlain: *Morphology of Gymnosperms*. Univ. of Chicago Press, 1910.

relation of the cells composing this tissue are also extraordinary in some cases. In every ovule examined the prothallus had grown abnormally into the nucellar tissue above, a feature which was remarked upon in connexion with the younger abnormal ovules. In several instances this growth is astonishing. In the ovule in Text-fig. 15, the upper part of the prothallus is a large, cone-shaped mass, the apex of which has pushed into the pollen-chamber. In the ovule in Text-fig. 16, a mass of prothallial tissue has grown out through the pollen-chamber to the cavity between nucellus and integument. In all these cases the tissue of prothallus and integument is very intimately connected.

The cause of the abnormalities in the two sets of ovules just described is probably twofold: first, the unnatural conditions under which the plants grew, and secondly, the lack of pollination. The first reason seems to account for the abnormal appearance of the younger ovules. It is clear from comparing one of these ovules (Text-fig. 14) with a normal ovule just before pollination (Text-fig. 4), that at an early age it must have ceased to follow the usual line of development and yet have produced a prothallus and pollen-chamber. The influence which caused this departure must have been felt before the ovule was normally ready for pollination, for the ovule is actually less in size than the younger ovule with no prothallus and pollen-chamber. The lack of pollination, however, would probably account for the unusual appearance in the older ovules.

MORPHOLOGY OF THE POLLEN-CHAMBER.

From a comparison of the different stages of development of the nucellus in *Bowenia* and other Cycads it seems probable that the pollen-chamber arises similarly in all cases. Before pollination the nucellus has a central strand of cells differentiated from the cells of the surrounding tissue (Fig. 7, Pl. LXI). About the time of pollination the apical cells of this strand begin to break down. They apparently separate from each other and are then completely dissolved. The first result of this 'resorption' is that a small cavity, such as that figured in *Stangeria*,¹ termed here the upper pollen-chamber, is formed in the apex of the ovule. This small cavity has walls which are cutinized and taper off to a fine point above. It seems probable that pollination would normally take place about the time of the formation of this upper cavity, and that it is by reason of the breaking down of the cells in that region that the pollen ever reaches the nucellus. The passage of a pollen-grain through the micropyle, which has become very narrow at the time of pollination, would be very difficult unless there were some suction from below; cf. Webber on *Zamia*.²

In *Bowenia*, before the pollen-chamber has begun to form, the micropylar tube contains mucilage, which probably at a rather later stage assists in

¹ Lang, loc. cit., Fig. 15.

² Webber, loc. cit.

catching the pollen-grains. The breaking down of the nucellar tissue which would occur about this time, sets up a suction drawing the fluid and the pollen-grains contained in it down towards the nucellus. The grains are then accommodated in the small upper pollen-chamber, but they do not grow any further whilst in that position. By a further deliquescence of the cells of the central strand downwards and also outwards, a larger and wider cavity is formed—the lower pollen-chamber. The pollen-grains drop into this cavity and continue their development in it. There is sufficient room in this lower cavity for the stalk cells and generative cells to grow out from the pollen-grain and also a surrounding tissue of sufficient thickness for the rooting ends to burrow (Figs. 14 and 15, Pl. LXI). The upper pollen-chamber, which is now functionless, appears as a pointed black cap of hard and shrivelled tissue on top of the lower pollen-chamber.

The passage for the sperms to the archegonia is made partly by a further deliquescence of the cells below the lower chamber, and partly by the upward growth of the prothallus and consequent crushing of the nucellar tissue immediately above. In the abnormal ovules this upward growth of the prothallus and absorption of the nucellus is very marked; it takes place to a less extent in the normal ovule, cf. *Dioon*.¹ The part of the nucellus marked out by the central strand in the young ovule, therefore, breaks down and deliquesces, and the remaining part, separating the sperms from the archegonia, is absorbed by the upward growth of the prothallus.

COMPARISON WITH THE POLLEN-CHAMBER AND OVULE OF PTERIDOSPERMS.

Since the living Cycads are practically the only plants in which it is possible to study the actual development and working of the pollen-chamber, it is clearly necessary that the data should be critically examined with what has been described for that interesting region of the seed of Pteridosperms. A comparison of the pollen-chamber mechanism of the Cycads with that of the Lagenostomales² emphasizes the relatively simple character of the former. Although two parts have been described above in the pollen-chamber of Cycads, which seem to correspond in position and function with the upper and lower parts of the pollen-chamber of these fossil seeds, they are not such differentiated regions as the 'lagenostome' and 'plinth'. There is no such specialization as one sees in the small cup-shaped lagenostome of *Conostoma* with its sculptured walls, nor the circular cavity with the central cone of tissue in *Lagenostoma*. Again, the development of the pollen-chamber of the Cycads is a much simpler process than that which has been assumed to take place in *Conostoma* and *Lagenostoma*. In the

¹ Chamberlain, loc. cit.

² Oliver and Salisbury: Palaeozoic Seeds of the *Conostoma* Group. *Annals of Botany*, vol. xxv, 1911.

Cycads a lysigenous cavity forms by progressive disintegration of cells and eventually becomes large enough for the storage and growth of the pollen. A very different and more elaborate type of development of the storage cavity or plinth has been assumed to take place in the Lagenostomales. The whole pollination of this group is in striking contrast to the simple development and arrangement of the pollen-chamber of Cycads, in which there is no suggestion at any stage of the previous existence of such a specialized type of nucellus as was present in the Lagenostomales.

A closer comparison can, however, be made with the pollen-chamber of the seeds of the Medulloseae.¹ In *Trigonocarpus*, *Stephanospermum*, &c., the pollen-chamber consisted of a prominent nucellar beak which engaged with the base of the micropyle; the cavity of which led below to a larger chamber, where the pollen-grains developed. The seeds of the Cordaiteae also had a pollen-chamber of this type. Some of Brongniart's² figures of apparently young ovules of Cordaiteae show the method of development of the pollen-chamber. In his Fig. 13, Pl. III, he shows the apex of the nucellus of *Cardiocarpus angustodensis*, in which a median cavity, evidently formed by disintegration of tissue, leads to a larger cavity containing pollen-grains. The upper passage is described as a 'canal conduisant à la chambre pollinique'. From the appearance of the tissues in these figures it seems probable that the development of the pollen-chamber was upon the same lines as has been described in Cycads. Although there are no figures of young stages of *Trigonocarpus* it is probable that the pollen-chamber, which so closely resembled that of *Cardiocarpus*, developed along similar lines, and therefore along similar lines to the Cycads.

As regards structure and development of the pollen-chamber, therefore, the closest parallel to the Cycads among fossil seeds is to be found in seeds of the *Trigonocarpus* affinity, and there seems to be no evidence in either of them that this structure had resulted from simplification of a more complicated type, such as that of the Lagenostomales.

The general morphology of the Cycad ovule has long been a problem of interest, and since the discovery of the relationships of Lagenostoma, comparisons have been made between the two, which scarcely seem justified. The Cycad integument has been described as a morphologically double structure,³ formed by the fusion of a cupule-like structure with a single integument, the line of fusion being in or near the stone layer. If such were the case it might reasonably be expected that the development of the Cycad integument would show something indicative of its double nature. The integument of *Bowenia* develops as a single homogeneous tissue, which later gradually differentiates into the three characteristic layers, but shows no indication that it is morphologically a double structure. Similar

¹ Scott : Studies in Fossil Botany. Part II, 1909.

² Brongniart, loc. cit.

³ Stopes, M.C. : The Double Nature of the Cycadean Integument. *Annals of Botany*, vol. xix, 1905.

development has been found in all the genera thus far investigated. The facts of ontogeny, therefore, do not support the supposed phylogenetic development of the integument.

The vascular supply of the Cycad ovule was also held to agree closely with that of *Lagenostoma*. In certain genera of Cycads, Stopes¹ found that the bundles of the inner vascular series ran into the free part of the integument, and therefore this supply was held to be the equivalent of the integumental bundles of *Lagenostoma*, while the outer Cycad bundles were the equivalent of the cupule bundles. The vascular supply of *Bowenia* shows evidence of a conflicting nature which makes it impossible to accept the above comparison. In certain cases described the bundles of the inner vascular series ran into the nucellus, certainly only for a short distance; yet, if one accepts such a fact as a criterion, the inner vascular supply of *Bowenia* must be regarded as nucellar. Until more direct evidence on this point appears one can only leave the question of the exact position of the inner vascular series an open one. The general distribution and arrangement of the bundles of the Cycad seed, however, differ considerably from those in *Lagenostoma*. The bundles of the inner series in Cycads are almost concentric in structure, with little phloem, and form together a much branching system around the nucellus; the integument bundles of *Lagenostoma*, which were held to be their equivalent, were collateral with mesarch xylem, and ran without branching almost to the tip of the integument. These facts seem to show that the connexion between the Cycad ovule and *Lagenostoma* is not so close as has sometimes been assumed.

On the contrary, the evidence strengthens the suggested² close resemblance of the Cycad ovule to seeds of the *Trigonocarpus* affinity. It was seen above that as regards development and structure of the pollen-chamber Cycads agree closely with *Trigonocarpus*. The close correspondence between the integument of the two was emphasized by Scott and Maslen,³ for in both it consists of three similarly differentiated layers. The outer fleshy layer of *Trigonocarpus* was lacunar, a condition which may well have led to the formation of mucilage passages, and also in this layer cells similar to the tannin cells of Cycads occur. The sclerotesta was differentiated into two regions of cells such as are found in many Cycads. Considering the vascular system—both have an outer supply of a constant number of unbranching collateral bundles and an inner, much branching system, which in *Trigonocarpus* directly enclosed the nucellus, and in Cycads lies usually in the plane of fusion of nucellus and integument. In both cases these bundles are small and consist only of a group of tracheides with little or no phloem.

¹ Stopes, loc. cit., 1904.

² Scott, loc. cit., p. 649.

³ Scott and Maslen: Structure of the Palaeozoic Seeds *Trigonocarpus Parkinsonii*, &c. *Annals of Botany*, vol. xxi, 1907.

The great point of difference between *Trigonocarpus* and the Cycad seed is in the degree of union of nucellus and integument, but this does not seem to be a serious obstacle in the general argument. Oliver¹ has pointed out that the free or fused character of the nucellus is probably determined by the method of growth of the ovule, and one assumes that in these two seeds the region of growth in the one case has been apical, in the other basal. Such a difference of growth, then, would account for the greatest feature of dissimilarity between the seeds of *Trigonocarpus* and the Cycads. The general structure of the ovule of *Bowenia*, therefore, in respect to the integument and vascular supply, as well as the pollen-chamber, points to a very close connexion with seeds of the *Trigonocarpus* affinity.

In conclusion I should like to express my thanks to Professor W. H. Lang, F.R.S., for the greater part of the material on which this investigation is based, the facilities he has given me in his laboratory, and his help and criticism during the progress of the work.

SUMMARY.

1. The general development of the ovule of *Bowenia* is found to be similar to that of other genera of Cycads.

2. The embryo-sac arises from the lowest of a row of three cells, which are differentiated from the mass of sporogenous tissue. Free nuclear division proceeds in the embryo-sac, and during the subsequent growth the sporogenous tissue serves as a nutritive layer. This layer is used up by the time the prothallus is formed, i. e. at an earlier period than in other genera of Cycads.

3. The pollen-chamber forms by a solution of the tissue in a region of the nucellus previously recognizable by the arrangement of its cells. It has been distinguished into *upper pollen-chamber*, which developed first, and serves as a storage place for the pollen on entering the ovule, afterwards becoming hard and shrivelled; and the *lower pollen-chamber*, a larger cavity forming later into which the pollen-grains pass, and where they develop the spermatozoids.

4. The male gametophyte consists of two prothallial cells and a large terminal, generative cell with large nucleus and a pair of blepharoblasts. From this one stage observed it is evident that development is similar to that described in *Zamia*.

5. The vascular supply of the ovule is derived from one foliar bundle of the sporophyll, and consists of an outer ring of seven to nine unbranching bundles, collateral with mesarch xylem, which lie in the outer part of the integument; and an inner series of concentric bundles which branch frequently. The most interesting point of the vascular supply is that in

¹ Oliver : The Ovules of the Older Gymnosperms. *Annals of Botany*, vol. xvii, 1903.

some cases the bundles of the inner series pass beyond the level of the origin of the integument, into the free portion of the nucellus.

6. There is held to be a close agreement of the general structure of the ovule of *Bowenia* with seeds of the Medulloseae.

The Evolutionary History of the Foliar Ray in the Wood of the Dicotyledons : and its Phylogenetic Significance.¹

BY

IRVING W. BAILEY, A.B., M.F.

Assistant Professor of Forestry at Harvard University.

With Plates LXII and LXIII.

EVOLUTION OF THE FOLIAR RAY.

IN 1909 Mr. Eames (4) and the writer (1, 2, and 3) conducted a series of investigations upon the broad rays and so-called 'false rays' of the Fagales. The conclusions drawn from these studies have since been published, and may be summarized briefly as follows :

1. Oaks from the Miocene of California are characterized by possessing 'false rays', such as are a distinctive feature of the wood of a large number of living representatives of the Betulaceae.

2. The mature wood of certain Live Oaks of America and Japan possess large rays which are composed of congeries of smaller rays.

3. *Alnus rhombifolia*, Nutt., and *A. maritima*, Muehl, develop in the older wood large homogeneous sheets of ray parenchyma homologous to the large rays of oaks with deciduous foliage.

4. The earliest formed secondary wood of seedling oaks and alders possesses solely uniseriate rays, such as are a characteristic feature of coniferous plants and many other Gymnosperms.

5. In the mature wood of different species of *Alnus* a perfect series of stages occur, which demonstrate the 'building up' of a homogeneous sheet of ray parenchyma from congeries of uniseriate rays and the parenchymatization of fibres included between them.

6. In the development of individual alders and oaks a similar progressive series of compounding stages occur in passing from the younger to the older portion of the stem.

7. Wood which possesses highly developed types of compound ray tissue when injured severely reverts to the primitive uniseriate condition,

¹ Contributions from the Phanerogamic Laboratories of Harvard University, No. 47.

[*Annals of Botany*, Vol. XXVI. No. CIII. July, 1912.]

and in subsequent growth a recapitulation of the compounding process occurs.

8. Upon the basis of the comparative and developmental anatomy of living and fossil plants and the phylogenetic significance of seedlings and traumatic regions, the uniseriate ray appears to be the primitive type of ray structure in the Fagales, and the large sheets of ray tissue, either of the homogeneous or aggregate type, have developed from them by a process of aggregation and fusion.

In subsequent investigations by the writer (1, 3) additional evidence was secured in regard to the origin and development of these structures and their effect upon the stem.

1. Small twigs of *Quercus*, *Alnus*, *Carpinus*, and *Betula* revealed upon the removal of the bark a striking and diagrammatic relation between the sheets of aggregate or compound tissue and the traces of the leaves.

2. A study of the development of ray structures in the Fagales made by means of transverse and tangential serial sections cut through the seedling, young and mature twigs, and large stems, showed the leaf to have been the stimulating influence in the formation of these large sheets of storage tissue.

3. The latter originated as aggregations of uniseriate rays in the immediate vicinity of the leaf-traces, and have been 'built up' and extended vertically and horizontally considerable distances from the node.

4. The large sheets of aggregate or compound tissue which may be called *foliar rays*, in view of their origin about the entering trace, have an important effect upon the development of the stem, since their rate of growth is in most cases less rapid than that of the rest of the xylem (Pl. LXII, Fig. 2). This is generally expressed by a strong retarding influence upon the growth of adjacent radii of lignified tissue and produces a marked 'dipping in' of the outline of the annual rings in their vicinity (Fig. 2).

5. The retarding influence of foliar rays is most diagrammatically expressed in small mature twigs of oaks with deciduous foliage, in the stems of certain highly specialized Angiosperms of vine-like and semi-herbaceous habit, and in the fluted trunk of the Blue Beech, *Carpinus caroliniana*, Walt. In the case of the Blue Beech large groups of approximated foliar rays of the 'false type' produce by their retarding effect upon growth the large furrows which are a characteristic feature of the bole of this tree, the ridges corresponding to the segments in which foliar rays are feebly developed or absent. In the mature twigs of oaks with deciduous foliage there are strongly developed foliar rays related to the lateral traces of the leaves. These lateral leaf-trace rays extend downwards through several nodes, and owing to the phyllotaxy of the plant (see Pl. LXIII, Fig. 15), sheets of storage tissue are formed which are relayed from node to node in ten more or less continuous vertical lines along the stem. As is shown in

Fig. 15 the ten sheets of ray tissue are distributed in five pairs of approximated rays. This approximation of the lateral leaf-trace rays enables their concentrated retarding influence upon growth to depress the included segment of tracheal tissue below the general contour of the stem (Pl. LXII, Fig. 3, and Pl. LXIII, Figs. 13, 15). In addition to the lateral leaf-trace rays foliar rays are developed in oak and other plants in relation to the median traces of the leaf. However, in oak these rays are in most cases less strongly developed in the young twig than are the rays related to the lateral traces.

6. The origin and development of foliar rays show clearly that the statements of Sanio, Sachs, and de Bary, pointing to the origin of large rays as inclusions of fundamental tissue or ground parenchyma between putative fibro-vascular bundles and the development of so-called fascicular and interfascicular segments from supposed fascicular and interfascicular cambiums, lead to extremely misleading conclusions.

7. All segments of the stem are essentially 'fascicular', since in the seedling plant of primitive Dicotyledons the stele is an undivided tubular cylinder without indication of the putative fascicular and interfascicular segments and large rays.

8. The development, in relation to the traces of the leaves, of large sheets of storage tissue from congeries of uniseriate rays has a strong dissecting effect upon the stele, producing the supposed fascicular and interfascicular segments of oak, vines, and semi-herbaceous plants.

Eames (5), in an investigation of herbaceous and semi-herbaceous Angiosperms, secured interesting evidence which indicates strongly that herbaceous Angiosperms have been derived from forms which possessed strongly developed secondary growth. In the life-history of many plants there occurs a transition from a tubular stele, in younger portions of the plant, to a ring of separate fibro-vascular bundles in subsequently formed parts of the stem. For example, the prostrate biennial or perennial stems of *Potentilla palustris*, Scop., as well as the seedling plant, possess an unbroken central cylinder, whereas the cylinder of the erect annual stem a short distance above the rhizome breaks down into a typically herbaceous ring of separate bundles. The herbaceous type of central cylinder has resulted, therefore, from the reduction in size of Dicotyledonous plants in later geological periods, coupled with the evolution of foliar rays whose dissecting effect has been progressively increased.

More recently Professor Groom (6) has published the results of an investigation upon the annual ring and medullary rays of *Quercus*. There are certain fundamental objections to the conclusion reached by Professor Groom, that 'it is impossible at the present to decide whether in *Quercus* the broad-rayed or the narrow-rayed type was primitive'.

In studying lines of evolutionary modification in plant structures it is essential not only that a careful study be made of the comparative anatomy

of normal mature plants, but in addition an intensive study is necessary of the development of structures during the life-history of individual plants. Such developmental studies should be made to cover numerous species selected from as many genera and families as possible. Furthermore, since ancestral characters are known to persist in the seedling, reproductive axis, leaf, and first-formed portion of vigorous mature shoots of plants which have suffered vegetative reduction, and to be recalled in traumatic regions of plants which have been similarly reduced, it is essential that these regions be examined with particular care. Finally, palaeobotanical material, when available, must be regarded as an invaluable check upon conclusions of phylogenetic significance reached from living material.

It is unfortunate that Professor Groom's conclusions are based upon rather narrow foundations. The material used by him consisted evidently almost exclusively of mature oak wood, a large part of which was composed of American species cut from a collection in the possession of this Laboratory. An extensive study of the development of ray structures in the life-history of different species of oak (such as was made by Eames in the case of certain vines and species of the Rosaceae, Ranunculaceae, and other families, and by the writer in the case of many species of the following genera of the Fagales, *Quercus*, *Pasania*, *Alnus*, *Betula*, *Corylus*, *Carpinus*, *Ostrya*, *Castanea*, *Castanopsis*, and *Fagus*) was not attempted by Professor Groom. Nor did he examine those regions of the plant which retain ancestral characters.

In view of these facts certain criticisms by Professor Groom of the results secured by Eames and the writer are of interest. Professor Groom states: 'From the point of view of the assumption that the seedling is a seat of phylogenetically early structure features, these facts lose their significance if it be shown that a similar "linking up" of small rays to form large ones takes place in older parts. I find that such a "linking up" does take place, at least in connexion with some of the rays of the inner rings of the twigs of *Quercus Robur*, L.'

It is necessary at this point to emphasize the important fact that the foliar ray has reached varying stages of aggregation and fusion in different species of the Fagales. In *Alnus japonica*, Sieb. et Zucc., *A. rhombifolia*, *A. maritima*, and many evergreen oaks the foliar ray is of the *aggregate type* composed of congeries of smaller rays more or less imperfectly fused. The first-formed wood of the seedling possesses solely uniseriate rays, and the development of foliar rays is a progression in the direction of compounding. In most oaks with a distinctly deciduous foliage and in certain somewhat ring-porous evergreen oaks from the western and south-western part of the United States, the foliar ray is of the *compound type*, composed largely of a nearly homogeneous mass of parenchyma. In the highest types of this group the fused or compound condition of the foliar ray occurs except

in primitive parts, e.g. the seedling. In passing from these regions to subsequently formed portions of the stem the development of the foliar ray tissue is a progression in the direction of compounding. The significant facts to be kept in mind are that in *Quercus* the first-formed wood of the seedling possesses solely uniseriate rays, the development of foliar rays is a progression in the direction of compounding, and more primitive stages of the 'linking-up' process occur in the young plant. The 'linking up of small rays to form large ones in the first rings of the twigs of *Quercus Robur*' does not invalidate seedling evidence, since in this species the solidifying of the foliar ray may not have worked back to the region of the pith in the early wood of the stem and branches.

An unfortunate difficulty has been introduced by Professor Groom : that the broad solid ray may be primitive in oak, since it apparently undergoes subdivision in many cases. In view of the progression in the direction of compounding which occurs in the development of ray structures in the life-history of oak, alder, and other genera of the Fagales it is difficult for the writer to concur in this turning of the *foliar compound ray* inside out. That the foliar ray is dissected into shallower sheets of ray tissue in passing horizontally from the young to the older portions of a thick stem is true for all species of the Fagales. This is as true for species in which foliar rays are of the aggregating type as for those higher types in which nearly homogeneous masses of fused ray tissue are related to the traces of the leaves. In 'exogenous' stems which are increasing rapidly in circumference a multiplication of elements, fibres, vessels, parenchyma, and rays must occur with added layers of growth. Therefore the dissection of foliar rays is essential to maintain the proper proportion of ray tissue in the older zones of the stem. However, the impulse which produces this dissection of foliar rays is fundamentally different from that which results in the evolution of storage tissue in relation to the traces of the leaves, and cannot be considered evidence for believing that the broad, solid type of ray is primitive in *Quercus*. Both phenomena are often active in the same foliar ray. For example, in *Alnus rhombifolia*, *Quercus virginiana*, Mill, or *Q. densiflora*, Hook. and Arn., foliar rays of the aggregate type are gradually 'built up' in passing from the vicinity of the leaf-trace to the mature portion of a wide stem, yet a dissection of this aggregating mass of tissue takes place in the older wood, resulting in the formation of 'lower' and more numerous sheets of compounding tissue.

In this connexion Professor Groom's conclusions in regard to '*Quercus* (*Pasania*) *fenestrata* (*Q. spicata*)' are of interest: 'In *Q. fenestrata* these characteristic high rays are often approximated in pairs, and between the two rays forming a pair the boundary of the annual ring is much nearer the centre of the stem than it is elsewhere (Pl. LXXXV, Fig. 12). Moreover, the space between the two rays forming a pair is devoid of vessels. These

three sets of facts denote that in some way the pair of high rays, together with the tissue between them, is equivalent to a single broad ray; and the very considerable inward dip of the annual ring between the two rays finds simplest explanation in the assumption that in the ancestor the complex mass represented solely ray tissue.' This conclusion is somewhat remarkable in view of the facts pointed out by the writer in a former paper, that the depressed segments of the oak stem are produced (see Pl. LXII, Fig. 3, and Pl. LXIII, Figs. 13 and 15) by the concentrated retarding effect upon growth of two closely approximated foliar rays. Since these rays are usually related to the traces of different nodes it is difficult to conceive of their origin from the dissection of a single large ray. The writer recently examined material of *Quercus spicata*, sent from India by courtesy of Mr. R. S. Pearson, Imperial Forest Economist, and is unable to agree with Professor Groom in stating that vessels are absent from the depressed segments included between approximated pairs of foliar rays. Professor Groom for some unexplained reason completely ignores the important relation of the leaf-trace to the formation of large rays, although he refers to the paper by the writer in which this evolutionary process was described.

Since conducting the investigations which have been summarized earlier in this paper a more comprehensive study has been made of Dicotyledonous plants. This investigation has included not only numerous species of the more primitive or supposedly primitive families, but also of the higher or supposedly more recent families. The material used comprised not only species from the temperate regions of North America, Europe, China, and Japan, but in addition representatives of a more tropical flora from India and Australasia. In connexion with instruction upon the anatomy of American woods material of practically all American trees and larger shrubs has been examined. This investigation has confirmed strongly the conclusions reached in regard to the origin, development, and dissecting effect of foliar rays, and has served to emphasize the important part that these structures have played in the evolution of modern Angiosperms. As might naturally be expected in viewing this evolutionary movement from a broader and clearer standpoint, certain obscure and imperfectly understood features have been clarified.

That the evolution of the foliar ray occurred in the early history of Angiosperms is seen from the fact that the most convincing evidence of the compounding process is confined largely to primitive Dicotyledons or to regions of phylogenetic significance, and from the fact that in the majority of woody Angiosperms this primitive type of foliar ray has been changed structurally or completely reduced. This conclusion is further emphasized by the occurrence of well-developed foliar rays in Angiosperms of the upper Cretaceous (11).

In the light of recent investigation the foliar rays appear to have

developed as aggregations of uniseriate rays about the persistent leaf-traces of evergreen plants of the warmer Mesozoic times. These sheets of storage tissue were subsequently extended increasingly greater distances from the leaf-traces, and gradually compacted by the coalescing and enlargement of the uniseriate rays and the parenchymatization of fibres included between them. Rays of this primitive type which occur side by side with uniseriate rays have persisted to the present time in certain of the more primitive Dicotyledonous families, e.g. Fagales, Casuarinaceae.

DIFFUSION OF THE FOLIAR RAY.

With changes of environment during later geological periods the primitive foliar ray was modified in the evolution of the majority of modern trees and shrubs. This change consisted in the diffusion of the constituent smaller rays of the aggregate sheet of foliar ray tissue. Evidence of this transition, as has been shown by Thompson (12), has persisted in certain Dicotyledons and is particularly well shown in the Casuarinaceae and Ericaceae. In certain species of *Casuarina*, e.g. *C. equisetifolia*, L., *C. glauca*, Sieber, &c., the typical primitive foliar ray of the aggregate type exists in the younger portion of the stem, but in passing to the older portion the individual rays of the aggregation are diffused throughout the wood. A similar condition exists in *Rhododendron punctatum*, Andr., *Ledum groenlandicum*, Retz., and *Kalmia angustifolia*, L. In somewhat higher types, *Fagus atropunicea*, Sud., and *Platanus occidentalis*, L., the foliar rays have been diffused throughout the wood and evidence of the former congeries has been lost. However, serial transverse and tangential sections show that the diffused parts of the former aggregate ray are related to the leaf-traces. It is to be emphasized in view of the conclusions drawn by Groom from Jost's (8) study of *Fagus sylvatica*, L., that the so-called broad, high rays of *Fagus* represent diffused and enlarged portions of former *foliar aggregate* rays. In the majority of higher Dicotyledonous trees and shrubs the process of diffusion is so complete that evidence of the former connexion between the multiseriate rays and traces of the leaves has disappeared entirely.

REDUCTION OF THE FOLIAR RAY.

In the wood of a large number of Dicotyledonous plants the foliar ray, either in its aggregate, compound, or diffused form, occurs with the primitive uniseriate ray. There are, however, numerous exceptions to this general rule. Thus the uniseriate ray is seen to disappear entirely from the wood of certain highly specialized Angiosperms (5). Furthermore, individual species of many families of Dicotyledons are characterized by possessing only uniseriate rays. In Pl. LXII, Fig. 1 is illustrated the tangential section of the mature wood of the common American Chestnut, *Castanea dentata*,

(Marsh) Borkh. It will be observed that the wood is characterized by the primitive type of ray structure. A similar condition is found to exist in other members of the Cupuliferae. Thus the mature wood of *Castanea pumila*, (L.) Mill, *Castanopsis hystrix*, A.DC., *C. Indica*, A.DC., *Alnus acuminata*, H.K.B., *A. mollis*, Fernald, *A. yasha*, Matsum, &c., possess characteristically only uniseriate rays. In view of the fact that the first-formed wood of primitive Dicotyledonous plants possesses only uniseriate rays and the foliar ray has been 'built up' from congeries of small rays, it might naturally be supposed that the plants under consideration possessed the primitive type of Dicotyledonous wood from which have been evolved the higher and more complex forms. However, before accepting this supposition as a correct one, a more detailed examination of their structure is necessary. The fallacy of inferring that less complex plants are of necessity more primitive has in recent years been clearly illustrated by the study of the comparative anatomy of living and fossil plants. The pines, which, owing to their complex structure, have been commonly considered the most recent of Coniferous plants, have been shown to be very old geologically, and the supposedly primitive Cupressineae are now known to be of comparatively recent origin, and to have been evolved from more complex ancestors. In other words, in the evolution of living plants may be traced the gradual reduction and disappearance, as well as the origin and development, of specialized tissues. Among Coniferous plants the reduction of resin canals and ray tracheides can be observed in the Abiceteae, Cupressineae, and Taxodineae, as well as the evolution of ray tracheides and wood parenchyma in the Pinaceae. Similarly, among Araucarian plants there exists the reduction of resin canals and Abietineous pitting. It is, therefore, to be expected that among living Dicotyledons reduced forms occur with less complex structures than those of more primitive forms from which they have been derived, and an examination of those regions which are known to retain ancestral characters is essential in determining their real phylogenetic position.

FIRST-FORMED WOOD OF VIGOROUS MATURE TWIGS.

In Fig. 4 is illustrated the cross-section of a vigorous mature shoot of *Alnus mollis*. It will be observed that in the first annual ring are numerous large rays of the foliar type. These rays gradually die out in the second and third annual layers of growth, and the wood of the older portion of the twig possesses only the uniseriate rays characteristic of the mature wood of the species. In the first annual ring of twigs of normal growth the large rays are absent and the wood resembles that of the mature stem. Since the phylogenetic importance of the first annual ring of vigorous branches of plants which have suffered vegetative reduction has been pointed out by Jeffrey (7) in the recapitulation of resin

canals in *Sequoia washingtoniana*, (Winsl.) Sud., it is to be inferred that the foliar ray has undergone a process of reduction in the alder under consideration. Furthermore, since similar conditions exist in other lower Dicotyledons which possess only uniseriate rays in the mature wood, the conclusion is reached that a considerable number of plants, although not in reality primitive, have reverted by the reduction of the foliar ray to a type of ray structure which characterized primitive Angiosperms.

VIGOROUS MATURE ROOTS.

Fig. 6 illustrates a cross-section of a vigorous mature root of *Castanea dentata*. Six more or less feebly developed large rays (x) radiate from the clusters of protoxylem. A similar condition is illustrated in Fig. 7, a cross-section of a vigorous root of *Alnus yasha*. In this root five much reduced aggregate rays (x) are seen to radiate from five clusters of protoxylem. In view of the phylogenetic importance of vigorous mature stems the persistence of large rays in vigorous mature roots is significant.

THE NODE.

In primitive plants which possess well-developed foliar rays these structures originate in the vicinity of the leaf-trace and gradually 'build up' and enlarge in passing from the earliest formed wood of the node to that of the more mature portions of the plant. Fig. 5 illustrates a cross-section of the node of *Alnus yasha*. The foliar ray, which is strongly developed near the leaf-trace and in the first annual layer of growth, gradually disappears in the older wood. This reduction rather than compounding of ray tissue, which occurs also in *Castanea*, *Castanopsis*, *Alnus mollis*, and *A. acuminata*, indicates, as do the vigorous ramifications, that the foliar ray was once well developed in these plants and has gradually disappeared except from regions which are known to retain primitive characters. The retention of the foliar ray at the node is to be expected, since ancestral characters have been shown by Scott, Jeffrey, and others to persist in the vicinity of the leaf. The nodes of vigorous mature stems are, therefore, particularly favourable regions for the recapitulation of primitive features, and retain indications of the existence of foliar rays after they have disappeared from the rest of the stem.

TRAUMATIC REGIONS.

Valuable evidence confirming the phylogenetic importance of the recapitulation of primitive characters in the regions just mentioned is afforded by a study of the traumatic reactions of the wood of these plants. It has been pointed out above that severe injuries, in wood which possesses well-developed foliar rays, produce a reversion to primitive stages of aggregation and fusion or to the uniseriate condition. From

this it might naturally be inferred that injuries to the wood of these reduced plants would recall the foliar type of ray. That such is indeed the case is shown by Fig. 8, a cross-section of the wood of *Alnus mollis*, cut in the immediate vicinity of a severe injury. The injury has obviously produced a large aggregate ray which may be clearly recognized by its retarding influence upon the growth of neighbouring elements and the distinct sag in the outline of the annual rings. A similar condition is illustrated in Fig. 9, a cross-section of the mature root of *Alnus mollis*. The wood at the lower side of the photomicrograph, which was formed before the injury occurred, possesses only uniseriate rays, but in the upper portion of the figure may be seen numerous aggregate rays which originate at the injury. Additional illustrations of the traumatic recurrence of large rays have been observed by the writer in *Castanea*, *Castanopsis*, and *Alnus*, as well as in woods which have replaced the compound or aggregate by the diffuse type of foliar ray. Fig. 10, a cross-section of the outer portion of an insect gall in a mature twig of *Ostrya virginiana*, (Mill) Koch., illustrates the recurrence of an aggregate ray in a type of wood that possesses normally only small bi- and triseriate and uniseriate rays.

CONTOUR OF MATURE TWIGS.

There remains for consideration a striking piece of evidence in regard to the reduction of the foliar ray in lower Dicotyledonous plants. A characteristic and important feature of the foliar ray is its retarding influence upon the growth of neighbouring radii of the stem (see Figs. 2 and 3). This influence is so strongly developed in many plants that the depression in the outline of the annual rings which marked the former position of the foliar ray persists for some time after the disappearance of the ray. The writer has shown (3) that the fluted stem of the Blue Beech, *Carpinus caroliniana*, Walt., is produced by congeries of aggregate rays whose concentrated retarding influence upon the growth of certain radii produces the large grooves in the stem. A careful study of this plant shows that the foliar rays of the aggregate type are gradually being replaced by the diffuse condition. (In the closely allied genus *Ostrya* the diffuse condition is dominant.) In specimens growing under unfavourable conditions the writer has found large stems from which the aggregate ray has disappeared almost completely. However, the characteristic flutes remained, although less strongly developed. These plants were later cut down, and during subsequent growth of the stump (by means of stool shoots) congeries of aggregate rays were recalled in the depressed segments of the new layers of growth. The stimulation of the injury and surplus supply of food substances in the root produced evidently a reversion to conditions which existed before the plant suffered vegetative reduction. In Pl. LXIII, Fig. 17, a cross-section of a vigorous mature shoot of *Castanea pumila*,

may be seen five depressed segments. In this twig the foliar ray has disappeared except from the immediate vicinity of the leaf-traces. The normal twig possesses a circular outline, and the foliar ray is not conspicuously developed at the node. This recurrence of depressed segments in vigorous shoots of *Castanea* indicates that five pairs of approximated lateral leaf-trace rays existed formerly in the mature twigs of these plants, and have disappeared except from the nodes of very vigorous stems. In *Castanopsis* indications of depressed segments which were once a well-developed feature of the plant persist in the normal mature twigs. A cross-section of the node of *Castanopsis hystrix* is illustrated in Pl. LXIII, Fig. 16. Two segments (*y*) are more strongly depressed upon the upper side of the photomicrograph, due to the fact that the rays related to the lateral leaf-traces are persistent at the node. Owing to the phyllotaxy of the plant the three remaining segments (*x*) are less strongly depressed. Fig. 14 shows a cross-section of the mature stem of *Castanopsis indica*. In this species the five depressed segments are more persistent between the nodes, and indicate that the reduction of the foliar ray is less complete in this plant than in the preceding species. In Fig. 13 may be seen the cross-section of a mature twig of *Castanopsis tribuloides*, a plant whose structure resembles that of *Quercus*, since the lateral leaf-trace rays are strongly developed in the wood of small twigs. A careful study of the life-history of the plant reveals the fact that the aggregated rays are disappearing in many portions of the root and stem. In Pl. LXII, Figs. 11 and 12 are illustrated the remains of aggregate rays which were once strongly developed by the cambium to maintain the proper proportion of ray tissue in the widening stem and root. These facts, considered in connexion with evidence afforded by the recapitulation of primitive characters which occur in vigorous mature ramifications, nodes, and traumatic regions, point conclusively to the reduction of foliar rays in certain Fagales, and indicate that *Castanopsis* and *Castanea* are reduced members of the oak family, just as *Alnus mollis*, *A. acuminata*, and *A. yasha* must be considered reduced species of the genus *Alnus*.

The uniseriate rayed species of the Salicales (9) and Sapindales (10) have been studied by Miss Holden, and have been found to represent a reduced condition where complex ray structures have been lost in a reversion to the primitive uniseriate type, but among the higher families of Dicotyledonous plants the uniseriate condition has resulted largely from the reduction of foliar rays of the diffused type rather than of the aggregate or compound types.

SUMMARY AND CONCLUSIONS.

1. The central cylinder of primitive Angiosperms was a tubular cylinder or siphonostele which possessed strongly developed secondary growth.

2. The wood of the most primitive Angiosperms possessed only uniseriate or linear rays, such as are a well-developed feature of the wood of Conifers and other Gymnosperms.

3. During the warmer times of the Mesozoic sheets of storage tissue were 'built up' from congeries of uniseriate rays, about the persistent leaf-traces of evergreen Angiosperms, and were subsequently extended vertically and horizontally considerable distances from the node.

4. This primitive type of foliar ray tissue has persisted, in more or less unaltered form, in certain species of primitive families of the Dicotyledons, e.g. Casuarinaceae, Fagales, &c.

5. With changes of environment in later geological periods storage conditions were fundamentally modified in the wood of Dicotyledons.

6. In the evolution of the majority of living Dicotyledonous trees and shrubs the individual units (varying greatly in size owing to the enlargement and fusion of the original uniseriate rays which formed the incipient aggregation) of the aggregating mass of foliar ray tissue have been diffused more or less uniformly throughout the stem, and evidence of their former relation to the traces of the leaves has disappeared, except from certain primitive forms, e.g. Casuarinaceae, Ericaceae, Fagales, and Platanaceae.

7. In a comparatively limited number of forms the primitive foliar ray of the *aggregate type* has been progressively compounded or solidified, and has resulted in the formation of foliar rays of the *compound type* composed of homogeneous masses of parenchyma, e.g. oaks with deciduous foliage, *Casuarina Fraseriana*, Miq., *Alnus rhombifolia*, &c.

8. In many families of Dicotyledons species exist in which a reversion to the primitive uniseriate condition has occurred as a condition of reduction from foliar rays.

9. Evidence of the reduction of the foliar ray in the Fagales consists of a more or less complete series of progressively reduced species, and of the persistence or recurrence of foliar rays in regions of phylogenetic significance in forms which are very completely reduced.

10. The importance of experimental plant morphology in the study of phylogeny is clearly illustrated by the Fagales. In its later history the family has suffered vegetative reduction. At the same time storage conditions have been fundamentally changed in the family, resulting in modification of the sheets of aggregated ray tissue which originated about the

persistent leaf-traces of more luxuriant ancestors. In modern species the foliar ray of the primitive aggregate type has been or is in the process of being *reduced, diffused, or compounded*. Rapid accumulation of nutritive substances, such as occurs in mature twigs of unusual vigour or in regions where traumatic stimulation exists, tends to produce a reversion to ancestral structure. Thus in reduced forms the foliar ray is relegated to the first annual rings of vigorous mature roots and shoots. Similarly, in species which have suffered reduction or diffusion, the foliar aggregate ray may be recalled traumatically. Furthermore, species which possess foliar rays of the aggregate or compound type under the stimulus of a slight injury accelerate the 'building-up' process. However, diametrically different results are secured by slow or impaired nutrition. Under conditions of this sort the reduced or diffused condition is hastened by the arrested development of the primitive foliar ray. This is clearly shown in specimens of the Blue Beech which have been grown under unfavourable conditions, and by the fact that the common *Alnus incana* in the northern and colder part of its range has suffered more complete reduction of the foliar aggregate ray than in the warmer southern part. Arrested development due to impaired nutrition occurs also in plants which possess foliar rays that are of the compound or nearly compound type. Thus *severe* injuries in the oak produce a reversion to primitive stages of aggregation and fusion or to the uniseriate condition.

11. *Castanea* and *Castanopsis* are reduced members of the oak family, just as *Alnus mollis*, *A. acuminata*, and *A. yasha* must be considered reduced species of the genus *Alnus*.

12. Owing to the important part that the foliar ray has played in the structural development of Dicotyledons, the study of its evolution and reduction yields evidence significant in a natural classification of Angiosperms.

13. A more detailed consideration of the comparative anatomy and phylogeny of Dicotyledonous plants indicates conclusively that the existing conceptions of the origin and development of the woody cylinder of Angiosperms must be fundamentally modified to agree with actual conditions which exist among the higher seed plants.

In conclusion, the writer wishes to express to Major Gage, I.M.S., Superintendent of the Royal Botanic Gardens at Calcutta, to Mr. G. H. Cave of the Lloyd Botanic Garden at Darjeeling, and to Mr. R. S. Pearson, Imperial Forest Economist at Dehra Dun, his keen appreciation of their courtesy in sending valuable material of Indian plants. To Dr. Jeffrey the writer is much indebted for material and kind assistance in the course of the investigation, and to Mr. James Austin for assistance in photomicrography.

EXPLANATION OF PLATES LXII AND LXIII.

Illustrating Mr. Bailey's paper on the Foliar Ray.

PLATE LXII.

Fig. 1. *Castanea dentata*. Tangential section of the mature wood, showing the uniseriate rays. $\times 60$.

Fig. 2. *Casuarina*, sp. Transverse section of the mature stem, showing the depression in the outline of the xylem produced by an aggregate ray. $\times 20$.

Fig. 3. *Castanopsis tribuloides*. Transverse section of the mature stem, showing a small segment of wood which is depressed by two closely approximated foliar rays. $\times 20$.

Fig. 4. *Alnus mollis*. Transverse section of a mature vigorous twig, showing numerous rays of the aggregate type in the first and second annual layers of growth. $\times 20$.

Fig. 5. *Alnus yasha*. Transverse section of the node of a mature twig, showing a well-developed aggregate ray in the vicinity of the leaf-trace. The ray is seen to die out in the third annual ring. $\times 20$.

Fig. 6. *Castanea dentata*. Transverse section of a vigorous mature root, showing the retention of aggregate rays. $\times 20$.

Fig. 7. *Alnus yasha*. Transverse section of a vigorous mature root, showing the retention of aggregate rays. $\times 20$.

Fig. 8. *Alnus mollis*. Transverse section of the mature stem in the vicinity of a severe injury, showing a large aggregate ray which has been recalled traumatically. $\times 40$.

Fig. 9. *Alnus mollis*. Transverse section of the mature root, showing aggregate rays recalled by a severe injury. $\times 20$.

Fig. 10. *Ostrya virginiana*. Transverse section of an insect gall in a mature twig, showing the traumatic recurrence of an aggregate ray. The ray produces a sag in the outline of the xylem and is capped in the phloem by a dark-coloured cluster of sclerenchyma. $\times 100$.

Fig. 11. *Castanopsis tribuloides*. Transverse section of the mature wood of the stem, showing the remains of a once strongly developed aggregate ray. $\times 60$.

Fig. 12. *Castanopsis tribuloides*. Transverse section of the mature root, showing evidence of the reduction of aggregate rays in the root. $\times 60$.

PLATE LXIII.

Fig. 13. *Castanopsis tribuloides*. Transverse section of a mature twig, showing the strongly depressed segments produced by well-developed approximated foliar rays. $\times 10$.

Fig. 14. *Castanopsis indica*. Transverse section of a mature stem, showing the persistence of five well-developed depressed segments. $\times 10$.

Fig. 15. *Quercus velutina*. Transverse section of a mature twig, showing five small depressed segments which are produced by five pairs of closely approximated lateral leaf-trace rays. $\times 20$.

Fig. 16. *Castanopsis hystrix*. Transverse section near the node of the mature twig, showing the persistence of two strongly depressed segments (*y*) which are related to the lateral leaf-traces of this node. Indications of the three other depressed segments (*x*) are more or less feebly developed. $\times 10$.

Fig. 17. *Castanea pumila*. Transverse section of a vigorous mature twig, showing the retention of five depressed segments after the disappearance of the foliar rays. $\times 10$.

Contributions to our Knowledge of the Anatomy of the Cone and Fertile Stem of Equisetum.

BY

ISABEL M. P. BROWNE.

With Plates LXIV and LXV and ten Figures in the Text.

HISTORICAL SUMMARY.

IN 1864 appeared Duval Jouve's 'Histoire Naturelle des Equisetum de France'; this work contained many new and important researches and also gave an excellent summary of the earlier literature concerning the Equisetaceae. In 1865 Milde published his 'Monographia Equisetorum'; in 1867 appeared Pfitzer's account of the structure and distribution of the endodermis in the German species of *Equisetum*; this paper also contains excellent anatomical observations. In 1876 Famitzin and Janczewski, working independently, published more correct accounts of the branching of *Equisetum*; the following year appeared a short paper by Tomaschek, and in 1878 one by Sadebeck on the embryology of the genus. In 1886 Goebel published a short note on the cones of the Horsetails, and in 1888 Buchtien gave a detailed account of the prothallus and young sporophyte. The same year Müller published an account of the leaf-sheaths of the Equisetaceae, written almost entirely from the point of view of resistance to mechanical strains and tensions. In this year, too, Van Tieghem and Douliot treated of *Equisetum* in their paper on the origin of endogenous members, and in 1890 Van Tieghem published additional observations on the endodermis in the genus. Two years later Leclerc du Sablon described the structure of the tubers, and in the following year Cormack investigated the nodal structure of *Equisetum*, describing what he believed to be secondary xylem. In 1893 Bower, in the first of his papers on the Morphology of the Spore-producing Members, dealt with certain features of the Equisetaceae. Campbell's 'Mosses and Ferns', published in 1895, gave a general account of the group, while in 1899 Jeffrey published a paper dealing in detail with the structure and affinities of the genus. In 1901 Gwynne-Vaughan, in a short communication, suggested a fresh interpreta-

tion of the Equisetaceous bundle; in 1902 a general account of the Equisetaceae was given by Sadebeck in Engler and Prantl's 'Natürliche Pflanzenfamilien'; the same year appeared Chauveaud's account of the anatomy of the root, while the next year the origin and affinities of the Equisetaceae were discussed by Lignier. In 1905 the affinities of the genus were considered by Campbell, and in 1906 Sykes recorded peculiar nodal tracheides in a specimen of *E. maximum*. In 1907 appeared Queva's important paper on the stem and leaf of *Equisetum* and also a short note on the sporangium by Hawkins, while next year was published a second edition of Campbell's 'Mosses and Ferns'. The year 1908 also witnessed the publication of Bower's 'Origin of a Land Flora', in which *Equisetum* is treated at some length, and of Halle's account of the Mesozoic Equisetaceae of Sweden. In the next year Eames published a paper dealing with the anatomy of *Equisetum*, and Jeffrey discussed this subject in a paper entitled 'Are there foliar gaps in the *Lycopsida*?' In this year, 1909, there also appeared a short account of fossil Equisetaceae by Fritel and Viguiet, and a note by Stiles on the anatomy of a branched cone of *Equisetum maximum*. In 1911 Ludwigs published an account, largely biological, of the genus, while in 1912 Vidal dealt with the segmentation of the apical cell and the early stages of anatomical differentiation in *E. palustre*.

MATERIAL.

The present investigations were confined to the cone and the upper part of the fertile stem in three British species of *Equisetum*: *E. arvense*, *E. palustre*, and *E. limosum*. In the case of the first species two complete cones, henceforward termed A and B respectively, were cut into continuous series of transverse sections. Cone A was very young; it was dug up in October and would, therefore, have remained another five months underground. Nevertheless, the xylem of the cone was almost completely differentiated; this series of sections extended downwards below the cone and included four of the vegetative nodes. Cone B was more or less mature, and the series of sections below it only extended to beneath the annulus. Of a larger cone, C, serial transverse sections were made from below the annulus through the lowest seven whorls of sporangiophores. To confirm the phenomena observed in Cones A and B the upper parts of two cones, D and E, were cut serially; the latter cone, though otherwise normal, had two annuli; satisfactory series through this region of the cone could not, however, be obtained. Another cone, F, also had two annuli, and of this specimen a continuous series of sections extending from below the lower annulus through the three basal whorls of the cone was prepared. The transitional region from below the annulus through the basal whorl of the cone was also studied in two cones: in a very large one, G, the diameter of

the stele of which was about $2\frac{1}{4}$ mm., and in a smaller cone, H. Another cone, I, was cut serially into longitudinal sections. As regards *Equisetum palustre*, a cone which I shall term Cone A was cut serially from above the uppermost vegetative whorl into transverse sections; serial sections extending to below the annulus were made of another cone, B. Of another cone, C, serial sections extending from below the annulus to a point just above the second whorl were made. Cone D, a very small and young cone of the variety *polystachion*, was also cut into serial transverse sections, the series including the uppermost whorl of leaves. Serial longitudinal sections through the base of a young cone were also made.

In the case of *E. limosum* a complete young cone, A, was cut into serial transverse sections; these extended downwards to the uppermost vegetative whorl, but did not include quite the whole thickness of the nodal xylem. The whole of a still younger cone, B, with the uppermost vegetative whorl beneath it, was cut up serially into transverse sections. Another series of transverse sections extended from below the uppermost leaf-sheath through the lowest five nodes of an older and much larger cone, C. For all the three species the results obtained were confirmed by numerous longitudinal, transverse, and oblique hand-sections through different cones.

THE CONES OF *E. ARVENSE* AND *E. PALUSTRE*.

The xylem in the cone of *E. arvense* is relatively much developed compared with that of the cone of *E. limosum*; *E. palustre* is intermediate in this respect between these two species. Taking first *E. arvense* we find that below the basal fertile whorl, but some little distance above the insertion of the annulus, the strands of xylem lose the appearance of typical internodal bundles of the vegetative region. The two lateral groups of metaxylem become united by a curved band of tracheides and the carinal canals begin to diminish in size. This curved band of xylem is several cells thick in a radial direction and its concavity at first faces outwards; its ends, continuous downwards with the lateral bands of metaxylem, project like them slightly beyond and externally to the phloem. The latter also forms a slightly curved band, the concavity in this case facing inwards, so that the phloem lines the interior of parts of the pericycle. As we approach the fertile node the band of xylem straightens out and eventually it comes to form a band slightly curved in the reverse direction, so that the xylem assumes the same contour as the phloem and the stele generally. Meanwhile, the xylem of each bundle begins to narrow in a radial direction, though it may still be locally three to five cells thick. As a rule, too, as we approach a node the xylem of a bundle begins to spread laterally towards the xylem of its neighbours. Generally, many of the bundles of the cone of *E. arvense* become united in the nodal regions by the formation of fresh tracheides; usually these develop in continuity

traces of a whorl we should have an internodal ring of wood; occasionally, when all the strands become united at the node—and this of course involves the closure of all the parenchymatous meshes of the internode below—we get a nodal ring of xylem and bast (Pl. LXIV, Fig. 1).¹ Such a local ring is present twice in Cone A, twice in Cone B, and once in Cone E; it was not met with in Cones C, D, F, G, and H, but may have occurred in them, since the series of sections did not include the whole of any of these cones. To judge from isolated hand-sections a ring of xylem occurs locally at the nodes of many cones of *E. arvense*. Milde in 1865 stated that at the level of the fertile whorl the xylem-strands become united into a ring. This is too sweeping a generalization, and curiously enough Milde figures this condition diagrammatically in *E. limosum*, a species in which I have never seen even a near approach to a ring (Milde, i, p. 162, Pl. XVI, Fig. 18).

The cases in which a parenchymatous mesh arises some distance up the internode are clearly intermediate between the forms in which the mesh arises at the usual small distance above the node and those rare cases in which no parenchymatous mesh occurs above a trace. The parenchymatous meshes of *E. arvense* do not, as a rule, attain any considerable width; they are frequently narrower, even in their widest part, which is usually in the middle of the internode, than the strands of xylem between which they pursue their course. As regards their vertical extent, by far the greater number are closed at or before the next node, and these meshes I shall, for convenience' sake, term meshes of the first order. Other parenchymatous meshes that extend into two, three, or more internodes will be termed meshes of the second, third, and higher orders. In Cone A there were 90 meshes originating above fertile whorls and closed before we reach the apex of the cone; of these 81 were of the first, 8 of the second, and 1 of the third order. Within the limits of Cone B 37 meshes originated and were closed: 33 of the first, 3 of the second, and 1 of the third order. As only seven whorls of Cone C were cut serially many of the meshes were still unclosed when the series ended; if the figures of all the meshes closed within the series of sections were given, the proportion of meshes of the first order would appear to be larger than it is in nature; for, of the meshes arising above the upper whorls, more of those of the first order would have space, so to speak, to be closed before the end of the series. But all meshes of all orders that arise above the lowest four whorls are closed before the end of the series of sections; by considering these only we may see the relative proportion of meshes of different orders in this Cone C. On this basis we find that out of 22 meshes 10 are of the first, 9 of the second,

¹ Owing to the fact that the sporangiophores are inserted at slightly different levels, all the meshes may be closed at a node and yet no *single* transverse section will show a complete ring of xylem. This tendency is increased by the fact that occasionally meshes are not closed before, but at, or even just after, the departure of the trace.

and 3 of the third order. It will easily be realized that the persistence of a parenchymatous mesh through a node is the result of a poorer development of xylem. Thus Cone C has relatively less xylem than Cones A and B. For instance, the presence of a very little more xylem between the

TEXT-FIG. 2. Longitudinal reconstruction of the xylem of Cone C of *E. arvense*. Axial xylem black; leaf-traces and parenchyma white. Magnification circa 12.

fifth and sixth traces of the second whorl of Cone A would lead to the division of a parenchymatous mesh of the second order into two meshes of the first order. When the xylem developed at a node is less markedly deficient, the mesh that persists appears to be sharply constricted in the nodal region; when, on the other hand, the strands show little or no

increase of xylem at the node, the mesh separating them is little or not at all constricted in this region.

Of none of the other cones were the series of sections sufficiently extensive in a vertical direction to afford useful data as to the height of the meshes; Cone E, however, seemed to have about the same relative amount of xylem as Cone C, and Cone F relatively rather less. The proportion of xylem in Cone G seemed to be about the same as that in Cones A and B. The series of sections of the other cones were too short to allow of such generalizations.

The nature of the meshes originating below the lowest whorl of sporangiophores will be considered in discussing the region transitional from cone to fertile stem.

Even a superficial glance at a reconstruction of the xylem of a cone of *E. arvense* in which the wood is relatively well developed, as it is in Cone A, gives the impression of nodal bands or a nodal ring of xylem, broken up in the internodes by meshes of parenchyma and usually broken too at the nodes by the persistence of one or two of these meshes. The cone of *E. palustre* does not give this impression. Here, too, parenchymatous meshes originate above the sporangiophore traces, but many of them persist upwards through more than one internode. Thus Cone A of this species, which had the largest proportion of xylem, had 19 meshes of the first, 9 of the second, 2 of the third, 4 of the fourth, and 1 of the fifth order; Cone B of the same species had 6 of the first, 7 of the second, 1 of the third, 1 of the fourth, 3 of the fifth, and 1 of the seventh order. Cone D of the reduced variety *polystachion* had only four whorls; it had one mesh of the first, one of the second, and one of the third order. Besides these, other meshes originating below the sporangiophores, and therefore below the cone proper, persist through one or more internodes of the cone; they are relatively more developed in Cones B and D, which have less xylem than in Cone A. Their nature will be considered in connexion with the transitional region. The series of sections of Cone C of *E. palustre* was too short to afford data as to the height of the parenchymatous meshes.

In *E. arvense* the sporangiophore traces are never, except at the extremely reduced apical region of the cone, given off from the edge of a strand or band of xylem, though when a relatively wide parenchymatous mesh persists through a node, the traces of the strands abutting on it may depart from a point very near to the edge of the xylem. In *E. palustre*, however, correlated with the less vigorous development of the axial xylem, traces not infrequently arise from the edge of the strand; i. e. at their point of origin they abut on a mesh persisting through the internode, while many other traces depart from a point very near the edge of a xylem-strand (cf. Text-figs. 3 and 4). These kinds of traces may conveniently be referred to as lateral or slightly internal. Traces that depart from what is more or

less the middle of a xylem-strand may be termed median. When the internodal strands remain isolated the median position of the traces is very obvious, but when the bundles are united into bands or into a ring at the nodes, as they often are in *E. arvense*, the median position of the traces is often not so clear (Pl. LXIV, Fig. 1). Such formation of nodal bands giving off median traces also occurs in *E. palustre*, though it is not so marked a feature of this species (e.g. the band from which the third, fourth, fifth, and sixth traces of the first whorl depart in Cone A, and the band giving rise to the fifth, sixth, seventh, and eighth traces of the fifth whorl of the same cone). In reality we find three sorts of structure above median traces. Firstly, there is the form in which the xylem of the axis is most developed; here there is no mesh, and a relatively wide band of xylem persists through the internode; this type, never common, occurs in *Equisetum arvense*, and apparently in the upper part of some cones of *E. palustre*. Secondly, a parenchymatous mesh may appear above a median trace; this is by far the most widely spread form in *E. arvense*; it is very common too in *E. palustre*, especially in cones with well-developed xylem. The third form of structure is associated with a reduction of axial xylem; here the trace departs from the middle of a relatively narrow strand; this often continues its isolated course upwards, and then of course involves the persistence of meshes on either side of it; above such a trace no mesh is formed. When the meshes on both sides of a strand persist through several internodes the latter pursues an isolated course through several nodes (e.g. the strand arising between the sixth and seventh traces of the fifth whorl of Cone A of *E. palustre*). These conditions are obviously associated with poor development of the xylem. A variation in the behaviour of the strands in the internode above the departure of a median trace of this type occurs when one of its neighbours gives off a median trace of the other type, above which trace there appears a fresh parenchymatous mesh; or in other

TEXT-FIG. 3. Longitudinal reconstruction of the xylem of Cone A of *E. palustre*. Axial xylem black; leaf-traces and parenchyma white. Magnification *circa* 9.

words, when two neighbouring strands give off median traces and one forks a little higher up and the other does not. In this case one of the branches of the forking strand may fuse with the strand in which no mesh appeared. This particular variation, fairly common in *E. limosum*, seems to be very rare in *E. palustre*, where I only observed it twice. Another variation

TEXT-FIG. 4. Longitudinal reconstruction of the xylem of Cone D of *E. palustre* (var. *polystachion*). Axial xylem black; leaf-traces and parenchyma white. Magnification circa 24.

which may occur, though rarely, in *E. palustre*, associated with a reduction in number of the strands and traces of the next node and internode, consists in the fusion of two strands, from which median traces not subtending meshes have departed, to form a strand giving rise to but one trace at the next node (e.g. the strands giving rise to the sixth and seventh traces of the ninth whorl of Cone A). In all these variations the absence of a mesh is due to poor development of xylem, and is associated with the persistence of meshes of the internode below. In the cases mentioned first the absence of a mesh is due to the unusually strong development of xylem in the upper internode, and is associated with closure of meshes of the internode below.

In *E. palustre* no fresh meshes originate above the departure of a lateral or slightly internal trace; for though in many cases the xylem-elements superposed to the trace soon die out, the parenchyma which replaces them is laterally in contact with an adjacent parenchymatous mesh originating lower down. The relatively wide band of parenchyma resulting from the congenital fusion of a mesh with one originating lower down may, from a phylogenetic point of view, be considered as biseriate. When the meshes in the cone of *E. palustre* persist through numerous internodes they appear in longitudinal reconstruction to be widened first on one side and then on the other; this sudden widening usually occurs above a node by the dying out of the xylem superposed to a trace

at or near the edge of one of the strands bordering on the mesh. This gives to the parenchymatous meshes of the higher orders a very sinuous outline. As in *E. arvense*, it is sometimes easy to see that the persistence of a mesh into two or more internodes is due to poor development of xylem at the nodes. For instance, the lignification of a small group of cells between the first and second traces of the third whorl and the

fourth and fifth ones of the fourth whorl of Cone A would have closed the meshes between these traces, and we should in both cases have had two meshes alternating, though somewhat irregularly, with one another. In many cases the amount of xylem present at the node, though not so great as in the two cases mentioned, yet produces a marked constriction of the mesh in the nodal region; where there is no perceptible increase of the xylem in the nodal region the mesh remains of the same width at this level. Another phenomenon, only observed once in *E. palustre*, occurs at the apex of Cone A of this species. Here two meshes originating above the tenth whorl fuse in the upper part of their course by the dying out of the strand between them. The conditions are here complicated by the fact that the strand, by the dying out of which the two meshes come into contact, is unusually wide, and gives off two traces; it is clearly one of those stretches of xylem that extend uninterruptedly through a whole internode. Allowing for the convergence of the lines of superposition of the diagram (Text-fig. 3) owing to decrease in diameter of the stele, we can see that the two convergent meshes originate above the third and sixth traces of the tenth whorl.

Another tendency when the xylem is less developed is for a parenchymatous mesh to be slightly decurrent on one side and below the trace above which it may, phylogenetically, be considered to have originated; in such a case a trace-bearing strand appears to branch just below the departure of a trace. Such a trace would have been median and have subtended a mesh had no premature branching of the strand bearing it occurred; it now appears to be lateral and adnate to one of the branches of the strand. This expression of less lignification is common in *E. limosum*, and an example of it may be noted at the eighth node of Cone A of *E. palustre*, where a mesh, apparently associated with the fourth trace, is decurrent some way below the latter and the third trace. (This mesh might at first sight appear to be between the third and fourth traces, but this appearance is due to the fact that the third trace is very nearly lateral; and as the middle line of the mesh is very nearly directly over the fourth trace the mesh presumably belongs to the latter.)

Only one clear case of the decurrence of a parenchymatous mesh was observed in *E. arvense*, and it was of a different type. The second whorl of Cone B of this species had nine traces, of which two were about half the size of the others and entered one sporangiophore. The smallness of these two traces and the fact that the whorl below and the three succeeding whorls each have eight sporangiophores indicate that we are here dealing, not with two fused sporangiophores, but with one of those cases, to be considered later, in which the first division of the vascular supply of the trace is so premature that the trace is double at its point of departure from the axial stele. Such cases of traces originating as two bundles are not rare, but this

one is exceptional in that the two bundles of the trace are not closely approximated at their point of origin, but are separated by a parenchymatous mesh; the two bundles destined to the sporangiophore do not even depart from the edges of the two strands bordering the mesh, but from points slightly internal to the edges of the axial strands. The middle line of the parenchymatous mesh when followed upwards passes midway between the two xylem-strands entering the sporangiophore; below them it only extends downwards through one-third of the internode, and its origin is clearly quite unconnected with the departure of the traces of the whorl below. The conclusion to be drawn would seem to be that here a single mesh, such as commonly appears above the two halves of a bifascicular trace, has, phylogenetically speaking, slipped down between them for a certain distance.

Quite apart from the diminution in number of the sporangiophores of a whorl, due to the narrowing of a cone at its apex, there is a certain irregularity in the number of members in successive whorls of the cone of *Equisetum* (e. g. the seventh and eighth whorls of Cone A of *E. palustre*). Moreover, traces receiving two bundles are by no means rare. Two forms may usually be distinguished. In the first case the sporangiophore receiving the two bundles is very much larger than the other sporangiophores, and obviously represents two approximated and concrescent primordia. Every stage between a complete concrescence and a merely basal fusion of the stalks can be observed with the naked eye if sufficient material is examined, especially of *E. arvense* and *E. maximum*, in which species concrescence is unusually frequent. In this form the two traces, though they usually arise markedly nearer to one another than to the neighbouring traces, are yet not closely approximated at their point of origin. In the second kind of sporangiophore that receives two traces these arise very close to one another, and the sporangiophore itself is hardly, if at all, larger than the other sporangiophores; generally either of the two traces considered by itself is markedly smaller than the other traces of the whorl. In this case we would seem to be dealing with a case in which the division of the trace is so premature that the latter actually originates as two separate strands. This interpretation is supported by the fact that a certain number of traces, though not completely divided into two bundles at their origin, were more or less deeply constricted in the middle; in this case the division of the trace, though still premature, was less markedly so. Another case intermediate between the traces that originate as two bundles and those that only divide in the sporangiophore was found in the upper part of Cone D of *E. arvense*. Here a trace originated as an already markedly constricted bundle and forked in the axial cortex before entering the sporangiophore. The latter received not only these two bundles, but another whole trace; it was thus a 'double' sporangiophore showing in

one of its two fused constituents a case of premature division of the trace. In some cases, however, it is not easy to decide if we are dealing with a rather large sporangiophore whose trace has divided prematurely, or with an exceptionally small 'double' sporangiophore. The position of the meshes in the internode above and the number of members, when constant, in the whorls above and below may afford the means of judging if we are dealing with a single or a double sporangiophore. In normal cones a bifascicular trace is more often due to premature division.

CONE OF *E. LIMOSUM*.

If we pass to a consideration of the cone of *E. limosum* we see at once that the xylem is much less developed than in *E. palustre*. Though this poorer development of the xylem is very striking it follows the same lines as the reduction of xylem in *E. palustre*. Meshes arising above traces tend to persist through more numerous internodes; they are widened laterally owing to the dying out of the xylem above lateral or slightly internal traces; they tend to 'decur' below and to one side of the traces above which they lie; meshes originating separately also become confluent by the dying out of the strand separating them. This feature, only observed once in *E. palustre* and unknown in *E. arvense*, is very common in Cone B of *E. limosum*. This cone has relatively to its size less xylem than Cone A; in the latter only two pairs of meshes originally separate become thus confluent; in both cases this confluence took place above the seventh whorl. In Cone A 31 meshes arose, and were closed within the cone; of these 13 were of the first, 7 of the second, 7 of the third, 3 of the fourth, and 1 of the fifth order; two meshes persisted unclosed to the apex of the cone, and eventually fuse above the last whorl round the terminal sporangiophore. In Cone B 12 meshes arose and were closed within the cone; 4 of the first, 5 of the second, 2 of the third, 1 of the fourth order. Ten more meshes arose above sporangiophores, but these remained unclosed; of these, one arose above the lowest whorl, and therefore persisted through all the (nine) internodes of the cone; one unclosed mesh persisted through eight internodes, two through seven, one through six, two through five, and three through four internodes. Yet another mesh was unclosed; this originated above the insertion of the annulus (cf. the account of the transitional region), and therefore persisted through the whole of the cone. These unclosed meshes become confluent with one another in a very irregular manner as we approach the apex of the cone; above the tenth and last whorl the number of independent meshes is reduced to three. But if traced downwards these three meshes have a very different history; one of them, that lying between the second and third traces of the tenth whorl of the diagram, consists only of two fused meshes extending a very long way downwards; they become confluent by the dying out of a strand that pursued an isolated course

between them through seven internodes. Each of the other two meshes, if traced downwards, is seen to be built up by numerous confluent meshes of very different lengths. Above the three traces of the uppermost whorl the

TEXT-FIG. 5. Longitudinal reconstruction of the xylem of Cone A of *E. limosum*. Axial xylem black; leaf-traces and parenchyma white. Magnification *circa* 16.

xylem dies out, and in this way the three remaining meshes become confluent round the terminal sporangiophore. The confluence of meshes distinct at their origin is not confined to unclosed meshes; it occurs, though

less commonly, between meshes that are closed before the apex of the cone is reached ; the two cases of confluence of meshes of Cone A are of this type, and another example may be seen above the insertion of the third whorl of Cone B. The reason why the confluence of unclosed meshes is commoner than that of closed meshes is that confluence means the dying out of a strand and thus reduces the number of members of the next whorl. Such reduction is, of course, especially characteristic of the upper part of the cone, and meshes arising above the upper whorls of sporangiophores have less

TEXT-FIG. 6. Longitudinal reconstruction of the xylem of Cone B of *E. limosum*. Axial xylem black ; leaf-traces and parenchyma white. Magnification circa 16.

chance of being closed, partly because they reach the apex of the cone if they persist through many internodes, and partly because they are continually widened by confluence with other meshes owing to the dying out of strands. Nor are these facts the only ones that indicate reduction of xylem ; the strands of xylem of *E. limosum* are much narrower, compared with the parenchymatous meshes separating them, than those of the other two species studied.

The series of sections of Cone C of *E. limosum* was too short to afford reliable data as to the height of the meshes.

The meshes originating below the cone and persisting into it will be considered in discussing the region transitional from fertile stem to cone.

It has already been shown that where a strand pursues an isolated course through a node, the absence of a mesh above a median trace—or, in other words, the failure of a strand to branch above a median trace—is an effect of poor development of xylem. This is confirmed by the distribution of this type of median trace. In Cone A of *E. limosum*, the reduction in the number of members in a whorl begins above the seventh node; in the seven lowest whorls, 31 median traces out of 40 subtended parenchymatous meshes. Similarly, the seven lowest whorls of Cone B (in which there was no definite reduction, though the number of the traces varied slightly in different whorls) showed 27 median traces, of which 21 subtended meshes. The five lowest whorls of Cone C, which showed no signs of reduction in the number of members of a whorl, had 34 traces, of which 26 subtended parenchymatous meshes. But when we consider the regions of the cone in which reduction of the number of appendages has set in, we find very few parenchymatous meshes above median traces. This region was not available in Cone C, and in Cone B the region of reduction showed no median traces of either sort; but in Cone A there were in the four uppermost whorls only three median traces subtending meshes, while above six such traces the strand pursued its course upwards without branching. As already pointed out, Cone B has relatively to its size much less xylem than Cone A; in its upper part a large number of traces depart from strands so narrow that the traces are attached to the whole width of the strand. Such traces abutting on both edges of the strand cannot be called median; but they clearly represent a further stage of reduction of the axial xylem to which a median trace not subtending a mesh is attached; in the upper part of Cone B they replace the median trace. They are not, however, confined to the upper part of the cone, and an example may be seen in the eighth trace of the second whorl. No examples of such narrow trace-bearing strands were found in the other species or in Cone A of *E. limosum*. Some parts of the latter had rather more internodal xylem than others; this may cause the closure of the meshes a little way below the node; or the greater development of the xylem may take place above the node; for instance, the third and fourth traces of the fourth whorl of this cone depart from the *edges* of a band which persists upwards through the whole of the next internode; if these two traces were median instead of lateral, the absence of a mesh above them would be due, not to the xylem being poorly developed, but to its being well developed. I have not, however, observed such a case in this species.

Occasionally in *E. limosum*, isolated strands pass through a node without giving off a trace (e. g. two of the strands in the lowest whorl of Cone A, two of the strands in the lowest whorl of Cone B, two of the strands of the third whorl, and a strand of the fourth whorl of the same cone). In such

cases, and a few occur also in Cone C, the strand that does not give off a trace is never wide, but it is no narrower than many trace-bearing strands. Such excess of strands over traces must not be confused with an apparent increase in the number of strands due to the forking of a strand above a median trace occurring a little before the fusion of one or both of its branches with a neighbouring strand or branch of a strand, or to the decurrence of a parenchymatous mesh below and to one side of what would otherwise be a median trace. This apparent increase of the strands at a node may be exaggerated by the fact that the sporangiophores of a whorl are not all inserted at exactly the same level. Thus in one transverse section just above a node of Cone C, there were twenty-five strands and parenchymatous meshes, though the number of sporangiophores in the whorls above and below was but twenty. Such apparent increase of strands is, however, strictly localized to the neighbourhood of the nodes, and the supernumerary strands, if traced upwards or downwards for any distance, soon cease to be independent strands, and may thus be distinguished from those much rarer distinct and separate strands that pass through a node without giving off a trace.

ALTERNATION AND SUPERPOSITION OF WHORLS OF THE CONE.

* In *Equisetum* generally, the sporangiophores appear externally to alternate with remarkable regularity; in the young state before the internodes have elongated the shields are closely imbricated. But in internal anatomy there is throughout the three species examined no such regular alternation in the insertion of the vascular traces of successive whorls. It is obvious that when a parenchymatous mesh extends through more than two internodes, all the members of a whorl cannot be accurately superposed to those of the second whorl in a downward direction as they are when succeeding whorls alternate regularly. In fact, the greater or less regularity of alternation of traces of successive whorls depends chiefly on the regularity with which successive meshes are closed at the nodes. In cones of *E. arvense*, especially in those that, like Cones A and B, have their xylem well developed, meshes persisting through a node are in a small minority, and the traces are much more often alternate with those of the node below. Even here the alternation is liable to be disturbed by the occasional occurrence of meshes of the second and third orders; by a change in the number of members of a whorl; by the fact that sometimes, though very rarely, a mesh may originate not vertically above a trace, but at a point above and to one side of it; and by the fact that when two sporangiophores become partially concrescent, their traces tend to become slightly approximated at their point of origin. When a trace has divided prematurely into two closely approximated bundles the mesh is superposed to both, and its position is one of the means of distinguishing a case of premature division of a trace (cf. Text-fig. 2, traces 6 and 7 of the first whorl). When by a close approximation of

neighbouring strands a mesh is very nearly closed at the level of a whorl, and when a trace departs from the edge or very near the edge of one of these strands, it may alternate more or less accurately with the traces of the whorl below, despite the persistence of the mesh through the node. When a strand pursues an isolated course through several nodes (i.e. when the parenchymatous meshes on both sides of it extend upwards through several nodes and internodes) the traces which it gives off, whether lateral or median, are necessarily superposed, though not always accurately so. For when the strand is markedly wider than the traces, successive traces may depart from portions of the strand not in the same vertical line; the traces may, however, be accurately superposed, and when the strand is hardly, if at all, wider than the traces, the superposition is necessarily accurate. The giving off of superposed traces from an isolated strand seems to be an effect of reduction of the xylem, whereby neither of the meshes bordering the strand is closed at the nodes; it is, therefore, natural that this form of superposition of the traces should be commonest in *E. limosum*, especially in Cone B: but it is common, too, in *E. palustre*, and occurs, though rarely, in *E. arvense* (e.g. the ninth and tenth traces of the second whorl of Cone C are given off from isolated strands, and are superposed respectively to the tenth and eleventh traces of the whorl below; and the tenth and eleventh traces of the fifth whorl of Cone C are borne by isolated strands, and are superposed to the tenth and eleventh traces of the whorl below).

In *E. limosum*, though the xylem at the nodes is in excess of that in the internodes, it is only rarely sufficient to close a mesh before the departure of the trace at that node, i.e. to unite two trace-bearing strands, as, for instance, the strands giving off the seventh and eighth traces of the third whorl of Cone A are united. More often the strand, though relatively wide, is not wide enough to come into contact with its neighbours; when a trace departs from the median portion of such a strand a parenchymatous mesh appears a little way above it so that the strand appears to fork just above the node. When two neighbouring strands branch in this way their adjacent branches diverge obliquely and fuse a little higher up to form the trace-bearing strand of the next internode (Text-fig. 7, B); we thus get a regular alternation such as obtains in the vegetative stem. But in the latter, generally in the cone of *E. arvense*, and frequently in the cone of *E. palustre*, there is no need for this fusion to constitute fresh strands alternating with those of the internode below, for the strands are, as a rule, laterally in contact with one another at the nodes at or before the departure of the traces, and by the appearance of parenchymatous meshes above the latter, strands arise alternating regularly with those of the internode below (Text-fig. 7, A). In both these cases, represented respectively by Text-fig. 7, A and B, we get a regular alternation of strands at the nodes; but in the form of alternation illustrated in Text-fig. 7, B, rather less xylem is

in reality developed, and the parenchymatous meshes tend to dovetail into one another at the nodes, since those of the upper internode originate before those of the lower one are closed. In a longitudinal reconstruction of the xylem, the width of the latter at the node is increased by the fact that when the branches of a strand diverge obliquely the vessels are, of course, cut obliquely. A tendency for the parenchymatous meshes of the internode below not to be closed until after the origin of those of the internode above may be noted occasionally in the cone of *E. arvense*, and now and then in

TEXT-FIG. 7. Different forms of course of the strands at the nodes.

the vegetative nodes of the three species that I studied ; but it does not become a marked feature in any of them. According to Pfitzer (Pfitzer, p. 344) this type of alternation, shown in Text-fig. 7, B, is found in the vegetative nodes of *E. variegatum*.

In *E. limosum*, however, it is unusual, except in the fifth and sixth whorls of Cone A, for two or more adjacent strands to give off median traces and fork above their departure. Much more commonly one strand forks and its neighbour does not ; in such cases we get an irregular anatomical alternation between members of successive whorls. Of this irregular

alternation there are three forms : (1) the xylem-strand of the next internode may be formed by the fusion of a branch of a forking strand with a (whole) strand of the internode below (Text-fig. 7, C) ; or (2) by the fusion of two whole strands (Text-fig. 7, D) ; or (3) a strand may fork above the departure of a median trace and one (Text-fig. 7, E) or more, rarely both (Text-fig. 7, F), branches may constitute, independent of any fusions, trace-bearing strands of the internode above. The first form of irregular alternation is by far the commonest in *E. limosum* ; the second leads to reduction in the number of strands, and is therefore more characteristic of the upper part of the cone ; the third naturally leads to an increase in the number of strands in the next whorl unless it is counteracted by the fusion of two whole strands of the internode below. Such irregularities in alternation, when not caused by a change in the number of members of successive whorls, are due to failure to close some of the meshes at the nodes, and therefore to poor development of the xylem in this region ; a further reduction of xylem leads, as already pointed out, to the formation of strands pursuing an isolated course through the nodes, and therefore to the superposition of traces.

A case occurred in Cone C of *E. limosum* in which a xylem-strand appeared to branch without any relation to the departure of a trace. A narrow strand, after giving off a trace, comes temporarily into connexion with one of its neighbours, about three-quarters of the way up the internode (and thus closes a parenchymatous mesh) ; but this connexion only extends for a short distance, and less than half-way up the next internode the strand again detaches itself.

Another exceptional, apparently a unique, irregularity occurs in the lowest whorl of Cone C. Here all the xylem-elements above a xylem-trace do not die out ; but some of them pursue an oblique course and fuse with a neighbouring strand, thus closing a mesh of the internode below and initiating one in the internode above.

The lowest whorl in Cones A and C shows further anomalies ; in both, while certain strands pursued an isolated course through the node and gave off no traces, pairs of strands united to one another at the node gave off three traces.

APEX OF THE CONE.

The structure of the apex of the cone differs in the different species. Externally, the terminal sporangiophore of *E. arvense* is larger than the others, and the outer (in this case upper) surface of the shield of the sporangiophore, instead of being flat or slightly depressed in the middle, is prolonged into a drip point ; this relatively massive terminal structure never has, as the terminal sporangiophores of *E. palustre* and *E. limosum* have, a single more or less circular trace. Cone A was so very young that the terminal internode had not elongated at all, and the apical phenomena

were therefore indistinct; to ascertain the structure of more mature apices the upper parts of Cones B, D, and E were cut. In all three the last node gave off six traces, but in Cones D and E two of these seem to have entered one sporangiophore. In Cones B and E two unequal bands of xylem, much wider than the ordinary traces, entered the terminal sporangiophore, while in Cone D a similar wide band of xylem and two smaller strands enter the terminal sporangiophore; before entering the sporangiophore these two smaller strands approach very close to one another, but diverge again without fusing. These two small strands certainly seem to correspond to one of the bands that enter the terminal sporangiophore of Cones B and E.

In the cone of *E. palustre*, of the variety *polystachion* as well as of more typical specimens, the proportion of xylem at the apex seems to be relatively great. Here, indeed, it commonly forms a ring extending upwards from a point below the uppermost whorl of sporangiophores. In Cone A such a ring is only formed a little way above the last whorl, and as the stele has already narrowed considerably, the ring is very narrow; but even here the amount of xylem relatively to the diameter of the stele is above the average amount in other parts of the cone. In all three apices of cones of *E. palustre* examined the ring narrows rapidly as we pass upwards, and ere long its condensation gives rise to a small solid circular strand (i. e. it no longer encloses any parenchymatous cells); in the variety *polystachion* this narrowing of the ring and its condensation into a circular strand are effected partly by the fact that certain tracheides pursue an inward, centripetal course. This small circular strand is the trace of the terminal sporangiophore.

In *E. limosum* the trace of the terminal sporangiophore is formed as the continuation of one of the xylem-strands of the internode below. In Cone B the others seem to die out, while in Cone A they give off, after the departure of the traces, contributions to the strand of xylem that persists; the latter then narrows very rapidly, becomes circular and concentric, and passes upwards into the terminal sporangiophore as its trace.

As regards the structure of the sporangiophores, Eames has shown that their traces are concentric and mesarch, and I have nothing to add to his remarks (Eames).

THE STRUCTURE OF THE VEGETATIVE NODES.

Before considering the region transitional from fertile stem to cone a few facts as to the structure of the vegetative nodes must be reviewed. As is well known the bundles in an internode of the stem of *Equisetum* consist of three groups of xylem. Of these the carinal or protoxylem group is situated medianly and at the edge of the pith; its annular or spiral vessels early become disorganized, giving rise to the carinal canal, upon the edge of which abut a few tracheides that have not been torn. The two other groups

are situated at the periphery of the bundle and form bands or groups of elements, the long axis of each group pointing obliquely outwards. They develop some time after the carinal group, and the number of cells in each of these lateral strands varies according to the species from 3 to 15. Quéva states that the lateral xylem is less developed in the rhizome and may even be absent there. According to him, too, the lateral metaxylem is composed entirely of spiral tracheides (Quéva, p. 18); Eames, on the other hand, states that the elements of these lateral strands are in general scalariform, reticulate, or pitted, but that occasionally they contain annular or even spiral tracheides (Eames, p. 589). Bower (Bower (2), p. 389) quotes observations of Gwynne-Vaughan on *E. giganteum*, the details of which have not been published, but which were accessible to him; according to these the lateral strands of this species contain 10-15 tracheides; the smallest of these are at the outside, and they gradually increase in size inwards. The larger elements are coarsely reticulate, the reticulation becoming finer and more regular in the smaller elements until in the smallest it closely resembles spiral thickening.

Gwynne-Vaughan maintained, too, that the lateral metaxylem-strands show indications of centripetal development, especially in the larger species in which the lateral groups are better developed; but he admits he was unable to prove this centripetal development as he had no incompletely developed portions of the stem (Gwynne-Vaughan). Bower endorses Gwynne-Vaughan's opinion with a similar reservation (Bower (2), p. 309). Quéva, however, expressly states that the whole of the lateral metaxylem is centrifugal (Quéva, pp. 25 and 35). Eames also regards the lateral xylem as centrifugal, though he records examples of a certain irregularity in the direction of lignification; I have met with a few cases of similar irregularity in the fertile stem of *E. arvense* (Eames, pp. 591-3). My observations, which were not at all extensive, confirm Eames's view that the prevailing direction of lignification in the lateral strands is from within outwards, but that it is subject to occasional irregularities. In any case the lateral strands seem phylogenetically to represent centrifugal xylem. In the region of the annulus there is no reticulate nodal wood, and as we pass upwards towards the lowest whorl of sporangiophores the lateral groups of xylem become united by elements of a similar nature. Thus in the cone, both in the node and the internode, the xylem of the bundle consists not of three groups, but of a continuous band of tracheides. It seems very probable that in the vegetative internodes the lateral groups of xylem represent the free ends of a more deeply curved band of xylem. In that case the position of the tracheides of the lateral groups of metaxylem in a more or less radial series is due to the more or less marked curvature of a band of which only the carinal tracheides and the free ends are lignified. The primitive form of internodal bundle would then be that of the cone, an interpretation

in accordance with modern ideas as to the conservatism of reproductive axes. Quéva has figured and described a curved band of xylem in the vegetative bundles of the upper end of the internode of *E. littorale* (Quéva, p. 23, Fig. 21). The xylem of the internode of the cone, where the latter contains a circle of more or less equidistant strands, often forms curved bands with the concavity facing outwards, though the curvature is less than we should have to assume for the vegetative node if the lateral strands are supposed to mark the ends of such a band. When wide tracts of xylem involving more than one strand of the internode below persist through an internode of the cone, the curvature of the band of xylem is slightly in the inverse direction, so that the xylem forms segments of a circle concentric with the outline of the stele. Traced downwards the terminal tracheides of the curved xylem-strands of the cone are continuous with the tracheides of the lateral metaxylem of the internode below the cone. We may add here that according to Leclerc du Sablon the xylem in the bundles of the tubers of *Equisetum* is not broken up into a carinal and two lateral groups, but vessels and parenchyma are mixed irregularly (Leclerc du Sablon).¹ Milde has figured a similar bundle of a tuber (Milde, Pl. I, Fig. 22). In the tubers of the fossil Equisetaceae recently described by Fritel and Viguiet, the xylem of each bundle appears to consist of an oval mass of parenchyma mixed with tracheides. Quéva has shown that the elements of the nodal wood are lignified after those of the carinal group, but before the lateral metaxylem of the internode. In 1901 Gwynne-Vaughan, from a study of *E. giganteum* and *E. hiemale*, concluded that the lateral strands may be traced through the node and across the upper surface of the ring of nodal xylem; that after passing above and across the latter they fuse with the similar adjacent strand of a neighbouring bundle to form the alternating strands of the internode above (Gwynne-Vaughan). Quéva, however, writing six years later, seems to be unaware of Gwynne-Vaughan's remarks; he states that the nodal reticulate tracheides are 'in direct relation to the metaxylem, the elements of which show above the node transitional markings' (Quéva, pp. 18-19). According to this botanist, therefore, the tracheides of the lateral strands are gradually replaced by reticulate nodal elements as we pass upwards; higher up this xylem dies out, except at the points where the wood persists as the lateral metaxylem-strands of the internode above, and at these points the reticulate thickening of the elements is gradually replaced by spiral. Ludwigs in a recent paper seems to be of this opinion, though he expresses himself somewhat differently, saying that metaxylem-elements are initiated on both sides of the bundle, and are especially numerous at the level of the nodal diaphragms; that after the departure of the protoxylem into the leaf the two groups of metaxylem

¹ This author also states that throughout the tuber the bundles form an irregular network, a point which would repay further investigation.

fuse and fill up the carinal canal (Ludwigs, pp. 401-2). Quite recently, Vidal has recorded all forms of thickening intermediate between reticulate and annular in the stem of *E. palustre* (Vidal, p. 24). My observations, so far as they go, are in complete agreement with those of Quéva on this point and in contradiction to those of Gwynne-Vaughan; but they were not extensive, and were moreover limited to the fertile stem of three relatively small species in which the lateral metaxylem groups are not particularly well developed.

In 1893 Cormack suggested that there were traces of secondary xylem in the nodal region of *E. maximum* (Cormack). Quéva, after a careful study of the ontogeny, pointed out that though the 'zone génératrice' of the bundle persists later in the nodal region its activity is strictly limited, the divisions of its cells being merely the continuation of the earlier procambial division of the bundle; thus its secondary nature is not proved (Quéva, pp. 33 and 36). Ludwigs is of the same opinion (Ludwigs, pp. 400-1). Nevertheless, Eames states that a few of the living species of *Equisetum* have been shown by Cormack to possess the remains of secondary xylem, and that Quéva confirms the presence of such wood in *E. maximum* and records its occurrence in *E. arvense*. Eames further remarks that he has seen evidence for this ancestral character in both these species, in *E. hyemale* and in *E. hyemale*, var. *robustum*, A. A. Eaton. Finally, Ludwigs, speaking of the reticulate nodal tracheides, says: 'These vessels are supposed to be formed ("sollen sich . . . bilden") from without inwards by the activity of a cambium and represent that which Eames would have us regard as centripetal wood' (Ludwigs, p. 400). It is hard to see how xylem-elements formed internally by a cambium could be anything but centrifugal; nor does Eames regard the nodal xylem as centripetal. On the contrary, he expressly states that so far as he knows no question has arisen as to the centrifugal development of the nodal or supranodal wood, as he, in agreement with Jeffrey, calls it. He adds that it is clear that the innermost elements are protoxylem (Eames, p. 590). It seems clear that Ludwigs' statement that Eames regards the nodal wood as centripetal is incorrect; nor does Ludwigs himself express any agreement with this view. Whether the nodal wood is secondary or not is less clear; on the whole its secondary character seems not to be proved; though from the size of the Mesozoic Equisetales we should *a priori* regard secondary growth as an ancestral character, traces of which might well remain in certain species.

At the level of the uppermost vegetative whorl of the fertile stem of *E. limosum* a diaphragm of the usual type was not found. At the node, owing to the junction of the xylem of the separate bundles into a continuous ring, the separate endodermes of the internodal bundles are replaced by common inner and outer endodermes, this change being brought about

in the manner already described by Pfitzer (Pfitzer, pp. 336-7). The same author has noted that in the nodal region the cells of the outer endodermis have for a little distance thicker walls (l. c., p. 332). I have observed the same phenomenon in *E. limosum*. A little above the departure of the leaf-traces, where the ring of nodal xylem breaks up, the endodermis consists of relatively thick-walled cells that stain very deeply with Bismarck brown; as the breaking up of the ring proceeds these dark brown cells become involuted round the bundles through the parenchymatous

TEXT-FIG. 8. Reconstruction of uppermost part of fertile stem of *E. limosum*. *n.x.* = nodal wood, breaking up into the bundles (*b*) of the internode above; *l.t.* = leaf-trace; *i.b.* = bundle in the internode below; *p.* = parenchyma between the bundles; *p.¹* = torn parenchyma on the inner side of the bundles; *end.* = endodermis; *sc.co.* = inverted hollow cone of sclerenchyma.

meshes of the upper internode; thus we get a ring, three to four cells deep, of these dark brown cells lying inside the circle of strands; traced upwards this ring communicates through the parenchymatous meshes with the dark brown cells of the outer endodermis. Traced downwards into the lower internode the ring of thickened cells narrows rather rapidly; at first it is connected with the narrow band of parenchyma that persist on the inner side of the vascular bundles; but as we pass downwards it narrows so rapidly that in the mature stem is soon ceases to be in contact with this parenchyma, and in a transverse section lies free in the middle of the central cavity (Text-figs. 8 and 10). The thin-walled elements internal to this ring

TEXT-FIG. 9. Lettering as in Fig. 8.

TEXT-FIG. 10. Lettering as in Fig. 8.

also become torn as the stem increases in width, though not infrequently the torn remains of such thin-walled cells may be seen adhering to the inner side of the thickened ring. As the latter narrows, passing down the internode the cavity which it encloses becomes smaller, until we get a solid core of thickened cells lying free in the central cavity (Text-fig. 9). These phenomena were observed in Cones A and C, in which they were closely similar; the series of sections below Cone B was not sufficiently extensive to show the form of the mass of dark brown cells, but the presence of such cells was ascertained.

Pfitzer has described dark brown cells in the interior of the branch at its insertion on the stem, but he does not seem to have noticed similar phenomena in the main shoots. His description, which, *mutatis mutandis*, agrees with the description given above, runs thus: 'In a radial longitudinal section through the origin of the branch the brown internal mass of the cylinder is seen to widen out laterally . . . in such a way that it comes into connexion with the outer endodermis of the cylinder.' The cylinder ('Röhre') mentioned here is, of course, the ring of xylem found in the lower part of the branch; upwards this cylinder of xylem only breaks up into separate strands above the insertion of the first leaf-sheath of the branch, while below it is attached to two of the cauline bundles; its insertion here is also oblique with regard to the main axis.

E. palustre has in the internode only an external endodermis, but Pfitzer has shown that throughout the node there is also a common internal endodermis, which traced upwards and downwards passes over gradually into the typical pith without coming into contact with the external endodermis. He remarks that in the old stems of *E. palustre* all the cells within the inner endodermis are thickened and dark brown, and says that they constitute the brown diaphragm. In my young specimens the diaphragm was not at all brown. Pfitzer also gives a curious description of the brown cells within the base of the cylinder of the branch of this species. The branch has an inner endodermis, the inner longitudinal walls of which are thick and dark brown; the cylinder also contains thickened dark brown cells; these appear first in the middle of the cylinder, and their development is continued upwards and downwards; when it reaches its highest grade 'the whole interior of the cylinder is filled with a dark brown mass of cells which either shows a dilation ("Anschwellung") above or below or below only, and is surrounded by the unthickened external longitudinal walls of the (inner) endodermis'. If this description is accurate the form of the brown mass of cells would be that of a solid dumb-bell or of a solid normally oriented cone. Pfitzer also describes dark brown cells in the branch of *E. littorale* and in the stem of *E. variegatum*. In the latter species, when the nodal wood breaks up above the departure of the traces, the outer and inner endodermes are replaced by special endodermes round the bundles,

and the endodermal cells lying on the inside of the bundles are thickened, and the thickenings are dark brown. This thickening and colouring of the layers of thickening spreads a little higher up to the pith cells, so that we get a polygon of which the blunt ends project between the special endodermes. Thin-walled cells are often found inside this polygon (Pfitzer).

Jeffrey, working on *E. hiemale*, also records sclerized brown cells. He writes of his Fig. 2, Pl. XXIX, representing a tangential section of the nodal region of *E. hiemale*: 'The magnification is sufficient to show that the medulla of the branch is composed of brown sclerenchymatous cells' (Jeffrey, 1). As the photograph is of an obliquely oriented organ it is not easy to make out the exact form of the sclerenchymatous mass; from the above quotation it might be thought that the whole medulla is sclerized, but it is hardly safe to conclude this from a passing reference like that quoted above. Jeffrey states, too, that the diaphragm of the first node of the branch is very deep, and somewhat sclerified at the ends; this diaphragm does not appear to be connected at the origin of the branch with the above-mentioned mass of sclerenchyma. He also found that in the main stem of *E. hiemale* and *E. limosum* the diaphragm was partially sclerified; this he regarded as sclerified periderm and compared it to the non-sclerified periderm in the diaphragm of certain *Calamites*.¹

THE TRANSITION FROM FERTILE STEM TO CONE.

The annulus seems to mark the position of a reduced node, and the reasons for this must be examined. We have seen from the anatomy of the cone and stem that fresh parenchymatous meshes arise above the nodes; usually they arise at a relatively small distance above a trace that has departed; we have also seen that the closure of meshes of the internode below is effected in the region of the node. This closure of parenchymatous meshes and the formation of fresh ones in the region of the node causes a branching of the vascular strands at this level. We have seen also that when the xylem is much reduced at a node certain of the strands pursue an isolated course upwards into the next internode because sufficient xylem to close the meshes of the internode below is not present, and because the trace-bearing strand remains too narrow to give rise to an independent parenchymatous mesh above the node. We may generalize as to the fluctuating conditions obtaining in the fertile nodes by saying the greater the reduction of *nodal* xylem the larger the proportion of strands that pass through a node without branching. In the vegetative axis in which the nodal xylem is well developed and forms a complete ring (though the internodal xylem is less developed than in the cone), all the meshes are

¹ Since writing the above I have come across H. H. Thomas's record of a nodal diaphragm, hollow in the middle, in a Jurassic species of *Equisetites*. Cf. Mémoires du Comité Géologique de Saint-Petersbourg, N. S. 71, 1911.

closed at and fresh ones originate above the node. A branching of strands independent of the formation of a parenchymatous mesh above a trace that has departed is very rare. It is true that in cones with relatively little xylem, or in parts of cones with little xylem, a mesh may arise below and to one side of a trace ; but in such cases its form and position seem to show that it has, phylogenetically speaking, 'decurred' downwards below the trace to which it corresponds (cf. p. 673). True branching of strands, independent of the formation of meshes above traces, does occur, though rarely, both in cones and stems where the number of members in the next whorl is increased, and still more rarely owing to inexplicable irregularities. But even in cases in which an increase in the number of members causes branching of the strands the area of disturbance of superposition of meshes to traces is narrowly restricted. Branching of some of the strands above the annulus is common, and strongly suggests that we are dealing with a reduced node ; in *E. arvense*, however, the number of sporangiophores in a whorl often considerably exceeds the number of leaves in the fertile stem, and the formation of fresh meshes above the insertion of the annulus might be regarded as the expression of the increase in the number of appendicular members. In this species, too, the number of strands that pass uninterruptedly through the annular node is relatively large. The transitional region was studied in Cones A, B, C, F, G, and H of this species. In Cone A four out of nine strands forked, giving rise to fresh meshes above the annulus. Below the annulus of Cone B there were seven strands, and all passed through the annular region without branching ; in Cone C one only of the eleven strands branched above the insertion of the annulus. Cone F was exceptional and will be considered later ; in Cone G three out of nine strands forked above the insertion of the annulus, while in Cone H one of eleven strands forked. The forking observed in this last cone was the more significant as there were only ten sporangiophores in the lowest whorl of the cone ; thus the branching of the strand was not correlated with an increase of appendicular members, and seems clearly to be a vestigial nodal character. In Cones A, B, and D of *E. palustre*, too, the number of members in the uppermost vegetative whorl was equal to the number in the lowest whorl of the cone ; yet in all these cases a certain number of meshes were closed, and others originated in the neighbourhood of the annulus. In the four cones of *E. palustre* examined, after the closure of certain of the parenchymatous meshes in the region of insertion of the annulus, a band of xylem which effected this closure persisted upwards through the 'internode' lying between the annulus and the sporangiophores ; in this region the absence of meshes was due, as it appears occasionally to be due in the cone (cf. p. 671), not to poor development of nodal wood, but to unusual development of internodal wood.

Cases of closure of meshes of the internode below in the neighbourhood

of the annulus are difficult to observe in *E. arvensis*. In Cone A of this species the meshes below the first and second traces of the lowest whorl of sporangiophores are closed, and a fresh mesh of the first order originates between them (cf. Text-fig. 1). In this restricted region the branching gives rise to the formation of a mesh alternating with that of the internode below, and the nodal appearance is most clearly marked in a longitudinal reconstruction, though, of course, the fresh meshes are not subtended by traces. In other cases a mesh is closed in the neighbourhood of the insertion of the annulus, but no fresh mesh originates higher up alternating with it; this may, perhaps, be due, as in *E. palustre*, to the persistence of a band of xylem through the internode above the annulus. This seems to be the case with certain of the strands of Cone C of *E. arvensis*. Here the first, the second, the third, the fourth traces, the two bundles composing the prematurely divided sixth trace, and the eleventh trace, are all inserted not vertically above the middle of the strands of the uppermost vegetative internode, but lie more or less above the point of junction of two strands. Thus the meshes above these traces do not alternate with those of the uppermost vegetative internode, but lie more or less above them; on this assumption the meshes corresponding to the third and fourth traces have 'decurved' a little below the traces to which they phylogenetically belong. If parenchymatous meshes had appeared in this band of xylem above the annulus and had been closed again at the insertion of the sporangiophores they would be about half the height of the meshes of the first order of the cone. In Cone A, where two meshes actually arise above the annulus and are closed before the insertion of the basal whorl of the cone, their height is about half that of the meshes of the first order found in the lower and less immature region of the cone. The absence of branching in the region of the annulus in Cone B may perhaps be due, at any rate in part, to this same relatively great development of xylem in the internode above the annulus. The xylem is much more developed in this cone relatively to its size than in Cone C, and at the level of the basal whorl all the strands are united into a ring of xylem. But the fusion of the xylem of the bundles forming a ring takes place at very different levels, and some of the strands fuse as far down as 0.9 mm. below the sporangiophores; if meshes originated just above this lowest fusion and were closed at the height of the sporangiophores they would be, like the meshes of the first order arising above the annulus of Cone A, about half the average height of the meshes of the first order of the cone of the specimen in which they occur. In Cone B, however, it was difficult to be sure if the meshes above the sporangiophores were superposed to those of the internode below, for the diameter of the stele narrowed abruptly at and above the insertion of the basal whorl of the cone, and this narrowing confused the relations of alternation and superposition of the meshes. It is quite possible, therefore,

that in Cone B we are dealing merely with a case of early closure of certain meshes, and parallel cases of early closure are by no means rare in the cone of this species. But in Cone C such an explanation would not account for the fact that the traces of the first whorl seem in some cases to lie above and between the strands of the internode rather than above and in the middle of them; in this cone, too, one fresh mesh originates above the annulus and very much at the level at which some of the other meshes are closed.

To return to *E. palustre*, in which the percentage of closure and of origin of meshes in the annular region is highest and in which the nodal appearance of this region in longitudinal reconstruction is therefore most striking, we find that in Cone A six out of seven, in Cone B four out of eight, and in Cone D four out of six meshes are closed in the neighbourhood of the insertion of the annulus. Notwithstanding the persistence of bands of xylem into the internode above the annulus, four fresh meshes originated above the annulus in Cone A, three in Cone B, and three in Cone D. Cone C was exceptional; though there were eight strands below the annulus and nine sporangiophores in the second fertile whorl, the basal whorl of the cone consisted of but three sporangiophores. The increase in number of trace-bearing strands to nine in the second fertile whorl is due to the fact that above the lowest whorl of the cone a band consisting of three strands (that with two other single strands gave off no traces at this node) breaks up into four strands; thus the increase in the number of strands takes place between the first and second whorls of the cone and not between the annulus and the lowest whorl. Nevertheless, six out of eight meshes were closed and four originated in the neighbourhood of the annulus. It is curious that none of the fourteen meshes originating above the annuli of the cones of *E. palustre* examined were of the first order. It must, however, be remembered that meshes of the first order are much rarer in the cones of *E. palustre* than in those of *E. arvense*.

In *E. limosum* the indications of the nodal structure of the axis at the insertion of the annulus are less marked; in Cone A we notice one case of the origin of a mesh above the annulus. In Cone B there are four meshes which I interpret as arising above the annulus; like the mesh in Cone A they are of the second and higher orders. The mesh below the second trace of the lowest whorl of this cone appears to be closed in the region of insertion of the annulus and markedly below the level of the basal whorl; this is true, too, of the meshes above the twelfth and thirteenth leaf-traces; but this cone is still so young and has elongated so little that it is exceedingly doubtful if we are dealing with bands of xylem persisting through an unelongated supra-annular internode or with early closure of a mesh before the first fertile node. Cone C of this species showed two clear cases of meshes originating above the annulus. This tendency of meshes to be closed slightly above a node was noticed also in various cones (cf. pp. 680-1),

and seems to be one result of a lesser development of xylem. The latter being insufficient to bring the strands laterally into contact at the node, their connexion is effected higher up by the oblique course of the tracheides present.

Strong confirmation of the view that the annulus marks the position of a reduced node was afforded by the region transitional from the fertile stem to the cone in Cone F of *E. arvense*. This specimen had two annuli; the upper one was normal in appearance, the lower one was rather more developed than is usual in this species, especially on one side where the edge was slightly lobed. The insertion of this lower annulus on the axis was remarkably oblique, a phenomenon which may occasionally be observed in normal annuli. According to Duval Jouve the possession of more than one annulus and irregularities of the annulus are very common in *E. arvense*, *E. maximum*, *E. littorale*, and common in *E. sylvaticum*, *E. limosum*, and *E. ramosissimum* (Duval Jouve, pp. 150 and 154). Milde goes so far as to describe the cone of *Equisetum* as having one to two annuli (Milde, p. 161). But I know of no account of the anatomical relations of such abnormal forms. A little distance below the lower annulus of Cone F the anatomy of the stem was that of a typical internode of the vegetative region. There were seven more or less equivalent bundles, each with a large carinal canal and two small lateral groups of metaxylem. A little higher up reticulate tracheides, resembling those of a vegetative node, make their appearance in the adjacent halves of two bundles; these two groups of tracheides and the phloem external to them pursue a course so oblique that about 30 to 40 μ higher up they come into contact. The reticulate wood thus formed is of the same radial extent as that of an ordinary vegetative node; but in the direction of the circumference of the stele it at first occupies only the portion of the stele lying between the carinal canals of two adjacent bundles. The lateral groups of metaxylem at the free ends of these bundles persist for a little distance in the condition of typical internodal lateral metaxylem; but a little higher up they and the cells beyond them become connected with and assume the character of nodal wood. There results a band of reticulate tracheides extending over rather more than a quarter of the circumference of the stele. This band of xylem, however, very soon breaks up into three bundles by the dying out of portions of the woody band. About 320 μ above the first appearance of the reticulate tracheides the band of xylem has broken up into three normal sized bundles; the middle one is already in a typical internodal condition, each of the others consists of a curved band of typical 'nodal xylem'. Traced upwards these reticulate tracheides, the free ends of the band of reticulate wood, do not die out, but pursue an obliquely transverse course, passing in opposite directions round the circumference of the stele (Fig. 5, Pl. LXIV). Thus a mass of tracheides appears at different levels in all the bundles. When the two strands of reticulate tracheides and the phloem outside them have

girdled nearly the whole circumference of the stele they find themselves in adjacent bundles, and after becoming very closely approximated they die out without coming into absolute contact at a height of about 1.6 mm. above the first appearance of reticulate tracheides. When they die out the two strands are separated only by one or two parenchymatous cells. Each strand consists of the equivalent of a bundle, but while each may sometimes occupy the position of a single bundle it has of course to pass from one bundle to another, and frequently occupies a position between two bundles. While the masses of nodal wood have been journeying round the stele the number of bundles has increased from seven to ten, an increase very similar in amount to that found in many normal cones of *E. arvense*. It is interesting to note that this lower annulus, which only faintly recalled a leaf-sheath by its lobing on one side, possessed reticulate tracheides apparently identical in structure with those of an ordinary node; the distribution of these is of course different from their distribution in an ordinary node; but this is presumably due, in part at least, to the oblique insertion of the annulus. In one of the two bundles that first develop reticulate tracheides, a bundle situated on the side on which the annulus was most developed, there seemed to be indications of a reduced and abortive trace. A few phloem cells bend out into the cortex, and endodermal cells with exceptionally well-marked bands of cutinization may be seen cut longitudinally a little way out in the cortex. Moreover, one or two tracheides bulge out through the opening in the phloem and seem to be passing out into the cortex; unfortunately, two sections, each 10 μ thick, above the section showing these phenomena, were lost in mounting. If one or two tracheides did, as seems likely, pass out into the cortex they must have died out almost at once, for no further trace of them can be seen in other sections. The parenchymatous stelar cells that bend outwards, and those with endodermal markings, also die out ere long in the cortex; but for several sections they are distinctly discernible owing to the fact that they are cut longitudinally or very obliquely. No further indications of traces were observed in any of the other bundles.

Below the upper normal annulus there were ten strands, and the lowest whorl of the cone consisted of ten sporangiophores, so that there was no increase in appendicular members; yet six new meshes were formed above this annulus, two of which were closed at or just above the level of the lowest fertile whorl. No less than seven out of the ten meshes existing below the upper and normal annulus were closed in the region of its insertion. Thus the number of meshes closed and initiated in the region of the annulus was in the case of Cone F exceptionally high for *E. arvense*.

We may add that though annuli do not seem to have been described in most of the cones of the fossil Equisetales, Thomas records a possible example in *Calamostachys* (Thomas), and a structure which appears to

be of the same nature may be seen in one of Kidston's figures of *Pothocites* (Kidston, Pl. XII, Fig. 14).

GENERAL CONSIDERATIONS.

Equisetum is so isolated among existing plants that comparisons of the structure of its cone with the cones of recent plants seem at present to be futile from a morphological point of view. But the phylum of the Equisetales was well developed in the past, and a comparison with the varied cones of this great phylum offers the most promising field for conclusions as to the comparative morphology of the cone. The cones of the Equisetales may be divided into two great groups, those consisting only of fertile appendages, provisionally called sporangiophores, and those in which the cone also contains sterile appendages. Leaving abnormalities out of consideration the former group includes the cones of the recent *Equisetum*, those of the species of *Equisetites* in which the reproductive organs are known, namely, the carboniferous *E. Hemingwayi*, Kidston, the Liassic *E. Nathorsti*, Halle, and the Rhaetic *E. suecicum*, Nathorst (Halle, pp. 27-31); it also includes the cones of *Autophyllites furcatus*, Grand'Eury, *Bornia pachystachya*, Bureau, and perhaps of *B. transitionis*, Grand'Eury; these three species come from the Carboniferous (Jongmanns, pp. 26.5-7). In the cones forming the so-called genera *Calamostachys* (including Renault's *Calamodendrostachys Zeilleri*), *Palacostachya*, *Huttonia*, *Cingularia*, and in *Volkmannia pseudosessilis*, Grand'Eury, sporangiophores and sterile bracts succeed one another on the axis of the cone (Jongmanns, p. 279). These types of cones are of Palaeozoic age; most of them certainly, probably all of them, represent cones of the Calamariac in the widest sense of the word. In *Calamostachys* bracts and sporangiophores form equidistant whorls; in *Palacostachya* the sporangiophores are inserted in the axils above the bracts, while in *Huttonia*, in *Cingularia*, and in *Volkmannia pseudosessilis* they are situated below the bracts. *Archaeocalamites* (including *Pothocites* and *Bornia*, excepting perhaps *B. pachystachya* and *B. transitionis*) appears to be intermediate between the two groups, for its cone consists of whorls of sporangiophores, sometimes at least interrupted at considerable intervals by a whorl of sterile bracts. The best way of elucidating the anatomy of a cone is certainly by the study of its internal structure. But nearly all the cones mentioned above are known as impressions only; we are, however, acquainted with the anatomy of some species of *Calamostachys* and *Palacostachya*. It has been customary of late years to regard the sporangiophores and bracts of these two genera as phylogenetically lobes of a compound leaf of sporophyll. Such a view is admittedly based partly on an analogy with the Sphenophyllales, in which group the sporangiophore, when present, is usually inserted on a sterile bract. This view has been somewhat widely held, and different modifications of it were

favourably considered by Scott (Scott, pp. 158-62)¹, Lignier (Lignier), Jeffrey (Jeffrey (1), p. 185), and others. Bower, however, was strongly opposed to it, regarding the sporangiophore as an organ *sui generis*, not only in the Equisetales, but also in the Sphenophyllales (Bower (2), pp. 381-4), while Seward supported him as far as regarding the sporangiophore, at least provisionally, as an organ *sui generis* (Seward, p. 15). There are certainly much stronger reasons for doubting that the sporangiophore represents a lobe of a leaf in the Equisetales than in the Sphenophyllales. In the former group we are at once met with the difficulty of explaining those cones in which the bracts are either absent or present only at considerable intervals. Those that regard the sporangiophore as a lobe believe that it has been displaced in *Calamostachys*; some years ago Dr. Scott pointed out that if such displacement occurred in a form in which, as in *Sphenophyllum fertile*, both lobes of the sporophyll bore sporangia, we should get a near approach to the *Equisetum* arrangement (Scott, p. 162). Jeffrey also remarks that there are many reasons for regarding the sporophyll in the Equisetaceous series as dorsiventrally lobed. He suggests that in this case the sporangiophores of *Equisetum* represent the result of fusion of ventral and dorsal segments, or that they are ventral segments, the dorsal having become obsolete. No known cone seems to show such an obsolescence of bracts, and the sporangiophores of *Equisetum* do not seem to be dorsiventrally double.

I was at first inclined to accept Dr. Scott's tentative suggestion that in *Equisetum* each sporangiophore might represent a separated lobe of a dorsiventrally lobed sporophyll; in this I was influenced by the analogy with the Sphenophyllales, but principally by the fact that I felt unable to escape the conviction that the sporangiophores of *Archaeocalamites* are the homologues of those of *Calamites*, and these sporangiophores seem very closely to resemble those of *Equisetum* (Browne, p. 16). But a comparative study of the cone of *Equisetum* seems to show that the sporangiophores are whole appendages and that their insertion marks the position of a node. It is true that though the cone has more internodal xylem than the stem, the ring of wood at a fertile node is only exceptionally complete; such a ring is, however, by no means rare in *E. arvense*. Moreover, at the insertion of the whorled appendages there is (except in cases of great reduction of the xylem) a marked increase in the amount of xylem, leading to the formation of bands or of a ring of xylem. Above the departure of the traces of the sporangiophores, and often very much at the same height as the breaking up of the xylem above the leaf-traces, these bands or this ring of xylem breaks up owing to the appearance of parenchymatous meshes.² In this

¹ Dr. Scott subsequently pointed out that the spore-bearing organ might be a whole leaf or a lobe of a leaf (Studies in Fossil Botany, 1909, p. 623). I have been led to adopt this view.

² The nodal xylem of the stem of course differs markedly from the xylem at a fertile node, for, except for the protoxylem, it consists of large reticulate elements and has a considerable depth radially, while the xylem at a fertile node consists entirely of relatively small annular and spiral tracheids and is very narrow radially.

respect, however, the cone varies much more than the stem, for a portion of the band of xylem may be continued upwards through the greater part or the whole of the internode, or it may break up relatively near the departure of the traces.

Thus the anatomy of the cone supports the view that the sporangiophores of *Equisetum* are whole appendages. On the other hand, the anatomy of the cone of *Palaeostachya* and *Calamostachys* seems to show that in these genera the sporangiophores and bracts are lobes of a leaf (Hickling, 1 and 2). This is a very fundamental difference, and it would seem that these genera do not lie at all near the Equisetal line of descent. The anatomical evidence is at present insufficient to decide whether the sporangiophores of *Archaeocalamites* were lobes, as were those of *Calamostachys*, or whole appendages, as those of *Equisetum* seem to be. The latter view seems to me the more natural. The bracts found at irregular intervals in the cone of *Archaeocalamites*, which I was formerly inclined to regard as indications of sterilization of fertile appendages (Browne, p. 17), would seem more probably to be reduced vegetative leaves, and their occurrence in the relatively ancient *Archaeocalamites* might be a primitive character, indicating want of definition of the strobilus.

The parenchymatous meshes found in the cone, like those in the vegetative internodes of *Equisetum*, do not, except at the reduced or immature apex of the cone, originate immediately above the traces. Thus they are not foliar gaps as defined by Jeffrey. Speaking of the tracts of parenchyma of the internode of the stem of *Equisetum* this author says, 'They lack, however, one important feature of foliar gaps, for they do not occur *immediately above the traces*, as should be the case with true foliar gaps. All other foliar gaps with which we are acquainted show this feature'¹ (Jeffrey (2), p. 252). If this definition of a foliar gap is to be applied in all cases, the tracts of parenchyma above the traces of certain recent Osmundaceae are not foliar gaps. Sinnott, seeking to defend Jeffrey's view that the traces of siphonostelic and dictyostelic Pteropsida always leave gaps, claims that when in recent Osmundaceae a trace appears to leave no gap in the wood at its departure the trace-bearing xylem-strands always break a little further up while the trace is in the cortex. This is exactly what occurs in the axis of the cone when a strand branches a little way above the departure of a trace; very much the same thing occurs in the stem when the nodal wood breaks up a little way above the insertion of the leaf-sheath. In cones which, like that of *E. limosum*, have very little xylem, the 'gap' or break usually occurs very close to, though not immediately above the trace, and thus the mesh of parenchyma approximates more closely to Jeffrey's conception of a gap. In the cones of *E. arvense* and *E. palustre*, when the xylem is broken above a trace, pith and cortex remain separated

¹ The italics are Jeffrey's.

by the endodermis, which in these species surrounds the stele. In the stem of *E. limosum* (and presumably in all cases in which the vascular strands are surrounded by separate endodermes) even this barrier is broken down; for at the breaking up of the nodal ring of wood the external and internal endodermes found in this region become involuted round each bundle, so that pith and cortex are in direct communication (Pfitzer, pp. 336-7). Definite endodermal markings are, however, very difficult to distinguish in the cone of this species. It would seem that, phylogenetically speaking, parenchymatous tissue first arose in the internodal part of the siphonostelic xylem of the cone of *Equisetum*. It is not surprising that this parenchyma should have arisen vertically above the traces, since the current of water, being deflected into the sporangiophores, would be diminished above them. From the dimensions of the fossil *Equisetites* we have good reason to believe that existing species of *Equisetum* are reduced, and reduction of the xylem would tend to make the mesh arise closer to the trace. This is exemplified in the cone of *E. limosum*, in which there is very little xylem; here the traces are often only surmounted by a very few lignified elements, though even in this species the parenchymatous mesh sometimes originates at a considerable distance above the trace.

In the preceding pages we have traced the phylogeny of the irregular network of strands of the cone of *E. limosum* from the more regular stele of *E. arvense*, which is imperfectly siphonostelic at the nodes and dictyostelic in the internodes. Considered separately, the irregular network appears to baffle interpretation; considered in the light of a comparative study of the cones of *E. palustre* and *E. arvense*, we see that it has arisen in the phylogeny by the reduction of xylem, this reduction being manifested by extension of the parenchymatous meshes upwards, downwards, and laterally.

In 1899 Jeffrey published a photograph of a cone of *E. arvense* cut longitudinally in two; this photograph was intended to show that the majority of the bundles of the cone do not alternate at the nodes (Jeffrey (1), Pl. XXX, Fig. 3). This feature was, he said, more or less marked in the cones of all the species of *Equisetum* that he had examined. Some years later he returned to this point, and after commenting on the greater conservatism of reproductive axes as compared with vegetative ones he proceeded: 'It appears to have been shown above and beyond any doubt that the equisetaceous strobilus perpetuates both the alternating strands and the complete absence of foliar gaps of the oldest Calamitean forms' (Jeffrey (2), p. 254). While, as Jeffrey remarks, it seems obvious from the data of Stur, which have never been called in question, that the oldest Calamariae were without alternation of the strands at the nodes, and while, according to Hickling, the bundles of the cone of *Calamostachys* did not alternate at the nodes (Hickling, 2, p. 10), and those of *Palacostachya vera* seem to show no regular pectination, but probably occasional and irregular communication

(Hickling (1), p. 375), the non-alternation of the bundles in the cone of *Equisetum* seems clearly, from the comparative anatomy of the cone, not to be a primitive feature. Moreover, Renault says of his *Volkmannia gracilis*, which is clearly a *Palaeostachya* (cf. Jongmanns (1), p. 332), that the vascular bundles alternate from one internode to the next. It seems shown by the full discussion above that this non-alternation of the bundles at the nodes of the cone of *Equisetum* is due to the persistence of parenchymatous meshes on either side of a strand of xylem, and that this persistence is the direct result of poor development of xylem. More generally, when there is no marked reduction of xylem, and when the position of traces is not disturbed by changes in the number or size of members of successive whorls, the traces of successive whorls alternate with one another. When owing to reduction of xylem in the axis of the cone the traces are superposed, the sporangiophores which they supply still alternate regularly. This is, no doubt, due partly to exigencies of space in the young unelongated cone, but it may possibly be in part due to the retention of an ancestral feature. In Jeffrey's photograph of a cone of *E. arvense* cut in two, some of the strands may not have alternated at the nodes owing to persistence of parenchymatous meshes, while other strands may appear to be continued upwards above the node because the meshes of parenchyma originating above traces are generally narrow in this species, so that a longitudinal cut would not pass through many of them.

SUMMARY OF RESULTS.

1. The xylem at the node of a cone of *Equisetum* consists of a woody ring or of woody bands of varying width; in the internode the xylem usually breaks up into definite strands separated by parenchymatous meshes; these generally arise vertically above the points of departure of the traces, often close above them, but never, except perhaps in the reduced apical region, immediately above them.

2. When the xylem is relatively well developed these meshes are closed again in the neighbourhood of the next node; when less xylem is present some of the meshes tend to persist upwards through two or more internodes. When still less xylem is developed meshes of parenchyma tend to arise a little below and to one side of a trace; they also frequently become widened laterally by fusion with a mesh that has originated independently or by congenital fusion with a mesh above a trace departing from the edge of a strand of xylem.

3. The cones of *E. arvense*, *E. palustre*, and *E. limosum* form a series showing increased reduction of the xylem; *pari passu* with this decrease of the xylem the stele comes to form a more and more irregular network of strands.

4. The non-alternation of some of the strands of the cone at the node is due to poor development of xylem in this region causing the persistence of the meshes on either side of a strand.

5. The anatomy of the axis supports the view that the sporangiophores are whole appendages and not lobes of a sporophyll or leaf.

6. The branching of some of the vascular bundles in the neighbourhood of the insertion of the annulus affords an indication of nodal character at this level. This is confirmed by the anatomy of an abnormal specimen of *E. arvense*.

7. In the upper part of the fertile stem of *E. limosum* a diaphragm of the usual type was not found; instead there was an inverted hollow cone of dark brown cells, hanging freely down for a little distance in the central cavity and continuous upwards, above the breaking up of the nodal xylem with the locally somewhat thickened and dark brown endodermis.

My thanks are due to Professor Oliver, F.R.S., in whose laboratory at University College, London, this work was carried out; and to Mr. T. G. Hill for much advice and assistance.

EXPLANATION OF PLATES LXIV AND LXV.

Illustrating Lady Isabel Browne's paper on the Anatomy of the Cone of *Equisetum*.

FIG. 1. Transverse section of the stele of a node of *E. arvense*, showing the bundles united into a ring of xylem and phloem. At the upper side of the photograph the ring is not quite complete; the complete ring of xylem persists a little way below and above the departure of the traces; on one side the section passes through a region where the ring of xylem is complete and no traces are departing. $\times 80$.

FIG. 2. Transverse section of part of the stele at the node of a cone of *E. arvense*. This photograph illustrates a case in which the traces depart from strands unusually far apart, and there is no formation of a ring or bands of xylem. A trace has just departed from a bundle on the reader's left hand. $\times 80$.

FIG. 3. Transverse section of part of the stele of the internode of the cone of *E. arvense*. The separate bundles are wider, compared to the parenchyma between them, than in *E. palustre* or in *E. limosum*. $\times 80$.

FIG. 4. Tangential longitudinal section through part of the cone of *E. arvense*. This photograph illustrates the fact that sometimes the strands alternate at the nodes and sometimes they pass uninterruptedly through the nodes. $\times 22$.

FIG. 5. Transverse section of part of the stele of the axis at the insertion of an abnormal annulus in *E. arvense*. Some of the bundles are in the condition typical of the vegetative internode, while two masses of reticulate tracheides and the phloem outside them are passing in opposite directions and obliquely round the stele. $\times 65$.

FIG. 6. Transverse section of the stele at the node of the cone of *E. palustre*. Two of the trace-bearing bundles are united, the others are separate though more approximated and larger than in the internode. In this species the strands often become united just above the node by their forking, and by the fusion of adjacent forks of neighbouring bundles; all the bundles do not give off traces at exactly the same level, so that the photograph of any single section does not show as much xylem as is present in the nodal region. $\times 65$.

FIG. 7. Transverse section of part of the stele of the internode of *E. palustre*, showing small bundles. $\times 80$.

FIG. 8. Transverse section of part of the stele of the internode of a large cone of *E. limosum*. $\times 80$.

FIG. 9. Transverse section of the stele in a small young cone of *E. palustre*, var. *polystachion*, showing ring of separate bundles. $\times 80$.

FIG. 10. Transverse section of stele just above the annulus of small young cone of *E. palustre*, var. *polystachion*, showing the formation of bands of xylem owing to fusion of bundles, unconnected with the departure of any traces. $\times 80$.

FIG. 11. Transverse section of the stele at the node of a small young cone of *E. palustre*, var. *polystachion*; as in the more typical specimens, some bundles are isolated and others fused. $\times 80$.

FIG. 12. Transverse section of the stele of large, mature cone of *E. limosum*. Some of the bundles are giving off traces, but owing to the irregularity of insertion of the sporangiophores, others have done so lower down or will do so higher up. Some of the bundles have already forked above the departure of traces and the branches have begun diverging, but have not yet fused with their neighbours (e.g. the two small bundles in the middle of the photograph on the reader's left); this accounts for the slight increase in number of the bundles; in the internode below there were eighteen, and this is also the number of the traces. $\times 55$.

Studies in Spore Development.

II. On the Structure and Division of the Nuclei in the Compositae.¹

BY

RUDOLF BEER, B.Sc., F.L.S.

With Plates LXVI and LXVII.

IN 1900 Merrell (16) published an account of the life-history of *Silphium*, in the course of which some reference is made to the nuclear phenomena, both in connexion with the development of the embryo-sac and with that of the pollen-grains. He found that eight is the reduced number of the chromosomes in this plant.

In 1905 Juel (13) added materially to our knowledge of the nuclear divisions taking place in the Compositae by his studies of *Taraxacum*, *Hieracium umbellatum*, and *Crepis tectorum*. In the last-named species he found the reduced number of chromosomes to be only four.

Previous to this work, Juel had published (12) an interesting account of his investigation of *Antennaria dioica* and *A. alpina*, in which the mitotic phenomena were also noticed. The most comprehensive work, however, which has recently been published upon the nuclear phenomena of the Compositae is that which has been carried out by Rosenberg (19 and 20) and Lundegårdh (15).

A number of species were examined in these investigations,² with the result that they were believed to afford strong evidence in favour of the existence of prochromosomes in these plants and to furnish striking examples of the parasynaptic origin of the chromosomes. A condition resembling that of the second contraction described by Farmer and Moore (5) was recorded by both Rosenberg and Lundegårdh in several species of Compositae, but they regard it merely as a chance arrangement of the nuclear contents without any essential significance in the development of the heterotype chromosomes.

¹ I am indebted to the Government Grant Committee of the Royal Society for the loan of a Zeiss 2 mm. apochromatic objective (1.40 aperture) used during the research.

² *Hieracium venosum*, *H. Auricula*, *Tanacetum vulgare*, *Crepis virens*, *Calendula officinalis*, *Achillea millefolium*, *Anthemis tinctoria*, and *Matricaria Chamomilla*.

My own observations upon the pollen development of the Compositae were undertaken with the primary object of studying the structure and development of the membrane of these bodies.

I saw no reason to doubt the correctness of the results reached by the Swedish investigators in their study of the reduction divisions, and I, therefore, turned to my preparations of the dividing pollen mother-cells with the full expectation of finding that these would confirm the previous observations. I soon found, however, that my sections presented so many and such notable points of difference from what I had anticipated from Rosenberg's descriptions, that it was no longer possible to dismiss the nuclear phenomena of these plants in a few words, but that they would require a very careful re-examination.

I have, therefore, decided to divide my account of the pollen development of the Compositae into two parts, and to deal in the present communication with the nuclear divisions (both meiotic and somatic) alone, whilst I reserve the detailed description of the pollen-wall for a separate part of these 'Studies'.

In dealing with the meiotic phase I have examined *Tragopogon pratensis*, *Matricaria Chamomilla*, and *Crepis taraxacifolia*, throughout the different stages. In addition to these, I have also carefully examined the earlier prophases of the heterotype division in *Doronicum plantaginicum*, *Calendula officinalis*, and *Anthemis Cotula*. The later stages in the telophase of both the heterotype and the homotype division were also studied in the case of *Crepis virens*.

For comparison with the meiotic phase I have also made a careful study of the somatic divisions in *Crepis virens*.¹

PRESYNAPSIS.

In *Doronicum plantaginicum*, as the nucleus passes over from the telophase of the last premeiotic division to the 'resting' condition, we find that the gradual vacuolation of the chromosomes and the dispersal of their substance lead to the formation of a coarse reticulum. At one spot this reticulum consists of only delicate fibres, at another the strands of the network are coarse and thick, and the chromatic material may even be aggregated into irregular clumps. There can be little doubt that these thickenings upon the reticulum and the irregular clumps of material are derived from the incomplete dispersal of the chromosome bodies of the last somatic division. There is, however, no constancy in their number, size, form, or arrangement, and they cannot be regarded as prochromosomes in the sense in which this word is used by cytologists (Pl. LXVI, Fig. 1). The nucleus at this time contains either one large nucleolus or two to three some-

¹ The material was fixed, with all precautions, in the stronger Flemming's solution, and in an alcohol and acetic acid mixture.

what smaller ones. The nuclear reticulum has a peripheral arrangement and the nucleolus (or nucleoli) appears to lie in a cavity. When such a nucleus is viewed in section one can occasionally find two chromatic aggregates or two filaments of the reticulum which lie parallel with one another. This, however, is merely due to the sides of the meshes of the network appearing to be closely approximated when seen in section. In a surface view of such a nucleus, this appearance of a parallelism of its parts usually vanishes altogether. Nuclei of *Doronicum* at this stage are shown in Fig. 1, *a* and *b*.

In slightly older nuclei, that is to say, in nuclei which are nearer to synapsis, the reticulum has become somewhat finer and smoother. The chromatic aggregates have become much less evident and the thickened bars or meshes of the network tend to become more even. The nucleolus still lies in a clear cavity. It will be seen from Fig. 2, which represents such a nucleus, that the filaments of the reticulum often have a dotted appearance. This is due to the points of crossing of the filaments or the nodes of the network being seen in optical section, and does not represent a granular arrangement of chromatin particles within the linen threadwork. At this stage the delicate meshwork shows no distinction between chromatin and linen.

In *Tragopogon pratensis* the behaviour of the nucleus during pre-synapsis is very similar. Here also a rather coarse network tends to become smoother and more even before synapsis is entered upon.

In *Tragopogon* the reticulum often appears to reach up to and to be attached to the nucleolus, so that this body is not in such cases surrounded by a clear space. Fig. 3 shows this relation between the nucleolus and the reticulum. Mottier (18) has described a somewhat similar appearance in some of the nuclei of *Lilium Martagon* at a corresponding stage. He mentions, however, that the chromatin lumps are collected round the nucleolus in *Lilium*, but I do not find this in *Tragopogon*.

Calendula officinalis quite agrees with the Compositae which I have already described. A rather coarse network with chromatin aggregates which are irregular in size and form, and of no constant number, becomes more even and with less obvious chromatin lumps upon it before synapsis is reached. Fig. 4 shows these nuclei. *Crepis virens*, *Crepis taraxacifolia*, and *Anthemis cotula* are in no way different.

In *Calendula* and in both species of *Crepis* the nuclear reticulum is peripherally arranged and a clear space lies round the nucleolus.

The description which I have given above and the drawings which illustrate it will show the striking differences which exist between the appearance of my preparations of these stages and the figures and account given by Rosenberg and Lundegårdh.

For example, I have searched my preparations of *Calendula* repeatedly for a resting nucleus of a pollen mother-cell containing a number of regularly

paired prochromosomes such as Lundegardh (15) has illustrated in his Fig. 1, Tafel 2. My search has, however, always been in vain, and I have found no single instance in which the chromatic aggregates are regularly arranged in pairs as we see them in Lundegardh's figure, or in which they show any fixed relation to the chromosome number of this plant.¹ I have found, on the other hand, that the structure of these nuclei conforms much more nearly to Davis's account of the presynaptic nuclei of certain Evening Primroses (1, 2, 3). Here he finds a number of chromatic bodies derived from the chromosomes of the last premeiotic division gradually merging their substance with that of the reticulum, from which they cannot finally be differentiated. This reticulum, without any apparent chromatic bodies upon it, passes into synapsis.²

In the Compositae the vacuolization and breaking up of the chromosomes at the conclusion of the last premeiotic division are usually fairly complete, and by the time the prophases of the heterotype division are entered upon, any correspondence between the number of chromatic aggregates and that of the chromosomes of the last somatic division is quite lost. The small, irregular chromatic lumps and thickenings upon the reticulum during the early stages of the prophase of the division are, nevertheless, the last remains of the somatic chromosomes which have very nearly, but not quite, distributed their substance over the general reticulum of the nucleus. Before synapsis is entered upon there is usually a still further smoothing out of the reticulum, although there is some variation in the degree to which this progresses. Although, so far as the presynaptic pollen mother-cells of the Compositae³ are concerned, I find definite prochromosomes or gamosomes to be non-existent, there is no reason to doubt that in the cells of other organisms the chromosomes of the preceding division may possess a more marked persistence, and remain as clearly recognizable bodies which occur in the same number as the chromosomes. We have an example of this in the meiotic cells of the testis of *Triton* described by J. E. S. Moore and Miss Embleton⁴ (17).

SYNAPSIS.

The nucleus, containing this usually fine and smooth reticulum, next passes into synapsis. During this process there is an enlargement of the nuclear cavity, and the reticulum becomes gradually drawn together on one

¹ Lundegardh found the somatic chromosomes to number twenty-eight in this plant.

² Small, deeply staining bodies often occur in the nuclei of the vegetative cells and archesporial cells (previous to meiosis) of *Calendula*. These are sometimes single and sometimes paired. They are derived from the fragmentation and median vacuolization of the chromosomes of the preceding division. These bodies are, however, always absent from the nuclei of the pollen mother-cells shortly before synapsis (see Pl. LXVII, Fig. 77).

³ i. e. those species which I have examined.

⁴ Compare also the behaviour of the chromosomes of *Matricaria* during the interkinesis of the meiotic phase which is described below.

side of the nucleus. In the majority of cases there is now only a single large nucleolus, which sometimes lies pressed against the nuclear wall, but more often lies on the opposite side of the contracting reticulum. The most important alteration which can be seen to take place in the nuclear contents during the earlier stages of synapsis is the gradual transformation of the reticulum into a long, exceedingly delicate, and closely wound spireme (Figs. 5, 6, and 7). In no case have I found any indication of the occurrence of chromatic bodies which could be interpreted as gamosomes or zygosomes. The nuclear cavity contains no other visible constituent besides the nucleolus and the system of delicate, closely coiled threads. The threadwork is so closely wound together that it is quite impossible for any one to find in it the slightest evidence in support of the occurrence of two systems of threads lying parallel with one another. It would be just as reasonable to claim that a dozen threads could be counted lying parallel with one another in this coil as to assert that two such can be seen thus arranged. Moreover, the few loops which, in some cases, stretch from the margin of the coil into the nuclear cavity, are most certainly single structures. It is only necessary to glance at Fig. 6, which gives a true representation of a nucleus of *Doronicum* at this stage, to fully realize that there is neither any evidence for the existence of two parallel spiremes nor for that of paired gamosomes within the synaptic coil.

During synapsis the spireme becomes gradually thicker and at the same time shorter (compare Fig. 5 with Fig. 8, both of *Calendula*). In many cases this thicker thread appears quite uniform in structure, but where the differentiation of the stain has been carefully carried out, it can be seen that as the synaptic coil loosens and begins to open out, the filament exhibits an alternation of darker coloured areas (chromomeres) with lighter ones. The synaptic knot continues to unfold and passes into the stage of the hollow spireme (Fig. 11).

HOLLOW SPIREME.

As in the later stages of synapsis, so here also the thread often appears homogeneous, but in both cases, when the differentiation of the stain has been properly regulated, the filament can be seen to have a definite structure. In these cases there is an alternation of darker and lighter areas which no doubt signifies that, as is the case with many other plants which have been studied by cytologists, the spireme of the Compositae also consists of a linen thread in which chromatic bodies (chromomeres) are embedded. I have observed this structure of the spireme in all the species of Compositae which I have closely examined. Fig. 9 shows a portion of the spireme of *Calendula* which exhibits this structure very clearly.

The coils of the hollow spireme extend over the entire nuclear space as a series of broad, open loops.

I have found it very difficult to determine whether this spireme forms a continuous thread or whether it is segmented into several parts. In the majority of cases I can find no evidence of the existence of free ends (except where these were obviously due to the microtome knife), and the spireme appears as one long, continuous, much-wound thread. A few nuclei were, however, met with in which the existence of a continuous unsegmented spireme appeared somewhat more doubtful (Fig. 10). It is possible, however, that another explanation may be found for these rather exceptional cases in which free ends of the threads were apparently present. In any case, the segmentation of the meiotic spireme of these plants, if it really occurs at this stage, is very difficult to see, and contrasts strikingly with the obviously segmented spireme of the somatic divisions of the same plants. In the lily, as well as in a large number of plants and animals, a longitudinal split has been described in the spireme. This longitudinal division of the spireme has received very contrary interpretations at the hands of various investigators. Some regard it as a precocious division of the spireme which only reaches its consummation during the homotype separation of the chromosomes. Other cytologists look upon the split in the spireme, not as a true division of that filament, but as the approximation and conjugation of two separate and independent threads. In the case of the Compositae a longitudinal split of the spireme has been described, and very conspicuously figured by both Rosenberg (19, 20) and Lundegårdh (15). These writers adopt the view that the division in the spireme is not a true division, but that it really represents the approximation of two independent spiremes.

I have devoted much time and care to the study of this matter, but although many hundreds of sections of pollen mother-cells containing the hollow spireme, either completely developed or still unfolding from the synaptic knot, have been passed in review, I have not succeeded in finding a single unquestionable example of a split spireme! The filament is comparatively thin in these plants, and it is not easy to determine whether the row of chromomeres is single or double; but, however this may be, I have never found an instance in which the spireme was divided into two halves which divaricated in the slightest degree from one another. Other plants belonging to quite different orders to the Compositae have been very thoroughly studied by other cytologists, and the same difficulty in demonstrating a longitudinal division of the spireme has been met with. In the species of *Oenothera* examined by Davis (3), that writer was unable to find a longitudinal split in the spireme. After pointing out that such a split may still quite possibly be found in the future, he adds, 'but, as previously noted, the writer has found no evidence that such a division takes place or that there is a fusion of parallel spiremes.'

It would seem then that there is a good deal of difference in the

behaviour of the spiremes of different plants. In some, such as the lily, the longitudinal separation of the spireme into two halves is a conspicuous and unmistakable phenomenon, whilst in others, such as several species of *Oenothera* and in many (or possibly all) Compositae, this division is either entirely wanting at this stage or the two halves remain so closely pressed together that it is most difficult to demonstrate them.

In any case, whether the spireme of the Compositae obscurely divides longitudinally or not, the facts offer very little support to those who believe in the existence of two independent spiremes which are supposed to approach one another and to become closely approximated. No chromatin bodies (gamosomes) and no threads can be seen approaching one another in order to become intimately associated.

A fine reticulum, without prochromosomes or any other such definite chromatic aggregates upon it, passes into synapsis; here the reticulum becomes transformed into a spireme which is, at first, very delicate, but which gradually thickens and becomes shorter. No definite parallelism of the filaments can be seen other than is inevitably connected with any dense coil of thread. The close synaptic coil gradually unfolds and passes into the hollow spireme, but never once do we find parallel threads coming together to meet laterally in order to become intimately approximated.

This spireme has every appearance of being undivided, but should it prove to be longitudinally split there can be no doubt that the two halves are so closely merged together from the first that no other explanation is possible, but that they have arisen from the real longitudinal division of a previously single thread.

As will be seen below, the later stages of the second contraction often simulate the appearance of a longitudinally divided spireme when the long loops, with closely approximated sides, are viewed in thin sections. It is conceivable that some confusion between the two stages has taken place in the past and that some of the illustrations of a split spireme may more correctly be referred to the later stage.

SECOND CONTRACTION.

During the next stage in the history of the nucleus the hollow spireme again draws itself together to form the so-called 'second contraction', which has been met with by many observers of the reduction phenomena. The interpretation which has been placed upon this condition of the nucleus is, however, very contradictory.

Some writers, such as Farmer and Moore (5), Mottier (18), Lewis (14), Miss Digby (4), and Dr. Fraser (7, 8), regard this stage as an important one in the development of the bivalent chromosomes.

Other cytologists, however, amongst whom are Rosenberg (19, 20) and

Lundegårdh (15), place no importance upon this contraction and consider it to be merely a chance arrangement of the nuclear thread.

Lundegårdh (15), writing of *Trollius europaeus*, says, 'Ich will unten zu zeigen versuchen, dass die "second contraction" eine ganz sekundäre Erscheinung ist, die sich in Kernen kurz nach der Spaltung des Kernfadens zeigt, und dass ich ihr nicht wie Mottier u. a. eine tiefere Bedeutung für die Entwicklungsgeschichte der heterotypischen Chromosomen zuerteilen kann.' Again, in dealing with the Compositae he further writes of the 'second contraction', 'Ebensowenig wie bei *Trollius* habe ich bei den Compositen gefunden, dass dieses Stadium etwas spezifisch Eigentümliches mit sich bringe.'

Rosenberg, although he has not infrequently noted a second contraction in the Compositae, is equally sceptical of the importance of this phenomenon in the development of the heterotype chromosomes of these plants.

In my preparations a 'second contraction' has made such a regular and constant appearance at one particular stage in the history of the heterotype division that it seems impossible to regard it as a chance occurrence which has no importance. Moreover, it shows such a striking relation to the development of the bivalent chromosomes that prejudice alone can induce one to deny its significance in this process. I have confined my study of this stage to the three species *Crepis taraxacifolia* (Figs. 12-14), *Tragopogon pratensis* (Figs. 16, *a* and *b*, and 17), and *Matricaria Chamomilla* (Fig. 18), in all of which the contraction is very clearly and regularly shown.

During this stage the coils of the spireme have become arranged in a number of loops, the ends of which are drawn together at one point at which the nucleolus is very frequently situated. In some cases these loops are very long and bent round to accommodate themselves to the nuclear space. In these cases the ends of the loops can often only be seen by altering the focus, or, if the sections are very thin, they must be sought for in the succeeding section of the microtome series (Figs. 13 and 17). In other cases the loops are shorter and their entire extent falls within the field of vision (Figs. 12 and 18). A certain amount of twisting of the arms of the loops about one another can be seen, but this becomes more obvious at a later stage. One or occasionally two nucleoli occur in these nuclei.

It frequently happens, especially where the loops are long, that they tend to close together, and their sides become closely approximated. In such cases the long loops bending through the narrow limits of the nuclear cavity bear a striking resemblance to a hollow spireme consisting of two parallel parts which here and there separate from one another, whilst at other places they merge together. Where the sections are thin and the closed ends of the loops have been severed by the microtome knife the resemblance between the two stages is still further heightened. As was

pointed out before, it is not unlikely that some confusion may have arisen in the past through this behaviour of the loops and their resemblance to a double spireme.

In Fig. 15 I have drawn a long loop of *Crepis taraxacifolia* in which the sides have come closely together. In Fig. 14 is shown a nucleus in which several such loops and their simulation of a double spireme will be evident at once. It was quite easy, nevertheless, to entirely satisfy oneself that the structures in this nucleus were actually closed loops.

In some sections one can without difficulty observe the separation of the loops from their meeting point at the common centre (Fig. 19). At first they remain grouped together with their proximal ends free from one another but still directed towards a common centre. The distal ends of the loops at this time usually have their limbs still united. As the loops become separated from the common centre from which they all radiated just before, the two limbs tend more frequently to become twisted about one another than was the case at an earlier stage.

The isolated loops continue to separate from one another and to travel towards the periphery of the nucleus. Many remain as loops closed at one end, others break across the loop and the two limbs are then independent of one another, although they remain more or less closely associated together (Fig. 20).

DIAKINESIS.

The two limbs of the loops are for a time long and comparatively slender, but as they reach the nuclear membrane, and there take up the position characteristic of the nucleus during diakinesis, they shorten and become very much thicker. The two arms of the loops are variously arranged with regard to one another. They sometimes appear as crosses, or as rings, or loops still unbroken at one end, or as two rods which lie side by side or which have become closely twisted together. In fact, all the different forms which have been described by cytologists in dealing with the bivalent chromosomes during the diakinesis of various plants, can be found in the appearances presented by the two arms of the loops of the *Compositae*. It appears to me impossible to doubt that the arms of the loops of these plants correspond to single chromosomes, and that each association of the two limbs of a loop forms a bivalent chromosome (Figs. 20-3).

In *Matricaria* (Fig. 23) by far the most usual form assumed by the chromosomes during diakinesis is that of closed rings. In *Tragopogon* and in the two species of *Crepis*, however, the paired chromosomes occur as often in the shape of a cross, or a loop open at one end, or twisted rods free at both ends, as in that of the closed ring.

The diakinetik chromosomes can often be seen to be joined together by a number of delicate filaments (Fig. 23).

METAPHASE, ANAPHASE, AND TELOPIHASE.

Following on diakinesis we find the development of the spindle taking place in the usual manner. In Fig. 24 I have shown the six bivalent chromosomes of *Tragopogon* irregularly placed upon the multipolar, poly-arch spindle. A layer of denser cytoplasm lies just outside the spindle rudiment. The multipolar spindle later becomes bipolar in the way so often described in other plants. The chromosomes have meanwhile contracted very considerably, and some of their forms in this stage are shown in Fig. 25 for *Tragopogon*. In *Matricaria* the contraction of the bivalent chromosomes, which are nine in number, is even more noticeable, and they present considerable uniformity of shape in this plant. During the metaphase the univalent members of the bivalent chromosomes become drawn apart, and are distributed to the two poles of the spindle during the anaphase.

In Fig. 26 I have represented the end of the metaphase (or beginning of the anaphase) in *Matricaria*. The almost diagrammatic regularity in the form of the chromosomes is very noticeable in this drawing, and has not been at all exaggerated.

In Fig. 27 is seen a later stage in the anaphase of *Matricaria*, whilst in Fig. 28 the chromosomes have reached their destination at the two poles, and are very closely aggregated together. The early and late anaphase in *Tragopogon* are illustrated in Figs. 29 and 30, respectively.

In *Tragopogon*, as well as in *Crepis*, the chromosomes are at first very closely arranged together at the poles (Figs. 31 and 28). There is no nuclear wall about the groups of daughter chromosomes at this time, but a little later such a limiting membrane can be seen to have developed (Figs. 32 and 33a).

Just before the new nuclear wall is formed the chromosomes begin to separate slightly from one another. The appearance suggests that an unstained fluid is collecting between and around the chromosomes, and that this presses these bodies apart. Almost coincident with the separation of the chromosomes is the appearance of the new nuclear wall enclosing both the chromosomes and the fluid which has collected round these.

In the later history of the nucleus there can be no doubt that an interchange of materials takes place between the cytoplasm and the karyolymph, and that at least some of the constituents of this fluid are derived from the cytoplasm. The manner in which the *first* nuclear sap collects between the massed chromosomes suggests, however, that this fluid is secreted within the chromosomes themselves, and probably within the vacuoles which can so often be seen in their substance at this stage. The fluid passes out from

the interior of the chromosome bodies and surrounds these with the first karyolymph. Where this karyolymph meets the cytoplasm a precipitation membrane is deposited, and this constitutes the first nuclear wall. Subsequent to this, materials not only pass through the membrane from the nucleus to reach the cytoplasm, but the karyolymph is without doubt reinforced by materials which reach it from without.

As the chromosomes of *Tragopogon* and *Crepis*, which were at first crowded so closely together, begin to separate, their viscous substance remains attached at certain spots, and at these points of union the material of the chromosomes becomes drawn out into connecting bars and arms which become longer and finer as the chromosomes move further apart. At the same time that this is taking place vacuoles appear within the bodies of the chromosomes. These vacuoles not infrequently occupy the central region of the chromosome, and their gradual growth and union tends, in these cases, to divide the chromosome into two longitudinal halves (Fig. 34). This corresponds to the behaviour of the chromosomes observed by Miss Digby (4) during the telophase of the heterotype division in *Galtonia*.

In other cases, however, such a regular arrangement of the vacuoles along the middle of the chromosomes is not apparent, and these bodies resolve themselves into an irregular reticulum without any distinct separation into two longitudinal halves (Fig. 35). As the telophase proceeds the material of the chromosomes gradually becomes more and more distributed along the anastomosing bars and filaments, and at the same time opens out by the increase in alveolization. Complete 'rest' does not appear to be reached in any case, however, for distinct traces of the chromosome bodies of the preceding division can be seen right up to the time that the prophase of the homotype division are entered upon. Figs. 36 and 37 represent two daughter nuclei of *Tragopogon*, as near the 'resting' stage as they ever come.

In *Tragopogon* and *Crepis*, however, the resolution of the chromosomes goes comparatively far, but in *Matricaria* the chromosomes maintain almost their entire independence during interkinesis. In this case we might justifiably speak of the existence of prochromosomes in the nucleus.

On first reaching the poles of the spindle the chromosomes of *Matricaria* are closely crowded together, but a little later they again separate somewhat from one another. During this separation portions of their viscous substance remain adherent and become drawn out as the chromosomes move apart, so that these bodies are connected together during interkinesis by filaments of chromatic material. The formation of these connecting branches often gives the chromosomes an irregular, almost amoeboid, appearance during interkinesis, but they show no indication of alveolization or of becoming otherwise broken up (Fig. 33 b). The

karyolymph, if secreted by the chromosomes, is in this case excreted immediately without ever collecting in visible vacuoles within the chromosome bodies. The fact that these chromosomes enlarge somewhat as they move apart is probably due to the formation of karyolymph diffused within their substance, but which does not collect in definite, visible vacuoles.

HOMOTYPE DIVISION.

Some difference in the behaviour of the nuclei during this division is shown between *Matricaria* on the one hand, and *Tragopogon* and *Crepis* on the other. The prophases of this division, to a great extent, re-traverse the ground gone over in the telophase of the heterotype division, and since *Matricaria* maintained the individuality of its chromosomes almost intact throughout the period of interkinesis, fewer steps are required in their reconstruction and their arrangement upon the equator of the spindle. The fine, connecting branches joining together the chromosomes during interkinesis are withdrawn, and the substance of the chromosomes becomes concentrated into short, rounded bodies. These take up their position upon the equator of the spindle, and it can then be seen that each chromosome is divided into two halves (Fig. 38). The two halves of each chromosome are separated from one another during the anaphase of the division and travel to the poles. During this passage to the poles they remain short, stumpy bodies. Reaching the poles the daughter chromosomes become closely arranged together, as was the case at the conclusion of the heterotype division. A little later a colourless nuclear sap collects between and round the chromosomes, and separates these from one another, but, as in the preceding division, the chromosomes remain adherent at certain spots (Fig. 39). A nuclear wall is deposited, and the chromosomes move more widely apart. Fig. 40 *a*, Pl. LXVII, represents this stage. In the later history of these nuclei no vacuolization of the chromosomes is to be seen, but their substance appears to become gradually distributed along the anastomosing branches which connect them together. A successive series of stages is represented in Fig. 40, *a-d*.

There is some variation, however, in the degree to which the substance of the chromosomes becomes distributed in these nuclei. Sometimes, as in Fig. 40 *d*, the distribution is fairly complete, whilst in other cases the chromatin remains¹ aggregated in masses of varying number and size. Fig. 41 *a*, Pl. LXVI, is drawn from a young pollen-grain at the same stage of development as Fig. 40 *d*, whilst Fig. 41 *b* is from quite a late stage in pollen development (but some time previous to the division of the nucleus of the pollen-grain).

These differences in the state of aggregation of the chromatin no doubt

¹ Or it may possibly have again become aggregated into such masses after first having been distributed.

depend upon the physiological condition of the cell at the time when it was fixed. One or two nucleoli have, meanwhile, made their appearance in these nuclei.

In *Tragopogon* and *Crepis* (both species) the prophases of this division are not quite so simple. The material of the chromosomes of these plants, which was more or less distributed during the telophase of the heterotype division, now again becomes concentrated to reconstruct the chromosomes. In a number of cases this concentration is seen to take place from two sides, so that the young chromosomes are built up of two longitudinal halves with a clear space between them (Fig. 42). In these cases, therefore, the developing chromosomes (and probably also the fully developed chromosomes as well) are longitudinally divided. This is strikingly different from what was seen to occur during the heterotype prophases and, as will be seen below, resembles the behaviour of the somatic chromosomes of these plants. It must be pointed out, however, that this concentration of the homotype chromosomes in two longitudinal halves is not always apparent. In several cases the chromosomes appear to concentrate as single, more or less homogeneous bands (Fig. 43). This may, perhaps, in some instances be due to the aspect from which the chromosomes are viewed. Seen from a lateral or oblique direction the split would often be hidden by one of the sides, especially in those cases in which the chromosome material was still very diffuse. The chromosomes continue to become more concentrated, and they gradually assume a regular, smooth, and compact appearance. They become arranged in the form of a spireme (Figs. 44 and 46), which is probably discontinuous, although it is difficult to be quite certain of this point. In nuclei which are at a slightly more advanced stage the chromosomes are, however, very distinctly separated from one another (Fig. 45).

At first they are long and slender, but they gradually contract into shorter and thicker bodies. The rod-shaped chromosomes which, after the disappearance of the nuclear membrane, are drawn upon the spindle in *Tragopogon* are seen in Fig. 47. The metaphase of the division is illustrated in Fig. 48, which shows that the chromosomes of *Crepis taraxacifolia* are rather longer than those of *Tragopogon*. The early anaphase in *Crepis virens* is represented in Fig. 49. A later stage of the anaphase in *Tragopogon* is shown in Fig. 50, from which it will be seen that the chromosomes of the plant become much drawn out and elongated during their passage to the poles of the spindle. In Fig. 51 the chromosomes of *Tragopogon* have reached the poles, and they then shorten somewhat again. A late anaphase in *Crepis virens* is shown in Fig. 52. There are some points of difference between the telophase of these plants (viz. *Tragopogon* and *Crepis*) and that of *Matricaria*. There is the same coherence of the chromosomes with one another, and the same separation of their bodies by the accumulation of a fluid between them, as is the case in *Matricaria*, but in *Tragopogon* and

the two species of *Crepis* very obvious vacuolization of the chromosome bodies occurs at the same time.

Moreover, the vacuoles tend much more regularly than in the previous division to occupy a central position, and thus to divide the chromosomes into two lateral halves. Figs. 53, 54, and 55 show these facts in the cases of *Tragopogon*, *Crepis taraxacifolia*, and *Crepis virens*.

It will be observed from these figures that by the time that the division is completed and the daughter nuclei entirely reconstructed, the substance of the chromosomes has become more or less distributed through the nuclear cavity. As in *Matricaria*, there is some variation in the degree to which this dispersal of the chromatin attains, and in both cases the state of chromatin aggregation no doubt depends upon the metabolic activity of the cell.

No definite prochromosomes are, however, to be seen in the young pollen-grains. I have illustrated these nuclei in the young tetrads of *Crepis taraxacifolia* (Figs. 57-9).

From the time of the telophase of the first meiotic division until the second division is completed and the pollen-tetrads formed, the cytoplasm contains a number of deeply staining granules or droplets in *Crepis taraxacifolia* (Figs. 56-8), and also in *Crepis virens* (Fig. 55). In *Matricaria Chamomilla* deeply staining particles are also very obvious in the cytoplasm during, and for a short time after, the heterotype telophase, but in the later stages these seem to disappear in this plant (Figs. 28 and 33 a). The presence of chromatic granules in the cytoplasm during these stages of mitosis has often been described in other plants, and in one case at any rate the origin of these particles in the cytoplasm has been ascertained. In *Polypodium vulgare* Professor Farmer and Miss Digby (8) succeeded in tracing at least some of these droplets through the nuclear membrane into the cytoplasm.

In the two species of *Crepis* I have spent much time in the attempt to trace the origin of these granules lying in the cytoplasm during the later stages of the meiotic phase. Granules or droplets of chromatin often appear to be passing through the nuclear membrane, but in the great majority of these cases a careful change of focus shows that the granules are really lying against one side of the membrane and are not actually passing through. A few rare instances were, however, met with in which even with the most careful focusing the chromatin droplet still gave the impression of being in the act of passing through the nuclear membrane. I have drawn such a case in Fig. 60. In *Matricaria* several cases more or less similar to the one represented in Fig. 33 a were met with. Here the chromatin droplet is on the outside of the nuclear membrane, but it strongly suggests that it is derived from the nuclear chromatin, perhaps before the nuclear wall has been deposited, and that it is passing further into the cytoplasm of the cell. From these facts I believe that the chromatin granules lying in the cyto-

plasm of both the species of *Crepis* and of *Matricaria* may have a nuclear origin. The nucleoli which are cast into the cytoplasm during the divisions are no doubt also responsible for some of these granules.

SOMATIC DIVISIONS.

In order to make my account of the nuclear phenomena of the Compositae more complete, and for comparison with the meiotic phase described in the foregoing pages, I have also studied the somatic divisions in *Crepis virens* and *Tragopogon*. As the results were essentially similar in the two plants I will restrict my description to *Crepis virens* alone. This plant is particularly well adapted for our purpose on account of the low number of its chromosomes, viz. it possesses six somatic and three heterotype chromosomes respectively, as Rosenberg (20) has already pointed out.

The somatic divisions were studied partly in the vegetative cells of the anther and partly in the other vegetative tissues of the capitulum. The resting nucleus contains, besides the nucleolus, a very delicate reticulum. In some cases this reticulum is so fine that it appears more as a cloudy precipitate of chromatin than as a network (Fig. 61). When such a nucleus is about to divide we find that the chromatin tends to aggregate along certain lines. The manner of this aggregation is, however, not always the same. In what is probably the majority of cases the chromatin gathers together at certain spots from two directions, so that a double line of stainable material is formed (Fig. 62). In this way a spireme gradually condenses out from the indefinite reticulum of the resting nucleus, and this thread is composed of two parallel halves throughout its development (Fig. 65). This corresponds very closely to the descriptions which have been given of this process in other plants by Grégoire (10, 11), Miss Digby (4), and Dr. Fraser and Mr. Snell (9). In other nuclei of this plant (and also in *Tragopogon* and *Crepis taraxacifolia*) the chromatin appears to concentrate along the lines of the future spireme as an undivided whole in which no parallel halves are to be seen (Fig. 63). As was pointed out in the case of the homotype division, this may in some instances be due to the angle from which the spireme rudiment is viewed, but I believe that in both divisions there are cases in which the chromosomes develop as single undivided structures during the early stages. It is more particularly in those nuclei in which the chromatin has the appearance of a cloudy precipitate that this type of development is met with. Both Grégoire (11) and Miss Digby (4) have described an uneven concentration of the chromatin to form a spireme which has a corkscrew-like appearance. I have observed a similar zigzag arrangement of the developing chromosome bands in *Crepis virens* (Fig. 64).

Whichever plan of concentration is followed it results in the formation of a spireme which is most certainly discontinuous, and which is more or less clearly divided longitudinally (Fig. 66, *a* and *b*). Dr. Fraser and Mr. Snell (9)

have found in *Vicia Faba* that the somatic chromosomes form a continuous spireme which subsequently segments into the constituent chromosomes. Both *Allium* and *Galtonia*, upon the other hand, resemble *Crepis virens* in possessing no continuous spireme. This is clearly shown in the writings of Grégoire (11) and Miss Digby (4).

Although not always to be seen, a certain amount of polarization of the developing spireme is sometimes noticeable in *Crepis*. An exceptionally marked case of such polarization was observed in the premeiotic division of one of the archesporial cells of the anther of this plant (Fig. 67).

The chromosomes next proceed to shorten and thicken; a spindle develops in the usual way, and the chromosomes are drawn upon the equator of this structure. At this stage the form and number of the chromosomes are very clearly to be seen. In a large number of cases there appears to be, as Rosenberg has shown, a constancy in the relative sizes of these bodies. In Fig. 68 it is seen that there are present two large chromosomes, two small ones, and two of an intermediate size. Each chromosome is distinctly divided longitudinally. My figure corresponds almost exactly with Rosenberg's Fig. 4, Plate I (20). It must be pointed out, however, that this definite distinction in the sizes of the chromosomes is not always so easy to see. In Fig. 69, which shows the metaphase of another nucleus of *Crepis virens*, these relative sizes of the chromosomes are not nearly so clearly expressed. In such cases the action of the fixative may most likely have had some effect upon the form of the chromosomes and the direction from which they are viewed (whether slightly obliquely or not) may also influence the result. On the whole I am inclined to agree with Rosenberg that the six chromosomes of this plant occur constantly in the relative sizes which he has described. The two halves of each chromosome are drawn apart and distributed to the two poles. At this time (late anaphase) some of the daughter chromosomes have the form of bent rods with one long limb bearing a short hook at the end (Fig. 70 *a*). At the poles the chromosomes shorten considerably and become very closely pressed together (Fig. 70 *b*). They next again separate slightly from one another and become alveolized. No doubt the same causes which are at work in separating the meiotic chromosomes during the telophase are also active here.

A nuclear wall is then formed round the chromosomes and the karyolymph which has begun to accumulate between them (Fig. 71). In by far the greater number of cases which have been observed the alveolization of the chromosomes takes place in such a way as to divide these bodies into two longitudinal halves (Fig. 71). Moreover, during the loosening of the ball of daughter chromosomes their viscid substance has remained adherent at certain spots, and it becomes drawn out into connecting filaments as the separation of the chromosomes proceeds. In a much smaller proportion of cases the central vacuolization of the chromosomes is not so apparent, and

there seems to be instead a general opening out of the substance of the chromosomes so that they assume a spongy or porous appearance (Fig. 72). In either case the result is the same, and the material of the chromosomes becomes gradually dispersed through the nucleus until it again reaches the state of a more or less even reticulum, or assumes the appearance of a cloudy, flocculent precipitate which we have already seen characterizes the 'resting' nuclei of this plant. No definite aggregates of chromatin (prochromosomes) can be seen in such a resting nucleus (Fig. 73). It should be mentioned that throughout this division the chromosomes, or the bands of concentrating chromatic material which precede them, show no distinction of chromatin and linin. During the heterotype division the spireme could be very clearly seen to be composed of chromatin particles (chromomeres) embedded in a clear linin thread, but in the somatic divisions nothing of this sort is apparent.

From what has been said above it will be seen that in *Crepis*, as in *Galtonia* (examined by Miss Digby), there is no stereotyped plan which is invariably followed by the somatic chromosomes in their development or in their passage back to the resting state. Apart from minor variations, however, we may say that it is the general rule in this plant for an extremely early longitudinal division of the chromosomes or chromosome rudiments to provide for the separation of the daughter chromosomes during the anaphase of mitosis, and that in consequence of this precocious division a general parallelism of parts is often to be seen. In a large number of cases observed the daughter chromosomes themselves became centrally vacuolated and divided at the telophase of a division.

During the prophase of the following division it is very usual to find the chromosomes reconstructed in two halves, and this dual nature of the chromosomes is maintained until the separation of these halves is effected at the anaphase. In such cases as this, it does not appear to be straining the facts to consider the median division of the daughter chromosomes at the telophase of one division as an extremely early preparation for the separation of their longitudinal halves at the conclusion of the following division. This is quite in accordance with what has already been observed by both Miss Digby (4) and Dr. Fraser and Mr. Snell (9) in other plants. But I must again repeat that there are other instances in which no such distinct central vacuolization of the chromosomes can be detected during the telophase, and in which we must assume that their longitudinal division is deferred until a later stage.

The frequent occurrence of parallel filaments and bands during the somatic divisions of these plants forms a contrast to what is seen in the heterotype division in which such parallel parts are much more rarely met with.

In the preceding pages I have exclusively devoted my attention to the

nuclear phenomena of the Compositae, in so far as these are to be seen in the pollen mother-cells and (for comparison) in certain somatic cells of these plants. I have reserved all details regarding the structure of the pollen-membrane for a separate account, but I should like, before I conclude this article, to add one word concerning a general feature of the pollen-wall of the Compositae.

Among all the species which I have examined for this purpose I have found constantly two different types of pollen-wall.¹ In the one type the exine is flat and unfolded, whilst in the other type it is thrown into a number of distinct folds. These two types appear to be constant for the two great divisions of the Compositae. All the members of the Tubuliflorae which I have examined possess pollen-grains with an unfolded exine (Figs. 74, 76), whilst all the Liguliflorae which I have observed exhibited pollen-grains with a folded exospore (Fig. 75).

SUMMARY.

1. During the period just preceding synopsis the nuclei of those Compositae which have been examined were found to contain a more or less fine reticulum. No definite aggregations of chromatin which could be regarded as prochromosomes were in any case found upon this reticulum.

2. The reticulum passes into the synaptic contraction, during which it is gradually converted into a very long, delicate spireme. No chromatic aggregates were observed during this stage, and no definite parallelism of the threads occurs other than is inevitable in any closely coiled system of filaments.

3. The spireme which emerges from the closely wound synaptic knot has become thicker, and, in favourable examples, shows a series of chromatic particles (chromomeres) embedded in a less deeply stained linen thread. The spireme, during the hollow spireme stage, either remains unsplit or may be very obscurely divided longitudinally. No evidence was found of the existence of two parallel spiremes.

4. The spireme again draws itself together in the 'second contraction'. In doing so it forms a series of loops, radiating from a common centre. The loops become detached, thicken considerably, and pass towards the periphery of the nucleus. Here they assume the shape of rings, crosses, parallel rods, twisted rods, or remain as loops.

There can be no doubt that the loops which are formed in this way are actually the bivalent chromosomes of the heterotype division, and that they are constituted of two univalent chromosomes joined end to end.

¹ I have examined up to the present the following species: *Tragopogon pratensis*, *Matricaria Chamomilla*, *Doronicum plantagineum*, *Crepis taraxacifolia*, *C. virens*, *Arctium Lappa*, *Olearia Haastii*, *Sonchus asper*, *S. oleraceus*, *Cnicus arvensis*, *Ilitracium Pilosella*, *Tagetes plumilla*, *Gaillardia* sp., *Coreopsis* sp., *Hypochaeris radicata*, *Bellis perennis*, *Senecio vulgaris*, *Anthemis Cotula*, *Artemisia vulgaris*, *Tussilago Farfara*, *Petasites fragrans*, *Taraxacum vulgare*.

5. A spindle develops, the bivalent chromosomes are drawn upon it, and the single chromosomes separate from one another and travel to the two poles of the spindle.

6. Here they remain either almost unchanged in the daughter nuclei during interkinesis (*Matricaria*) or they may undergo partial dispersal of their substance (*Tragopogon*, *Crepis*). A condition of complete 'rest' is, however, not reached in any of these forms. In *Matricaria* there is no vacuolation of the chromosomes at this time, but in *Tragopogon* and *Crepis* vacuoles do make their appearance in these bodies. In these cases the vacuoles may occupy the central line of the chromosomes, and thus divide these structures into two longitudinal halves (as in *Galtonia*), or quite often no such regular disposition of the vacuoles is to be observed and the breaking up of the chromosome bodies takes place less regularly.

7. The homotype division which follows resembles, in most respects, an ordinary somatic division. The halves of the longitudinally divided chromosomes are separated during the anaphase of this division.

8. The somatic divisions were studied in *Crepis virens*, which was a convenient object on account of the low number of its chromosomes (6 somatic). Considerable variety was found to exist in the manner in which the chromosomes develop during the prophase of division. In a large number of cases this takes place by the condensation of the nuclear reticulum along the two sides of certain lines or bands. This gives rise to condensation-areas (rudimentary chromosomes), which consist of two parallel halves. Condensation may, however, take place differently in other cases, but sooner or later it leads to the formation of longitudinally divided chromosomes.

9. No continuous spireme is formed during the somatic divisions.

10. The daughter chromosomes of the somatic division are distributed to the poles, where they become joined together by delicate bars and filaments of chromatin and their substance undergoes vacuolization. By the continuation of this process the substance of the chromosomes gradually becomes dispersed over a delicate reticulum. No prochromosomes are to be seen in the resting nuclei which are in this way produced.

In the majority of cases the vacuolation of the chromosomes takes place along a median line so as to divide these bodies into two longitudinal parts.

There is reason to believe that this division of the chromosomes during the telophase may be identical with the one which so often reappears at the prophase of the following mitosis, and which marks the line of separation between the daughter chromosomes which are drawn apart during the anaphase.

It should be noted, however, that just as there was found to be considerable variation in the details of the condensation phenomena of the

prophase, so also is there no hard and fast line which is invariably followed by the chromosomes in the dispersal of their substance at the telophase.

11. There are two types of pollen-wall in the Compositae. All the Tubuliflorae which have been examined possess pollen-grains with an unfolded exine, whilst the exospore of all the Liguliflorae observed is thrown into a number of distinct folds. The details of the structure of the pollen-membrane is reserved for a separate part of these 'Studies'.

EXPLANATION OF PLATES LXVI AND LXVII.

Illustrating Mr. Beer's paper on the Structure and Division of the Nuclei in the Compositae.

All figures were drawn with the aid of the camera lucida. Either Zeiss's apochrom. objective 2 mm. (aper. 1.40) or Leitz's $\frac{1}{15}$ inch objective was used with various compensating oculars.

Figs. 1-37 refer to the heterotype division.

Figs. 38-60 refer to the homotype division.

Figs. 61-73 refer to the somatic divisions of *Crepis virens*, with the exception of Fig. 63, which represents the somatic division of *C. taraxacifolia*.

Fig. 1, *a* and *b*. *Doronicum plantaginicum*. Nuclei during presynapsis. *a*. Nucleus seen in section. *b*. Nucleus in surface view. $\times 2,600$.

Fig. 2. *Doronicum plantaginicum*. Nucleus shortly before synaptic contraction. $\times 1,900$.

Fig. 3. *Tragopogon pratensis*. Nucleus previous to synapsis. $\times 2,600$.

Fig. 4, *a* and *b*. *Calendula officinalis*. Nuclei previous to synapsis. $\times 2,000$.

Fig. 5. *Calendula officinalis*. Early synapsis. $\times 2,000$.

Fig. 6. *Doronicum plantaginicum*. Synapsis. $\times 2,600$.

Fig. 7. *Doronicum plantaginicum*. Synapsis, with a rather looser coil than in Fig. 6. $\times 2,600$.

Fig. 8. *Calendula officinalis*. Synapsis; later stage. $\times 1,900$.

Fig. 9. *Calendula officinalis*. Portion of spireme showing chromomeres. $\times 2,600$.

Fig. 10, *a* and *b*. *Crepis taraxacifolia*. Hollow spireme. $\times 2,600$.

Fig. 11. *Matricaria Chamomilla*. Unfolding of synaptic coil. $\times 1,900$.

Fig. 12. *Crepis taraxacifolia*. Second contraction. $\times 2,600$.

Fig. 13. *Crepis taraxacifolia*. Second contraction. Sides of loops rather near together and ends of loops out of the field of vision. $\times 2,600$.

Fig. 14. *Crepis taraxacifolia*. Second contraction. Sides of loops have become closely approximated, and the long, bent loops give the impression of a longitudinally divided spireme. $\times 1,900$.

Fig. 15. *Crepis taraxacifolia*. Single loop of second contraction with closely approximated sides. $\times 2,600$.

Fig. 16, *a* and *b*. *Tragopogon pratensis*. Second contraction. $\times 1,500$.

Fig. 17. *Tragopogon pratensis*. Second contraction. Sides of loops approximated and their ends not in field of vision. $\times 1,500$.

Fig. 18. *Matricaria Chamomilla*. Second contraction. $\times 1,500$.

Fig. 19. *Matricaria Chamomilla*. Loops (= bivalent chromosomes) separating from their common meeting point. $\times 2,600$.

Fig. 20. *Tragopogon pratensis*. Loops (= bivalent chromosomes) soon after they reach the periphery of the nucleus. $\times 1,500$.

Fig. 21. *Crepis taraxacifolia*. Single loop (= bivalent chromosome) in which the closed end of the loop is just breaking across. The arms of the loop (= univalent chromosomes) joined by delicate chromatic processes. Nucleus at about the same stage as that shown in Fig. 20. $\times 2,600$.

Fig. 22. *Crepis taraxacifolia*. Two bivalent chromosomes during diakinesis. $\times 2,600$.

Fig. 23. *Matricaria Chamomilla*. Diakinesis. The chromosomes have all assumed the form of rings which are joined together by delicate filaments. $\times 1,900$.

Fig. 24. *Tragopogon pratensis*. Multipolar spindle with six chromosomes upon it. $\times 2,600$.

Fig. 25. *Tragopogon pratensis*. The six chromosomes during metaphase. $\times 2,600$.

Fig. 26. *Matricaria Chamomilla*. Commencement of anaphase. The regular form of these chromosomes is to be noted. $\times 1,900$.

Figs. 27 and 28. *Matricaria Chamomilla*. Two stages of the anaphase. $\times 1,900$.

Figs. 29 and 30, *a* and *b*. *Tragopogon pratensis*. Commencement of anaphase and a late stage of the same respectively. Fig. 30 *b* shows a polar view of daughter chromosomes. $\times 1,500$.

Fig. 31. *Tragopogon pratensis*. Late stage of anaphase. $\times 1,500$.

Fig. 32. *Tragopogon pratensis*. Telophase. A nuclear membrane has developed round the daughter chromosomes. $\times 1,500$.

Fig. 33, *a* and *b*. *Matricaria Chamomilla*. *a*. Telophase of heterotype division. *b*. Interkinesis. $\times 1,900$.

Fig. 34. *Crepis taraxacifolia*. Telophase with median vacuolization of chromosomes. $\times 1,500$.

Fig. 35. *Tragopogon pratensis*. Telophase with diffuse vacuolization of chromosomes. $\times 2,600$.

Figs. 36 and 37. *Tragopogon pratensis*. Interkinesis. Fig. 36 $\times 2,600$; Fig. 37 $\times 1,500$.

Fig. 38. *Matricaria Chamomilla*. Metaphase of homotype division. $\times 1,900$.

Fig. 39. *Matricaria Chamomilla*. Telophase of homotype division. $\times 1,900$.

BEER—SPORE-DEVELOPMENT.

BEER.—SPORE-DEVELOPMENT.

Observations on the Seedling Anatomy of Certain Sympetalae.

I. Tubiflorae.

BY

E. LEE, F.L.S.

Lecturer in Botany, Birkbeck College, University of London.

With Plate LXVIII and eight Diagrams and Figures in the Text.

HISTORICAL.

DURING recent years our knowledge of seedling anatomy has been extended in nearly every direction. The researches of Van Tieghem (25, 26) about 1870 were followed by the published observations of many continental workers (chiefly 5, 7, and 28); but, as was almost inevitable in an unexplored branch of the subject, the researches carried out during this initial stage, with one notable exception (Vuillemin, 28), concerned only scattered species from the largest classes of plants. As published papers on this subject became more numerous, the method of attack changed. The publications of Sargent (13, 14, 15, 16) resulted in the systematizing of the observations on seedling anatomy. This has been especially the case with British workers, who have taken definite groups and have conducted their observations on large numbers of species within each group. The result is that, in place of the isolated observations often so favourable to theorists, there is now a solid body of evidence rather disturbing to certain phylogenetic hypotheses, but undoubtedly valuable in other directions. The recent work of Chauvcaud (2) has shown that seedling anatomy may possess an evolutionary value quite different from that hitherto assigned to it; while the physiological aspect of this subject still remains almost untouched.

Hitherto systematic research on seedling structure of Dicotyledons has concerned chiefly certain groups among the Archichlamydeae of Engler (4, 6, 8, 9, 11, and 20). Apart from the work of Vuillemin (28) on the Compositae, observations on the Sympetalae have, for the most part, been scattered. In 1849 Clos, who, perhaps, may be described as the first

seedling anatomist, showed that the *collet* could be defined anatomically, and referred very briefly to the vascular anatomy of a few species among the Sympetalae (3); and about twenty years later Van Tieghem (25, 26) described the transition phenomena in a few examples from the same group. A decade later was published an account of the careful work of Gerard (7), which included a description of the seedling structure of nearly a score of examples belonging to the Sympetalae. Several of the same species have been included in the present research, which, except in details, confirms and extends this branch of Gerard's work. Of Vuillemin's memoir on the Compositae (28) more will be said in a future paper on that group. P. A. Dangeard (5), who extended Gerard's observations on the Sympetalae, classified his results on the basis of the number of strands present in the root; while Van Tieghem, in defining his three types of transition (27), also included a few examples from the same group. In 1890 Scott (18) described the seedling anatomy of *Ipomoea versicolor*; and a little later Scott and Brebner, in their paper 'On Internal Phloem in . . . Dicotyledons' (19), and Lamounette (12), working independently on the same subject, incidentally included a description of the transition phenomena in various Sympetalae. It remains only to mention the more recent publications of Tansley and Thomas (21, 22), and Thomas (23), in which the seedling anatomy of certain members of this group is described in a more general manner.

SCOPE AND METHODS.

In the present paper only a few of the better-known orders of the Tubiflorae will be considered; in these the seedling anatomy of selected species will be described, and the results of other workers will be included. The methods adopted are similar to those described by Hill and de Fraine (10). When possible, series of transverse sections of three seedlings of each species were cut with the microtome, and longitudinal sections were also made for comparison. For staining, combinations of gentian violet and vesuvin, and safranin and lichtgrün, were found to give the best results.

For the majority of the seedlings and for much kindly advice as to methods I am indebted to Mr. T. G. Hill. The greater portion of the material was grown at the Chelsea Physic Garden, and to Mr. W. Hales, the Curator, I wish to express my sincere thanks.

DESCRIPTION OF SPECIES.

Convolvulaceae.

Convolvulus tricolor, L., var. *major*. Seedlings large, each with massive hypocotyl (often more than 6 cm. long) and two slightly unequal cotyledons (Pl. LXVIII, Fig. 1, A). Each cotyledon consists of a long slender petiole

bearing a large thin lamina with retuse apex. A definite midrib traverses the blade, and gives off a pair of branches before bifurcating near the apex. Thus each lobe of the cotyledon is supplied with two principal branch veins. Near the apex are ramifications of smaller vascular strands consisting solely of spiral vessels or tracheides, which end in curious cavities forming a kind of hydathode (24). The point of attachment of the seed-leaves is marked by a large swelling, but there is no cotyledonary tube.

Transverse sections of the lamina show the midrib with the lateral veins and their branches (Diagram 1, Figs. 1 and 2). The mesophyll is differentiated into palisade tissue and spongy parenchyma, and at various points are large secretory cells with vascular connexions. Coming down the lamina the lateral strands join on to the midrib. Anastomoses occur at the junction of blade and petiole and occasionally lower down, and in the

DIAGRAM 1. *Convolvulus tricolor*, var. *major*. Transition from cotyledons to root. In Figs. 3-7 and in the following diagrams, protoxylem is shown in black, metaxylem dotted, and phloem hatched.

upper part of the latter there is a large median bundle and two small laterals, all simple and collateral in structure. While still in the petiole the median strand divides, two groups of xylem and phloem moving away right and left, leaving a small protoxylem strand between them. In this condition (Diagram 1, Fig. 3) the bundles enter the hypocotyl, where the small lateral strands (A and A'), increased in size by the appearance of metaxylem elements, move towards their fellows (B and B') from the other cotyledon, the protoxylems turning outwards during the process (Diagram 1, Fig. 4). The protoxylem groups of these bundles become detached from the metaxylem masses, and taking up a position between the latter, they fuse together, and traverse nearly the whole of the hypocotyl in this condition (Diagram 1, Fig. 5). The group corresponding to the midrib, on the other hand, decreases in size, and while travelling down the hypocotyl its constituent parts assume different positions, and are not always well defined.

During the greater part of the transition, the four vascular groups in the hypocotyl are equal in size and similar in configuration, and it is impossible structurally to distinguish between the intercotyledonary strands and those in the plane of the cotyledon. The phloem is extremely small in amount, and at no point can internal phloem be recognized with certainty—an

DIAGRAM 2. *Convolvulus tricolor*.

observation which emphasizes the late appearance of this tissue noticed by other observers.

Finally, the protoxylem in each case becomes definitely external, and the metaxylem groups fuse; the xylem masses move towards the centre, the corresponding phloem groups meet and fuse, and a tetrarch root is

produced, in which the pith and endodermis are characteristic features (Diagram 1, Fig. 6).

Convolvulus tricolor, L. In this example, seedlings of which were obtained after the above description had been written, one or two differences must be noted. Externally the young plants are very similar, though in *C. tricolor* there is a tendency to form a slight cotyledonary tube. Internally, also, the arrangements in this species and the var. *major* show a general similarity in the broad features. In the petiole anastomoses occur between the median bundle and the lateral ones, and often strands of phloem can be detected connecting the bundles together (Diagram 2, Fig. 1). In the upper part of the hypocotyl the two lateral bundles approach the median one, and finally more or less complete fusion occurs (Diagram 2, Figs. 2 and 3). At a lower level the two lateral strands again separate, and, as in var. *major*, approach their fellows from the opposite cotyledons, giving rise to the intercotyledonary bundles of the tetrarch root (Diagram 2, Fig. 4, and Diagram 1, Figs. 6 and 7).

Another difference consists in the presence, in the petiole and hypocotyl, of abundant internal phloem. This fact was noted by Lamounette (12, p. 219), who, however, appears to have doubted the connexion between internal and external phloem traced by other observers (cf. Scott (18) and Scott and Brebner (19)). In the upper part of the hypocotyl, during the rearrangements in the cotyledonary strand so that the protoxylem becomes external, the internal phloem masses of that bundle fuse, and the fused mass gradually passes out between the metaxylem groups (before the latter meet to form the root bundles) and joins on to the external phloem. The same events take place at a lower level in connexion with the intercotyledonary bundles, so that finally an ordinary tetrarch root is produced.

Dangeard (5) investigated several examples belonging to the Convolvulaceae, but in most cases only a general description of the genus is given. Among others, he described the following:

Convolvulus,
Calystegia,
Quamoclit coccinea,
Ipomoea,

all of which follow the method already given. One difference, however, must be noted. Speaking generally of the Convolvulaceae, Dangeard described the cotyledonary traces as being bicollateral in the hypocotyl. In the present research, however, nothing of the nature of internal phloem was found in any part of the seedling of *C. tricolor*, var. *major*.

Ipomoea versicolor, Meissn. From the description by Scott (18,

pp. 174, 175) the transition phenomena appear to be almost exactly as described above for *Convolvulus tricolor*. In this case also internal phloem is present both in cotyledons and in hypocotyl. As the xylem groups of each bundle come together at the base of the hypocotyl, the corresponding phloem mass passes out between them and joins the external phloem.

Ipomoea leucantha was described by Lamounette (12, p. 220), and appears to differ from *I. versicolor* only in that 'internal' phloem is absent from the vascular bundles in the cotyledons.

Ipomoea purpurea, investigated by Gerard (7, p. 369), is not essentially different from *I. versicolor*.

Cuscuta Epilinum, Weihe. Much is generally known concerning the anatomy of *Cuscuta*. Seedlings of various species were re-examined, however, in the hope that a knowledge of the seedling structure of other genera might throw some light on that of *Cuscuta*. Unfortunately, no new observations can be recorded. Special attention was devoted to *C. Epilinum*. The seedlings investigated were 2-5 cm. in length, were quite undifferentiated, and had the appearance of a piece of fine string. In one case (Text-fig. 1) the upper part twice encircled the stem of the host, and haustoria were beginning to form. Internally, most of the tissue was cortical, the vascular elements being aggregated into an insignificant axile strand. The tissue composing the latter was much reduced, and in some cases (lignification being at a minimum) it was impossible, in transverse sections, to distinguish between wood and phloem. The sieve-tube tissue occupied the periphery of the stele, and enclosed the undifferentiated vessels, in which, however, no order of development could be recognized. In the upper portion of the larger seedlings the vessels became arranged into more or less definite groups, each with a little phloem. Up to the present it has been impossible to find anything even remotely resembling transition phenomena.

TEXT-FIG. 1.
Cuscuta Epilinum on
Linum usitatissimum (nat.
size).

Polemoniaceae.

No examples from this order were examined during the present research, but in *Polemonium caeruleum*, described by Gerard (7, p. 373), the transition follows Type 3. The same remark applies to

Hydrophyllaceae,

of which Gerard investigated *Hydrophyllum canadense* (7, p. 373);

Boraginaceae,

the same worker taking *Lithospermum gremil* as his example (7, p. 374);

Labiatae,

of which two species were examined :

Phlomis fruticosa

Galeopsis ladanum (7, pp. 379-80).

In all these cases the seedlings were small and slender, and the transition, with certain variations, followed Type 3. The two genera, *Phlomis* and *Ocimum* (with special reference to *O. basilicum*), were investigated by Dangeard (5), whose description agrees in all essential particulars with that of Gerard referred to above.

Solanaceae.

Nicandra physaloides, Gaert. Seedlings very small ; cotyledons shortly stalked, equal in size, and comparatively fleshy. There is no cotyledonary

DIAGRAM 3. *Nicandra physaloides*.

tube. The various aerial parts are covered with the pedicellate glandular hairs characteristic of the Solanaceae.

The lamina is traversed by a rather large vascular strand which gives off numerous small branches (Diagram 3, Fig. 1). Near the base of the cotyledon this midrib consists mostly of phloem, arranged on the upper and lower sides of a flattened strand of tracheae, of which the middle ones represent the protoxylem (Diagram 3, Fig. 2). As the strand enters the hypocotyl the internal and external phloem groups bifurcate, and at the same time the protoxylem becomes definitely exarch (Diagram 3, Fig. 3) by moving outwards in the cotyledonary plane. At this stage there are two strands of xylem with eight phloem groups, four of which are internal, the remaining and much larger groups being peripheral and situated on diagonal lines. Rearrangements continue to go on gradually ; the vascular groups

close in towards the centre, the pith disappears, and the xylem strands are only separated by the internal phloem masses, which have now fused together (Diagram 3, Fig. 4). Finally, a large trachea appears in the centre connecting the two xylem masses, and dividing the internal phloem into two parts (Diagram 3, Fig. 5) which pass out right and left and join on to the external phloem. The simple diarch condition seen in Diagram 3, Fig. 6, is thus obtained; and the transition is according to Type 3 of Van Tieghem.

Atropa Belladonna, L. This species was also investigated by Gerard (7, p. 377) and by Lamounette (12, p. 211). The latter, however, described the internal phloem as being quite distinct from the external phloem even at the base of the hypocotyl. The present observations agree with those of Gerard. The seedlings are larger than in *Nicandra physaloides*, but the transition is almost identical in the two species. In view of the statements by Lamounette it should be emphasized that, before disappearing, the internal phloem is in direct connexion with the peripheral phloem groups. In many cases, at one stage there is no line of demarcation between the internal and external phloem systems (Diagram 4).

DIAGRAM 4. *Atropa Belladonna*. In the hatched portion the phloem cannot be distinguished from the ground tissue.

Solanum guineense (Garden form of *S. nigrum*).

Transition exactly as in *Atropa Belladonna*, i. e. Type 3.

Solanum nigrum. From the description by Lamounette (12, p. 211), the seedling anatomy of this species is identical with that of his *Atropa Belladonna*, i. e. Type 3, with internal and external phloem systems quite distinct.

The genera *Solanum*, *Capsicum*, and *Lycopersicum* were investigated by Dangeard (5), and in the main the transition resembles that given above for *Atropa Belladonna*.

Datura Stramonium, L. This species was first investigated by Gerard (7, p. 375), with whose description the following agrees, except in one or two details. The genus was also generally referred to by Lamounette (12, p. 211).

The fairly large seedling has two fleshy, slightly unequal cotyledons, with swelling at point of attachment, but without any signs of a cotyledonary tube. The lamina, which passes gradually into the short petiole, has a definite midrib with slender branches which end near the periphery of the leaf. The mesophyll shows the usual differentiation.

In the lamina the midrib consists of a triangular mass of tracheae with the protoxylem at the upper apex, surrounded by phloem, the upper ('internal') part of which disappears near the apex of the cotyledon. All except the smallest branches are bicollateral in structure (Diagram 5, Fig. 1).

At the base of the lamina, often only a single bundle is present. In this strand, rearrangements begin in the upper part of the petiole, by the disappearance of the phloem elements from the sides simultaneously with the lateral elongation of the xylem. Almost immediately the lower ('external') phloem bifurcates, and traverses the remaining part of the petiole and the hypocotyl as two distinct groups (Diagram 5, Fig. 2).

In some cases the rearrangement of the xylem results in the production of three masses—a small median strand of protoxylem, and two lateral strands consisting chiefly of metaxylem, in which protoxylem elements can be distinguished for some distance. Even in the clearest cases, these

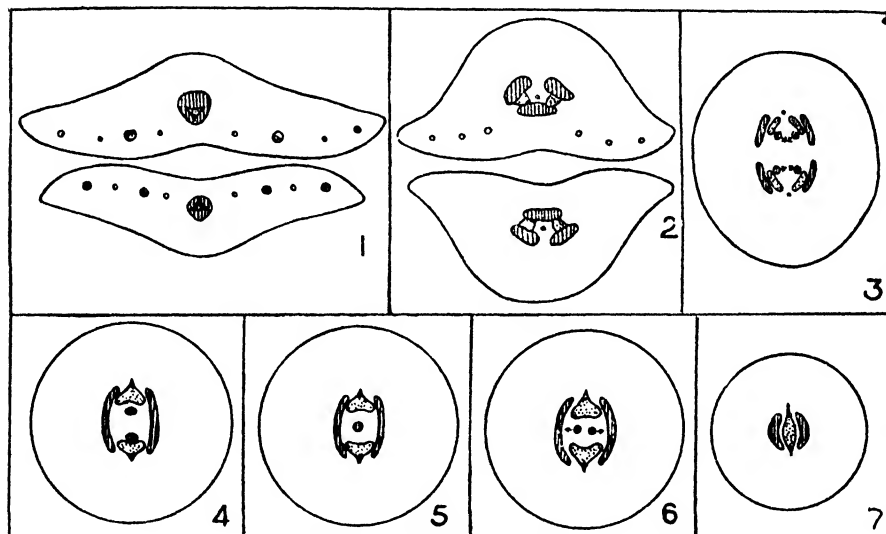

DIAGRAM 5. *Natura Stramonium*.

lateral protoxylem groups disappear after a longer or a shorter course, while in other examples the only definite protoxylem is the median one. The lateral xylem groups diverge, and take with them the corresponding external phloem mass and also part of the internal phloem, and further rearrangement in the upper region of the hypocotyl results in the production of the structure shown in Diagram 5, Fig. 3.

Further changes are due to the closing in of the various tissues. Each external phloem mass joins its fellow from the opposite cotyledon; the whole of the xylem derived from each cotyledonary bundle moves towards the centre of the hypocotyl, and at the same time the metaxylem strands of each bundle fuse and take up a position internal to their respective protoxylems (Diagram 4, Fig. 4). Finally, the two xylem bundles meet at the centre, and a typical diarch plate results (Diagram 4, Fig. 5).

The behaviour of the internal phloem groups is interesting. While still in the petiole, the internal phloem undergoes equal division, one part going to each of the lateral xylem masses. In these positions, and with occasional anastomoses, the whole of the hypocotyl is traversed. Previous to entering the root, however, the two groups belonging to one midrib come together and fuse (Diagram 5, Fig. 4); then, passing to the centre, they join on to the group derived from the other cotyledon (Diagram 5, Fig. 5). Occasionally, anastomoses with the external phloem are seen. Finally, the fused phloem mass elongates in the intercotyledonary plane, bifurcates, and the two branches pass out right and left to join the external phloem (Diagram 5, Fig. 6). A little pith is present at this time, but this soon disappears, and a solid xylem core results (Diagram 5, Fig. 7).

Many variations on this arrangement were found. The definite fusion and division of the internal phloem are not always so clear as has just been described. Fusion may take place irregularly, and one part may pass out and join the external phloem long before the other. In addition, the internal phloem masses are often more numerous than in the simple case described (cf. Gerard, 7, p. 375). Blind endings are seldom found, and even when they apparently occur, it is only after anastomosis with another phloem mass.

Datura Metel, L. Seedlings rather larger than in *D. Stramonium*, and the details of transition are better shown than in the last species. The division of the midrib xylem into three is more definite, as is also the possession of protoxylem by the two lateral masses thus produced. One difference is noteworthy, though there are indications of the same phenomenon in *D. Stramonium*, viz. the division of the internal phloem of the cotyledonary trace into three parts, one going to each of the three xylem masses. Anastomoses take place not only between the different internal groups, but also between the latter and the external phloem. In other cases the internal phloem groups were more numerous. The final result is the same; all the internal phloem masses come together in the centre, the fused bundle divides, and the two parts diverge and join the peripheral phloem. Another peculiarity was seen in one specimen in which the three protoxylem groups derived from one cotyledonary bundle remained distinct for a long time after the root was reached (Pl. LXVIII, Fig. 2). The lateral protoxylems were at first stronger, but after a time they decreased in size and finally disappeared. The metaxylem became more compact, and the median protoxylem assumed the exarch position in the plane of the cotyledons.

Nicotiana glauca, Link and Otto. In this species the seedlings are very small, and the transition, which takes place in the upper part of the hypocotyl, is according to Type 3. This species differs from the rest of the Solanaceae examined in the scanty supply of phloem, this tissue being entirely absent from the inner side of the vascular bundle, which, therefore, throughout the

cotyledons and hypocotyl, are of the collateral type. Lamounette (12, p. 211), on the other hand, describes the genus *Nicotiana* as being like *Solanum nigrum*, in which internal phloem is present.

Salpiglossis sinuatus, Hook. The seedlings of this species are very minute, and even in the smallest the transition phenomena are obscured by the presence of secondary thickening. The chief features, however, appear to be similar to those described for *Nicandra physaloides*.

Pectunia violacea, Lind. Seedlings very small, cotyledons slightly unequal, with trace of cotyledonary tube. The poorly developed vascular tissue suggests that the seedlings are immature, a condition which probably accounts for the absence (as in *Nicotiana alata*) of internal phloem. The transition, which begins in the petiole, is quickly completed, and conforms to Type 3.

Browallia viscosa, H.B. and Kth. This species was not examined during the present research. From the description by Scott and Brebner (18, p. 267) the transition is according to Type 3, but differs from the plants already described in the behaviour of the internal phloem. In the upper part of the hypocotyl there are 10-12 internal phloem masses. Passing down towards the root the pith gradually disappears, and the internal phloem strands successively pass out between the converging xylem bundles and one by one reach the external phloem strands. The two xylem bundles unite to form the diarch plate, and at this point the last of the internal phloem strands passes out and joins the normal phloem.

Schizanthus pinnatus, Ruiz. et Pav. Seedlings not more than a centimetre in length, and on the whole, both externally and internally, very similar to *Nicandra physaloides*. A few minor differences may be noted. The small epicotyledonary strands, two in number and arranged in the intercotyledonary plane, are peculiar in that they persist down to the base of the hypocotyl, the xylem groups especially remaining quite distinct until they fuse with the root bundles just as the latter approach to form the diarch plate. The xylem of the cotyledonary traces is rather irregularly disposed, a condition which is emphasized by the presence of intercellular spaces near the two protoxylems. The preliminary rearrangements which the internal phloem groups undergo are similar to those in *Nicandra physaloides*; but after fusion in the centre and subsequent division, the two phloem masses appear to die out instead of merging into the external phloem. With the disappearance of the last remnants of the pith, the two xylem bundles become continuous, and a diarch root is produced.

Nicrenbergia gracilis, Hook. Apart from the slightly larger size of the seedlings this species resembles *Schizanthus pinnatus* in all particulars. In one seedling, in which the primary tissues in the hypocotyl were not fully developed, there was scarcely a trace of 'internal' phloem in the cotyledons; while in another, whose hypocotyl showed much secondary

wood, the midrib of the seed-leaf was conspicuously bicollateral in structure. In all cases the transition was according to Type 3, and the internal phloem died out in the root.

Scrophulariaceae.

Verbascum pulverulentum, Vill. Seedlings about two centimetres long, with definite hypocotyl and two unequal cotyledons. Each cotyledon consists of a large lamina which passes gradually into the definite petiole. There is no cotyledonary tube.

In the lamina the midrib sends out small branches, but enters the petiole as a single rather small vascular bundle. The rearrangement of the vascular tissue begins before the strand enters the hypocotyl, and is completed very quickly. The transition, which is according to Type 3, is masked by the presence of two epicotyledonary traces situated in the intercotyledonary plane, which persist throughout the hypocotyl and enter the root. Thus for a long distance in the upper part of the root the arrangement appears to be tetrarch when it is really diarch, a condition which is indicated by the origin of the lateral rootlets. These are given off in four rows from the two ends of the diarch plate.

Alonsoa. As described by Dangeard (5) the transition in this genus appears to conform to Type 3.

Diascia Barberae, Hook. In most Scrophulariaceae examined, the rearrangement of the vascular tissue begins in the upper part of the petiole, and one of the first indications is the separation of the xylem strand into three more or less definite portions, of which the median one is the protoxylem. In *D. Barberae* the xylem remains throughout quite continuous. In the upper part of the petiole, the vascular bundle divides into two parts (Diagram 6, Figs. 1 and 2) connected towards the upper surface by means of protoxylem elements. Each semi-strand possesses its own phloem mass. The transition takes place by the passage of the phloem groups to a position in the intercotyledonary plane, where they fuse with their fellows from the other seed-leaf, and by a simple twisting on the part of the xylem, so that the protoxylem takes up an external position (Diagram 6, Fig. 3).

Linaria origanifolia, DC. }
Linaria heterophylla, Desf. } In both species the minute seedlings are provided with two equal petiolate cotyledons. There is no cotyledonary tube.

The transition, which is according to Type 3, commences in the petiole, and takes place very quickly.

Nemesia floribunda, Lehur. }
Nemesia versicolor, E. Mey. } With the exception of their larger size, the seedlings of these species are exactly like those of *Linaria*. The method of transition is the same, and the rearrangements take place in the upper part of the hypocotyl.

Antirrhinum Orontium, L., differs from *Linaria* externally only in the larger size of the seedlings and the slight inequality of the cotyledons. The region of transition is, on the whole, rather shorter; in the root the xylem plate is quite inconspicuous.

Scrophularia nodosa, L., in all essentials resembles *Linaria origanifolia*. In the petiole the xylem elements are arranged in a single row parallel with the upper surface of the leaf, while the diarch plate also consists of a single row of elements, but arranged in the cotyledonary plane.

DIAGRAM 6. *Diascia Barberae*.

Torenia asiatica, L. } In both species the transition is according
Torenia Fournieri, Linden. } to Type 3, and resembles that of *Antirrhinum Orontium* in all respects.

Mimulus luteus, L. Apart from the presence of a cotyledonary tube, the seedlings of this species, both externally and internally, are very similar to those of *Antirrhinum Orontium*.

Dischisma arenarium, E. Mey. Seedlings small, with narrow, rather fleshy cotyledons which form a slight tube at point of attachment. The rearrangements, which are according to Type 3, take place as in

Antirrhinum Orontium, but the region of transition is shorter, and is confined to the upper part of the hypocotyl.

Tetranema mexicanum, Benth. As in *Mimulus luteus*.

Zaluzianskya capensis, Walp. Seedlings differ in no respect from those of *Mimulus luteus*.

Veronica longifolia, L. }
Veronica hederaefolia, L. } (also described by Gerard (7, p. 378)).

Exactly similar to *Mimulus luteus*.

Rehmannia angulata, Hemsl. Both externally and internally similar to *Linaria organifolia*.

Digitalis ferruginea, L. }
Digitalis lanata, Ehrh. } Seedlings are much larger than in *Antirrhinum Orontium*, and consequently the vascular tissues throughout are more definite. There is, however, no essential difference in the transition phenomena of these three species.

Bignoniaceae.

Incarvillea Delavayi, Bur. et Franch. Seedlings large, with two slightly unequal cotyledons. Hypocotyl long and fairly stout, with a prominent swelling at the point of attachment of the cotyledons, where also a distinct cotyledonary tube is formed. Apart from this and the presence of peculiar glandular hairs, the seedlings are very similar to those of *Convolvulus*.

In the seed-leaves the mesophyll tissues are well differentiated. Each lamina has a large midrib, which is half-moon-shaped in section, and which gives off numerous branches in regular order (Diagram 7, Fig. 1). All the branches fuse with the median strand before the latter enters the long petiole, and as no further branching occurs a single laterally elongated bundle passes into the hypocotyl from each cotyledon (Diagram 7, Fig. 2). Previous to entering the hypocotyl, and often before the cotyledonary tube is reached (Diagram 7, Fig. 3), the phloem of each bundle bifurcates. In some cases also, the xylem shows distinct division into a middle portion consisting of protoxylem, and two lateral parts in close connexion with the phloem groups, and consisting of metaxylem with a few protoxylem elements (Diagram 7, Fig. 2 a). This condition, interesting for comparison with other species, is not constant; it was found in one specimen, and even there did not persist for very long. In all cases, in the upper part of the hypocotyl, there are two bundles of xylem each with a single protoxylem group (Diagram 7, Fig. 4), and the rearrangements that now occur take place very gradually. As each bundle passes down the hypocotyl, its protoxylem divides into three, each branch at first consisting of 1-3 elements (Diagram 7, Fig. 5, and Pl. LXVIII, Fig. 3). The middle one passes almost directly outwards and takes up an exarch position in the plane of the cotyledons. The lateral groups traverse an oblique path, and finally come

to rest near the periphery of the stele in the intercotyledonary plane, where each one fuses with its fellow from the other seed-leaf bundle (Pl. LXVIII, Fig. 5). There are thus formed four protoxylem groups, of which the two in the cotyledonary plane are much the stronger, and in these the metaxylem closes in behind so that typical root bundles are produced. At a lower level metaxylem also appears on the inner side of the other protoxylem groups, and a tetrarch root results, in which the metaxylem always preponderates in the intracotyledonary strands (Diagram 7, Fig. 6). No other condition was found in any root.

DIAGRAM 7. *Incarvillea Delayvei*.

It is to be noted that the transition in this species is remarkably like that of *Anemarrhena* (13), in both of which a tetrarch root structure is obtained from two cotyledonary traces. This type of transition has hitherto been found, among dicotyledons, only in certain Cactaceae (6), and possibly in *Eranthis* and *Podophyllum*.

Eccremocarpus scaber, Ruiz. et Pav. Only a single seedling of this species was available. This specimen was much smaller than those of *Incarvillea Delayvei*, and resembled the latter in no particular. The

cotyledons were petiolate, retuse, and markedly unequal. A number of small veins supplied the lamina, and these were collected at the base into a single bundle which entered the petiole. The transition, slightly obscured by the presence of secondary thickening in the hypocotyl, was of Type 3, and began in the petiole. In the shorter petiole, the protoxylem became external by simple rearrangement of the xylem elements. In the other the xylem divided into three portions, the median one (protoxylem) taking up an external position. The metaxylem in both cases moved towards the centre, became fragmentary, and finally disappeared, leaving only the protoxylem groups of the original cotyledonary xylem strands. These gradually closed in, and with the reappearance of the metaxylem a small diarch plate was produced.

Acanthaceae.

The only member of this order of which the seedling anatomy is known is *Acanthus*, which was investigated by Dangeard (5). The transition is essentially the same as in the Scrophulariaceae.

THEORETICAL CONSIDERATIONS.

On the present occasion it is not proposed to give a full discussion of the bearing of the above observations on the various phylogenetic theories. Quite recently, in discussing the theoretical importance of the seedling structure of the Cactaceae, de Fraine (6, p. 164) gave a summary of the principal theories based on, or influenced by, the seedling anatomy, which it is hardly necessary to repeat here. Briefly, the observations on the Tubiflorae entirely support the general conclusions of that author.

In the Tubiflorae examined there are two fairly well marked methods of transition :

- (1) Characterized by possession of a diarch root throughout. This method, known as Van Tieghem's Type 3, has been found in the majority of the plants investigated, e.g. Polemoniaceae, Hydrophyllaceae, Boraginaceae, Labiatae, Solanaceae, Scrophulariaceae, some Bignoniaceae, and Acanthaceae.
- (2) In which the root is tetrarch in structure. These can be further classified according to the number of bundles in the upper part of the hypocotyl.
 - (a) In the Convolvulaceae, a 'double' midrib and two small lateral bundles enter the hypocotyl from each cotyledon and become orientated to produce the tetrarch root. This is obviously merely a modification of Van Tieghem's Type 2.
 - (b) In some Bignoniaceae (e.g. *Incarvillea Delayvei*) a single bundle enters the hypocotyl from each cotyledon, where it undergoes division and orientation which result in the production of a tetrarch root structure.

The great majority of the species comprised in the Tubiflorae are herbaceous, and in many respects this extensive group is generally regarded as a remarkably natural one. Engler and (especially) Bentham and Hooker recognized certain sub-groups; and in the latest attempt to deal with the Tubiflorae, Wernham (29), discussing the question from the point of view of floral evolution, appears to hold that certain of these sub-groups are not only well defined, but possibly had a quite different course of evolution. In this connexion, it is perhaps worthy of note that in the principal sub-groups, i. e. in Polemoniales, Personales, and Lamiales of Bentham and Hooker, the prevailing method of transition is Type 3, while in each of the groups Polemoniales and Personales a single Natural Order shows (in part) a different arrangement. Although it is not possible to advance any external cause as being responsible for this difference in the seedling anatomy, the cases quoted serve to emphasize the fact that orders, and even genera (e. g. of Bignoniaceae) which are generally regarded as being closely allied, show different methods of transition. Conversely, just as de Fraine demonstrated in the delimiting of Cactaceous genera, so here with regard to the sub-groups and (rarely) orders of the Tubiflorae, no assistance is derived from seedling anatomy.

Perhaps the chief interest which emanates from the present study of the seedling structure of the Tubiflorae attaches to the occurrence of the *Anemarrhena* type of transition. Previous to the discovery of this type in the Cactaceae (6), it had been found only in certain Ranunculaceae among dicotyledons (13, 17), and on its occurrence here, as well as on other features common to this order and to certain monocotyledons, had been founded a theory of the origin of the latter group from a dicotyledonous ancestor. In opposing this view to the light of her discoveries in the Cactaceous genera, *Opuntia* and *Nopalua*, de Fraine concludes (6, p. 167): 'It cannot be considered that the resemblance of *Opuntia*, for example, to *Anemarrhena* is the result of a close genetic relation between the two; nor can it be conceded that it is due to the response of two unrelated forms to similar conditions; hence we cannot but conclude that the resemblance is accidental. This being so, then it is quite possible that the similarity of *Eranthis* and *Podophyllum* to *Anemarrhena* is also accidental.' The conclusion arrived at is that 'the evidence on which the "fusion" hypothesis [of Sargent (14)] was based has been considerably weakened by the discovery of the *Anemarrhena* type of seedling in such a specialized order as the Cactaceae'.

This conclusion, however, is not generally admitted. It has been called into question by (Mrs.) A. Arber (1) on the ground that the Cactaceae, while showing a high degree of specialization in their vegetative characters, may really be closely allied to the Ranales. A comparison was made between the floral structures in the two orders, Nymphaeaceae and

Cactaceae, the writer inclining to the view that the two groups 'are derived from the same ancestral stock', and that 'it is no longer necessary to look upon [the occurrence of the *Anemarrhena* type in the Cactaceae] as accidental. Among the Cactaceae this type of transition occurs in those genera whose seedlings are least modified, and it is in such cases that we should naturally expect to find that ancestral characters had been retained.' The conclusion of A. Arber is 'that Miss Sargent's view that the various monocotyledonous and dicotyledonous types of seedling anatomy were all originally derived from the *Anemarrhena* type is strengthened, rather than weakened, by the discovery of the ancestral type among the Cactaceae.'

In making this criticism the writer admits that the question depends very largely upon the systematic position of the group in question. The force of the criticism is, in fact, proportionate to the real distance between the Cactaceae and the group from which it was derived, which is assumed—an assumption that is itself not unquestioned—to have given origin also to the Nymphaeaceae and the other members of the Ranalian plexus. If, therefore, there exists a group which shows specialization in the 'parts of prime importance as regards affinities', i. e. 'in the reproductive organs, and not the vegetative features of the mature plant', and which also possesses the *Anemarrhena* type of seedling structure, it will perhaps be conceded that some ground exists for the view that the resemblance between the seedlings of this group and those of *Eranthis*, &c., is accidental. Such a state of affairs is found in the Bignoniaceae. Even assuming that this order was originally derived from the same group as the Ranales, there can be no doubt as to the want of affinity between the two, and that any character which is common to *Incarvillea Delavrei* (Bignoniaceae) and the Ranales serves to indicate nothing more than an analogy, and is, to use de Fraine's term, quite 'accidental'. Neither can there be any reasonable doubt that the discovery of the *Anemarrhena* type in this highly evolved group has not only 'considerably weakened the evidence on which the "fusion" hypothesis was based', but also has placed 'Sargent's view that the various monocotyledonous and dicotyledonous types of seedling anatomy were all originally derived from the *Anemarrhena* type' beyond the region of probability.

It is highly probable that many other species, more or less remote from the Ranunculaceae or Liliaceae, will be found to possess the *Anemarrhena* type of seedling anatomy. The observations on *Convolvulus* recorded above indicate the absence of any sharp line of demarcation between the *Anemarrhena* method and Van Tieghem's Type 2. What is practically the latter is seen in *Convolvulus tricolor*, var. *major*. If, in this example, the lateral cotyledonary strands fused with the median one, and, at a lower level, separated and became orientated to form the tetrarch root, the *Anemarrhena* type, with, however, two cotyledons instead of one, would

be obtained. As a matter of fact, this sequence is found to occur in *Convolvulus tricolor*, which, therefore, serves to connect Type 2 with the *Anemarrhena* type.

SUMMARY.

1. The present paper deals with the seedling anatomy of the following Natural Orders of the Tubiflorae: Convolvulaceae, Polemoniaceae, Hydrophyllaceae, Boraginaceae, Labiatae, Solanaceae, Scrophulariaceae, Bignoniaceae, and Acanthaceae.

2. Much variation occurs in the *size* of the seedlings belonging to different species. Broadly speaking, in the smaller seedlings the transition region is short, and the rearrangements are concluded in the upper part of the hypocotyl; while in the larger seedlings the region of transition is very extended (cf. Compton (4)).

3. Cotyledons invariably two in number, and while the members of each pair are often unequal in size, this apparently has no effect on the essential transition phenomena.

4. Cotyledonary tubes are present in members of all the orders examined, but their presence appears to have no bearing on the type of transition. Nearly related species having the same type of seedling structure show marked differences with regard to the cotyledonary tube.

5. The prevailing type of transition, which is present in all the smaller seedlings, is Van Tieghem's Type 3, and occurs in Polemoniaceae, Hydrophyllaceae, Boraginaceae, Labiatae, Solanaceae, Scrophulariaceae, some Bignoniaceae, and Acanthaceae. The larger seedlings possess a tetrarch root. In *Convolvulus tricolor*, var. *major*, the transition is a modification of Van Tieghem's Type 2, while the *Anemarrhena* type exhibited by *Incarvillea Delavayi* is approached through *Convolvulus tricolor*.

6. Internal phloem is present in all Solanaceae and Convolvulaceae examined with the exception of *Convolvulus tricolor*, var. *major*, *Nicotiana glauca*, *Petunia violacea*, and *Nierembergia gracilis* (one seedling). Indications are not wanting that the absence of internal phloem in these species is owing to the incomplete development of the tissues in the specimens examined.

A New Type of Spermogonium and Fertilization in Collema.

BY

FREDA M. BACHMANN.

With Plate LXIX.

THE question as to the true nature of the so-called spermatia in Lichens, many Pyrenomycetes, Rusts, &c., connected as it is with the general question of functional sexuality in the Ascomycetes, still remains an open one in the minds of some students of the Fungi.¹ I have undertaken further studies on the Collemaeae with a view to throwing light on both these problems.

What Tulasne has called the spermogonia of Lichens were thought by Fries (15) to be aborted apothecia. Flotow (14), a few decades later, describes them as perithecia without asci or paraphyses and containing only atom-like sporidia. Itzigsohn (21) believed the spermatia were motile and similar to the male cells of *Polytrichum* and *Marchantia*, hence he called them spermatozoids and called the spermogonia antheridia. A few months later, in a second paper (22), he confirms his earlier observations, but also adds that Rabenhorst and Kützing had written him of their failure to see any movement of these small cells, and that Flotow had observed a movement of the cells but, finding the same in material which had been in the herbarium for twenty years, had concluded that it was only a molecular movement. A year later, in a letter to Itzigsohn (23), Rabenhorst writes that he saw such a movement as had been described by Itzigsohn.

Tulasne (35), failing to see any resemblance between these flask-shaped filamentous structures in Lichens and the antheridia of Mosses and Hepatics, and not finding their contents motile, proposed to call them spermogonia and the small cells produced in them and set free through the ostiole spermatia. He figured the spermogonia and spermatia for about fifty

¹ Klebahn, H.: Die wirtswechselnden Rostpilze. Berlin, 1904. Bitter, Georg: Zur Morphol. u. Systematik v. *Parmelia*, Untergattung *Hypogymnia*. Hedwigia, xl, 1901, pp. 171-274.

different species of Lichens. He found that the size and shape of the spermatia vary in the different species, but in every case he found them borne on specialized hyphae, the spermatophores, in pocket-like depressions in the thallus, the spermatogonia, and finally extruded through the ostiole of the spermatogonium on the surface of the thallus. In a later paper (36) he described and figured spermatia in Fungi other than Lichens. Tulasne thought spermatia differed from conidia in that they would not germinate. He believed the spermatia were male cells, and the asci female cells.

Cornu (8) succeeded in germinating the spermatia of a number of Ascomycetes other than Lichens, and concluded from* his observations that spermatia are a kind of conidia. He continued to use the word spermatia, but would have it apply only to very small conidia which because of their very small size could easily be carried long distances.

Stahl (30) was the first to recognize the true female reproductive organ in the Lichens and to determine the real function of the spermatia. In the gelatinous Lichens which he investigated, *Collema pulposum*, *C. microphyllum*, *Physma compactum*, and *Synechoblastus conglomeratus*, the female organ or carpogone, as Stahl calls it, is a septate, spirally wound hypha at its base with a long terminal portion directed towards and protruding somewhat above the surface of the thallus. Stahl called this terminal part the trichogyne, a name which had originally been given by Bornet and Thuret (7) to a similar structure in the red Algae. In these Lichens Stahl found the spermatia to be small oval cells borne in spermatogonia. Stahl says it is easy to believe that the spermatia which are extruded in large numbers from the neck of the spermatogonium are spread over the surface of the thallus by means of rain-drops. At least he finds the end cell of the trichogynes which protrudes above the surface of the thallus with several spermatia clinging to it. He also finds that the spermatia become attached very firmly to the trichogyne, so that neither water nor a jarring of the cover-glass will detach them. He has figured three cases in which the wall has been dissolved between the spermatium and the trichogyne, resulting in a continuity of the protoplasm of the two cells. Stahl found that after a spermatium had fused with a trichogyne, the cross-walls of the trichogyne became gelatinized, and the cells of the spirally wound portion, or ascogone, increased in size. From this basal portion, as Jancewski (24) had described for *Ascobolus* and Kihlman (25) for *Pyronema*, came the ascogenous hyphae. That the spermatia are the male cells of Lichens and that we have in spermatia, trichogyne, and carpogone a genuine functional sexual apparatus seems conclusive, in spite of the attempts of Brefeld, Möller, and others many times reviewed,¹ to

weaken the evidence. Stahl notes that *Collema pulposum* is frequently entirely sterile, though well provided with trichogynes. In these cases spermogonia were lacking or were represented only by a few small rudiments embedded in the thallus. Whether such cases indicate an approach in the European forms of *C. pulposum* to the conditions which I shall describe below for the Wisconsin material is an interesting question.

Stahl's work on the Collemaceae was later confirmed by Sturgis and Baur. Sturgis (31) noted the presence of spermogonia in some species which he investigated, and very briefly and incompletely described the spermatia and the origin of the spermogonia. In *Collema chalazanum*, Ach., *C. pulposum*, Ach., *C. nigrescens*, (Huds.) Ach., and *Leptogium myochorum*, Tuck., he found the ascogones, trichogynes, and spermogonia exactly as described by Stahl. Baur's (4) results on *Collema crispum* are likewise in agreement with Stahl's. Stahl's observations have also been confirmed wholly or in part for a number of Lichens other than the gelatinous types in the work of Lindau (26), Baur (5 and 6), and Darbishire (10). Spermatia have not been found in all Lichens. Fünfstück (16) concludes that the genera *Peltigera* and *Peltidea* have no spermatia, and he described a vegetative origin of the apothecia in *Peltigera malacca*, *P. canina*, *Peltidea apthosa*, and *P. venosa*.

In all Lichens in which spermatia have been found up to the present time these cells are borne near the surface of the thallus in large numbers in cup-like depressions, the spermogonia, as described by Tulasne in 1850. The trichogynes, wherever they have been found, grow up to the surface of the thallus, protrude a short distance, and there fuse with the spermatia which are brought to them probably by rain as suggested by Stahl. In the *Collema* which I have studied I find no superficial spermogonia.

My material was obtained from a sandstone cliff overlooking Lake Mendota and from the bluffs along the Wisconsin River near Lone Rock, Wisc. The lichen has also been collected at Blue Mounds, Wisc. There has always been plenty of material for fixing and sectioning, but never an abundance for herbarium specimens. Only small amounts collected at different times have been preserved dry. *Preissia*, *Conocephalus*, *Marchantia*, Mosses, and a few small flowering plants, mostly in the sunnier places, are found in the same habitats. The *Collema* material grows in the more shaded parts or where it is partly shaded by flowering plants. Growth of the thalli is interrupted only in the winter and during very dry weather in summer. In the spring, as soon as the snow melts and the ground is thawed, the thalli resume growth.

Prof. Farlow has very kindly examined my material and finds that it agrees very well with Tuckerman specimens of *Collema pulposum*, (Bernh.) Ach., noting, however, that it approaches *C. tenax*, (Sw.) Ach. In view of the new results which I have obtained and which are unlike anything

found by Stahl, Sturgis, Tulasne, or others who have described either the carpogones or spermogonia of *C. pulposum*, the identification of the species has become a question of prime importance. It appears that what is known as *C. pulposum*, (Bernh.) Ach., varies considerably. Acharius (2) gives five varieties: *crispum*, *cristatum*, *aphancum*, *granulatum*, and *prasinum*. Schaerer (29), in 1842, gives two varieties, *vulgaris* and *prasina*. Nylander (28) gives five: *formosum*, *compactum*, *hydrocharum*, *prasinum*, and *tenax*. Tuckerman (34) writes of *C. pulposum*, 'It is without doubt largely represented in North America, but abounds peculiarly in difficulties which do not appear to be as yet resolvable in Europe; as certainly not here. With present knowledge, beside what may vaguely be taken for true *C. pulposum*, the group may be considered as represented with us by the five following, at least sub-species, the claims of which to higher rank are left open.' These five are: *C. tenaxum*, (Tuck.), *C. tenax*, (Sw.) Ach., *C. crispum*, Borr., *C. limosum*, Ach., *C. coccophorum*, Tuck., and *C. plicatile*, Schaer.

The form of *C. pulposum* which I have studied may be described as follows: Thallus, when young orbicular, later becoming quite irregular, 15 to 60 mm. long, upper surface smooth or sometimes granuloso-lobulate, especially about the immersed apothecia; when wet gelatinous but quite firm, dark olive green above and below, or lead-coloured or yellowish green; when dry brittle, much shrivelled and almost black, or, especially in case of yellowish green thalli, the shape and colour little changed in drying; attached to the soil by numerous light to dark brown simple or branched rhizoids 4 to 7 microns in diameter; marginal lobes more or less expanded, sometimes repand-crenate, sometimes imbricated, 1 to 1.5 mm. thick, sometimes showing a rosulate arrangement, or both marginal and central lobes somewhat erect; Nostoc filaments more numerous near the surfaces; apothecia developing quite close together and almost covering the central part of the thallus, rounded, 1.5 to 4.5 mm. in diameter; when young immersed in slightly raised areas of the thallus, sessile, at first concave, later concave or convex; disc at first pale green, later reddish-brown, margin from entire becoming rugose-crenate; hypothecium almost colourless to light brown; hymenium light brown above; paraphyses brown in potassium iodide, septate, 2 to 3 microns wide and 110 to 160 microns long, simple or branched near the base, tips somewhat enlarged; asci clavate, blue in potassium iodide, 18 to 25 microns wide and 95 to 140 microns long; spores 8, hyaline, brown in potassium iodide, oblong-ellipsoid, muriform, 10 or 18 celled, 17 to 30 microns long and 7 to 13.5 microns wide.

Stahl and those who have described the spermogonia in *Collema pulposum* may have had what Tuckerman (34) designates as the 'true *C. pulposum*'. Sturgis worked with some American form. He states that his observations agree in all respects with those of Stahl. He gives but one

figure, and this is of a young carpogone which has not yet developed a trichogyne.

The technique necessary for a cytological study of the Lichens has been found very difficult by most investigators. Baur found *Endocarpon minutum* the only lichen which he could cut in paraffin. For others he found it necessary to cut in celloidin after first saturating the block with glycerine. In this way he succeeded in getting sections 10 to 25 microns thick.

For killing and fixing my material I have used Flemming's medium solution of chrom-osmic acetic acids and a 1 per cent. solution of platinum chloride with very satisfactory results. After washing in water, the material was dehydrated in the different grades of alcohol. Better results in sectioning were obtained if the dehydration was somewhat rapid up to 95 per cent. alcohol. The use of cedar oil makes the material less brittle than xylol or chloroform. The difficulties of other students in this respect were probably due to failure to dehydrate perfectly and to secure perfect infiltration. I have left the material from eight to twelve hours in cedar oil and for the same length of time in equal parts cedar oil and 45° paraffin. The temperature of the paraffin bath should not greatly exceed the melting point of the paraffin. Perfect infiltration has been secured in four to five days in melted paraffin before embedding. Serial sections 5 to 25 microns thick were cut without any difficulty. Some of the slides were stained with Heidenhain's iron-hematoxylin, but the triple stain of Flemming gave the most satisfactory results.

In microscopic section the thallus is seen, as is well figured by Stahl, to be composed of a network of anastomosing fungal hyphae embedded in the jelly of the algal symbiont, Nostoc. The Nostoc filaments are much more abundant near the surface of the thallus, but are also scattered throughout its entire thickness (Pl. LXIX, Fig. 1).

Ascogones are formed as soon as growth begins in the spring, and in May or June are very abundant in both early and later stages of development. In lobes of small fruiting thalli about half of the sections (25 microns thick) show parts of ascogones. In order to facilitate tracing the ascogones and trichogynes I have cut some sections quite thick. With some practice in staining, these thick sections stain very well for cytological as well as morphological study. The ascogones are found singly or more often in groups of three or four and are usually about a fourth of the thickness of the thallus below the upper surface. Carpogones have been found in groups in a number of Lichens. In *Lecanora subfusca*, L., Baur (6) and Lindau (26) found the carpogones in groups of five to ten; in *Endocarpon minutum*, L., Baur (6) found three to eight. Except in one instance in the *Collemas*, Stahl found that the apothecia arise from a single carpogone, and he has figured the carpogones of *Collema* as isolated. In *Physma compactum* he found several trichogones in a single apothecium. In this

species the apothecium is compound, since it develops from several carpogones. Very often at least, the filament which is to bear one or more carpogones is differentiated from the other hyphae by having shorter, broader cells. From this filament branches arise which coil at once. The cells of a coil are short and broad, isodiametric or very slightly elongated. As the carpogone grows, the cells composing it elongate somewhat and become two to three times as long as they are wide (Figs. 1 and 2). There are from fifteen to twenty-five cells in a coil. Stahl found the number varied from twelve to twenty in *Collema microphyllum*, and for *Collema crispum* Baur (4) gives the number as fifteen to twenty. The number of spirals varies from two to about three and a half. Sometimes the spiral is loosely and unevenly coiled (Fig. 4), more often it is coiled quite evenly (Fig. 3). This is in agreement with what has been found in other species of the genus.

Very shortly after the spirals are formed, the terminal cell begins to elongate. It is 3 to 5 microns wide and reaches a length of 175 to 280 microns (Figs. 2, 3, and 4). The terminal cell of a carpogone is always easily distinguished from the vegetative hyphae in a stained section by its colour. It is coloured more deeply blue than the other hyphae. It is sometimes reddish if the exposure to the safranin has been prolonged, but very seldom appears stained by the orange. Also the width of the cell is slightly greater than that of most vegetative hyphae, and these two facts, with the absence of cross-walls, make it very conspicuous. Tracing this cell from section to section one finds that it does not grow vertically upwards towards the surface of the thallus, but more or less horizontally or parallel to the plane of the thallus. It is not straight, but often somewhat winding. Often several of the cells next to the terminal trichogyne cell are elongated more than those further back in the coils of the carpogone.

Stahl has distinguished three parts in the carpogone—the terminal cell which is the receptive portion, the ten to twenty cells (number varying with the species) next the terminal cell which is the conductive portion, and the coils at the base or ascogone from which later the ascogenous hyphae develop. The carpogone, then, according to Stahl, is composed of ascogone and trichogyne, and the latter again is divided according to function into a receptive and conductive part. In my material these three parts may be readily distinguished. The long terminal cell is the receptive cell, but of course it is largely concerned in conducting the male nucleus to the ascogone. Even before fertilization, then, the carpogones are easily recognized and distinguished from the vegetative parts in the section by the coiled basal portion and the long terminal cell.

As noted above, no superficial spermogonia have been observed in my material. The spermatia are, however, found abundantly in the same thalli, and in the same part of the thallus in which the carpogones are found.

There are no flask-shaped spermogonia such as have been described for other Lichens. The spermatia are simply borne in scattered groups embedded in the thallus at a depth of 100 to 300 microns (Fig. 1). They are oval or pear-shaped cells, often more or less constricted in the centre (Figs. 2, 4, and 5). They are 2 to 3 microns wide and 9 to 12 microns long. They stain lightly. There may be few in a group—only two (Fig. 3), or as many as fourteen or fifteen may be found in a single cluster. They are borne terminally if only one or two are present, or they may be both terminal and lateral if more are present. They arise by what appears to be a process of budding from certain slender lightly staining hyphae. The cells of the hyphae bearing them are often much shorter than the spermatia; sometimes the spermatia are long and narrow. Lindau (26) has described the spermatia of *Anaptychia ciliaris* as small cells, borne on many-celled sterigmata from which they are constricted off. He does not figure them. In *Collema pulposum*, Ach., according to Tulasne, the spermogonia are sunken in the thallus and contain many branched septate filaments, the spermatophores, which bear the spermatia laterally and terminally. In *Collema cheileum*, Ach., the filaments are more branched and the spermogonia not sunken in the thallus. In Tulasne's figure the spermatia are borne at the sides and ends of the intercalary cells very much as I find them in my material. Tulasne's figure of *C. pulposum* shows in some cases two spermatia arising from the same cell. The spermatia of *C. jacobaeifolium* and *C. pulposum* are small oval cells, sometimes constricted in the centre. Tulasne (35) gives the length of the spermatia of *C. nigrescens* as 4 to 5 microns. The spermatia of *C. microphyllum*, according to Stahl, are often constricted in the centre; those of *Physma compactum* are ovoid. In *C. crispum*, Ach., Baur (4) found the spermatia to be small ovoidal cells. He does not give the size nor tell how they are borne.

Sometimes the spermatia in my material form such dense groups that the exact manner of their origin is difficult to determine. Very commonly they are found free, suspended in the jelly of the Nostoc. Apparently when mature they are not at all firmly attached to the filament on which they are borne. There is no evidence in such sections that they have been torn away by the process of fixing and cutting.

As noted above, the trichogynes in my material do not grow vertically upwards to the surface of the thallus, but remain embedded in it, extending horizontally or in the plane of the thallus. If we follow them in their course the striking fact is at once noted that they grow towards the groups of spermatia. In fact, the groups of spermatia are most easily found by tracing the long terminal cells of trichogynes which are growing towards them. These trichogynes may, of course, run through several sections 25 microns thick. As one is nearing that section in which the spermatia are present, frequently more and more parts of trichogynes are

seen. Where there are only one or two spermatia in a group, a single trichogyne grows in that direction (Fig. 3); if a larger number of spermatia are present there is a correspondingly larger number of trichogynes converging towards them (Figs. 2 and 5). Frequently the trichogynes from ascogones originating rather close together grow towards different groups of spermatia.

We have thus a complete submergence of the sexual apparatus in the tissues of the thallus and the consequent complete disappearance of the protective spermatogonium about the groups of spermatia (Fig. 1). The trichogynes seek out the spermatia which have lost even their passive motility by means of water or insects.

The end of the trichogyne is oval, and becomes closely appressed to and flattened against the wall of the spermatium. In some cases the tip of the trichogyne coils closely about half-way around the spermatium, and the opening later between the trichogyne and the spermatium is at the tip of the trichogyne and about in the centre, and on the side of the spermatium. This is similar to the behaviour of the conjugating tube in *Pyronema* as described by Harper (17). Here, too, the egg-cell has produced a structure which grows out to the antheridium and coils partly around it before the conjugation pore is formed. Harper says the conjugating tube applies itself closely to the surface of the antheridium and becomes curved, and sometimes even hook-shaped, to conform to the surface of the antheridium. This behaviour is, in many cases, exactly like that of the trichogyne in the form of *Collema pulposum* here described. In other cases it does not coil around the spermatium, but becomes attached at the side or at the end of the spermatium (Fig. 5). In one case a trichogyne was found with two free spermatia attached to it. The figures of Stahl and Baur show the spermatium attached to the trichogyne a short distance from the tip of the latter and the opening at the side and near one end of the spermatium. In this species there is no coiling of the trichogyne around the spermatium.

The several cells next the terminal cell of the trichogyne now begin to exhibit characteristic changes. Up to this time the cross-walls have appeared thin and sharp in outline. As Stahl observed, however, the cross-walls now apparently gelatinize and become very much thickened. This thickening is greatest in the centre of the septum, so that biconvex lens-shaped walls result; only occasionally are they biconcave (Figs. 3 and 4). This process begins in the most distal of these cells and progresses towards the ascogone. The walls nearest the ascogone appear as a thick gelatinous plate with a broad opening in the centre. My results on these points are in agreement with those of Stahl and Baur. In my preparations made with the triple stain these swollen gelatinous cross-walls take a deep orange colour with even a very short exposure to orange G. This makes these cells extremely conspicuous and easy to find in the sections. The changes

in the thickness of the walls and their affinity for the orange is very similar to that described by Harper (18) for the antheridium of *Phyllactinia*, where, after the conjugation pore is closed, the wall of the antheridium increases in thickness by what seems to be mucilaginous degeneration. The swelling, too, is towards the interior of the cell. There is, however, a difference in that it is only the cross-walls of the trichogyne which gelatinize; the side walls remain as before. In *Phyllactinia* the thickening is less in the region of the closed conjugation pore and greatest on the wall of the antheridium opposite this pore. The blue-staining terminal cells and the brown cross-walls of the trichogynes are very conspicuous even after the apothecium has been formed. The cells of the trichogyne maintain their cylindrical shape for some time, but by the time the thickening of the cross-walls is greatest the protoplasm of the cells has become denser, the plasma membrane is pulled away from the side walls, and these walls begin to bend in towards the centre of the cell, giving the cell somewhat the shape of an hour-glass. The cells are even more conspicuous now because their apparently disintegrating protoplasmic masses stain deep red. The cross-walls are gelatinized but remain as wide as ever.

This change in the shape of the trichogyne cells was observed by Stahl, who thought it was connected with a loss of water and hence of turgidity. The disintegrating masses of protoplasm have the same appearance as that described for the antheridial cell of the Mildews and of the conjugation tube of *Pyronema*. Harper found that the cell sap disappears, allowing the denser portions to form a homogeneous mass which has then an affinity for the safranin. Harper also observed that as disintegration continued the mass stained less deeply, but that the brown walls were still conspicuous. This is true for my material. The brown cross-walls are still evident when the part of the cell between is scarcely noticeable.

As to the sexual nature of the structures described, my investigations confirm those of Stahl, Baur, and Darbishire, and leave no doubt as to the functions of the trichogyne and spermatia. The behaviour of the trichogyne in this *Collema* should put an end to the idea of the trichogyne being either a respiratory apparatus or a boring organ. It is very evident here that the trichogyne is exactly what it is in the red Algae, a structure developed from the egg-cell to conduct the male nucleus to the egg-cell. The very apparent attraction of the trichogynes to the spermatia, and the later changes in the ascogone and trichogyne, show plainly also that the reproductive organs are functional.

We may summarize the differences in the sexual apparatus of this form of *Collema pulposum* and that of all other Lichens so far described as follows: (1) The spermatia are reduced in numbers and are not enclosed in spermogonia. (2) The spermatia are embedded deep within the thallus and are never set free on its surface. (3) The trichogyne has fewer cells

and an unusually long terminal cell. (4) The trichogyne grows towards and seeks out the male cells. In all other Lichens the spermatia are borne in large numbers in specialized organs, the spermatogonia, and are extruded through the ostiole on the surface of the thallus, then to be carried by rain, dew, or possibly wind or insects, to the trichogyne, the tip of which is also above the surface of the thallus. If fertilization by means of water is more primitive, these then have more nearly retained or reverted to the aquatic habits of their ancestors in the production of large numbers of male cells and in the method by which the egg-cell is fertilized.

The conditions found in *Collema pulposum* have probably been developed with the land habit and approach those found in *Pyronema* and the Erysiphaceae. The greater activity of the trichogyne results in a certainty of fertilization which makes the production of a large number of male cells entirely unnecessary. There is here the same certainty of fertilization which exists in *Pyronema*, where there is usually but one and never more than two male cells for each female cell. The disappearance of large spermatogonia is correlated with the certainty of fertilization and the diminished number of spermatia. It is plain, however, that this is not a reduced or vegetative fertilization in Blackman's sense. The male cells are just as highly specialized as in other Lichens or the Red Algae. Whenever it has been possible to be certain of the manner in which the spermatia are borne, this has been found to be similar to that of other *Collemas* as well as of many other Lichens. The short, broad, faintly staining cells of the spermatophores with delicate cross-walls are quite different in appearance from the elongated, easily stained cells with heavy septa of the vegetative hyphae. These spermatia are also similar to those borne in spermatogonia in the apparent readiness with which they are separated from their place of origin. The limited size, the shape, the often constricted centre, the attraction for the trichogynes, and the fact that they are formed only at a particular stage in the life-history of the lichen, all show that they are specialized cells with a definite sex function. The trichogyne does not fuse with the vegetative hyphae, but seeks out these specialized cells exactly as in the case of all other sexual fusions.

In view of what has been described of the relation of spermatia and trichogynes by Stahl, Sturgis, Lindau, Baur, and Darbishire, it would seem as if the sexual nature of spermatia could not be doubted. Still Fink (13), after noting Möller's results in germinating spermatia, writes: 'This would seem to indicate that the spermatia, if they are sexual cells, have become so degenerate in certain Lichens as to lose their sexual function, becoming capable at the same time of reproducing vegetatively.' It seems very clear that the spermatia in my material are entirely homologous with those borne in the spermatogonia of other *Collemas*, and it is impossible to conceive, after what has been described above of their behaviour in this

species, that they are asexual conidia. Möller's results as to germination may or may not be correct, but the conditions in *Collema pulposum* certainly give a final and complete demonstration that the spermatia of the Lichens are male gametes and not asexual conidia. Even the author of such a tenuous hypothesis as that of the boring function of the trichogyne will hardly argue that these few cells buried deep in the thallus and never set free have their natural function as spores for the rapid asexual spread of the fungus.

The conditions in the lichen here described throw new light on the old and much discussed question as to the relationship of the red Algae and the Ascomycetes. Harper (17), as have others before, has emphasized the fact that *Pyronema*, like the Laboulbeniaceae, forms an interesting link between the Lichens and the red Algae because of its conjugating tube. In those red Algae which have been investigated, the trichogyne is a tubular outgrowth from the egg-cell. In *Pyronema* this outgrowth is separated from the egg-cell by a wall. In the Lichens there are perhaps several cells between the receptive portion and the egg-cell. *Collema pulposum* is intermediate between those Lichens in which the trichogyne is composed of many small cells and *Pyronema*, where it is but one cell. But this species resembles *Pyronema* more than other Lichens, especially in the greater activity of the trichogyne and the manner in which it grows towards and coils about a spermatium, and in the reduced number and greater fixity of the spermatia, thus making them more like antheridia. In attempting to homologize the spermatia of the Collemaceae and the antheridia of *Pyronema*, de Bary (11), with his usual morphological acumen, pointed out that 'If the spermatia of *Physma* remained fixed to their spermatophores in order to conjugate with the archicarp, the only difference between the two forms would be one of conformation'. In the *Collema* I have described we have just such a form, and one still more useful for the homology because the spermatia are not borne in spermogonia and are so few in number. In the number and nature of its spermatia and the manner in which they are borne, this species of *Collema* forms about the most perfect conceivable connecting link between the aquatic red Algae with many non-motile male cells, which are, however, set free, and such terrestrial Ascomycetes as *Pyronema* and the Mildews, where the male cells are reduced in number to one or two which remain permanently attached.

The conditions as to sexual reproduction in *Collema pulposum* are also quite the same in principle as those in some of the Laboulbeniaceae, as fully described by Thaxter (32 and 33). In *Zodiomyces* one to three antherozoids bud from the tips of the antheridial appendages. From here the antherozoids fall and are then found lying loose about the bases of the perithecial stalks. The behaviour of the trichogyne is like that of *Collema pulposum* in that it grows towards where the spermatia are formed and there

becomes attached to one of them. In *Rhynchophoromyces rostratus* the small rod-like antherozoids bud distally and laterally from intercalary and undifferentiated cells of the appendages. In some species of *Ceratomyces* the single rods are replaced by slender long filaments which eventually break up into rods that probably function as antherozoids. Through the motion of the plant the trichogyne is brought into contact with the antherozoids, and Thaxter says it is probable that such antherozoids, in order to be functional, must become detached at the moment when they come in contact with the trichogyne. In the discussion above it was suggested that the greater activity of the trichogyne and the permanent attachment of the spermatia are a result of the land habit. Thaxter suggests that the adherence of the antherozoids to the mother-cell or to one another is an adaptation to ensure fertilization where the antherozoids might otherwise be lost because of the rapidly moving host. This seems entirely reasonable for the special case in question; still, in general, it seems that the production of a large number of free male cells which are carried to the trichogyne in water is characteristic of the aquatic Algae, while the production of few and permanently attached male cells is equally a feature of the terrestrial Fungi. It may be that we have in the genera above mentioned land forms which have later become parasitic on aquatic insects, or it may be, as Thaxter (32) suggests, that we have here an adaptation to an isolated and rapidly moving host.

In a following paper I will describe the development of the apothecium, together with certain nuclear phenomena.

I am greatly indebted to Prof. R. A. Harper, at whose suggestion this work was begun, for helpful advice and criticism.

SUMMARY.

1. The spermatia of *Collema pulposum* are not borne in spermatogonia, but are few in number and are borne terminally and laterally on a hypha below the surface of the thallus. They are completely embedded in the thallus and are never set free. They are entirely homologous with the spermatia borne in spermatogonia in other species.

2. The carpogones, as in other Lichens, are embedded in the thallus. These consist of a coiled basal portion, the ascogone, and a long terminal structure, the trichogyne. The trichogynic, the end cell of which is exceedingly long, does not grow towards the surface of the thallus and protrude from it, but instead grows more or less horizontally within the thallus towards the region where the spermatia are borne. The sexual apparatus is thus completely submerged in the tissues of the thallus.

3. There is a very evident attraction of the spermatia for the tricho-

gynes, which is seen in the manner in which the latter converge about a group of spermatia. In growing towards a spermatium and often coiling about it the trichogyne shows a greater activity than that which has been described for other Lichens.

4. The spermatium fuses with the trichogyne to which it has become attached. After this fusion the cross-walls of the cells next to the long terminal cell exhibit the characteristic changes which have been described by other investigators.

5. It is very evident that the spermatia and trichogyne are functional, and that there is not merely a reduced form of fertilization in *Collema pulposum*.

6. In the number of male cells and the manner in which they are borne *Collema pulposum* forms an interesting link between the red Algae and such Ascomycetes as *Pyronema* and the Mildews. In its reproductive structures there are many points of resemblance to such representatives of the Laboulbeniaceae as *Zodionmyces* and *Rhynchophoromyces*.

EXPLANATION OF FIGURES IN PLATE LXIX.

Illustrating Miss Bachmann's paper on *Collema*.

Figs. 2-5 were drawn with the aid of a camera lucida, and have a magnification of 520 diameters.

Fig. 1. Diagrammatic representation of cross-section of thallus, showing location of sexual organs and growth of trichogynes towards spermatia.

Fig. 2. Trichogynes converging about a group of spermatia. End of trichogyne fused with spermatium at *a*.

Fig. 3. Few spermatia in group. Cross-walls of cells below terminal cell of trichogyne much thickened. Cells of ascogone somewhat enlarged.

Fig. 4. Several spermatia in group. Ascogone and trichogyne as in Fig. 3.

Fig. 5. Growth of trichogynes towards spermatia. End of trichogyne fused with spermatium at *a*.

The Development of the Perithecium of *Polystigma rubrum*, DC.

BY

V. H. BLACKMAN, Sc.D., F.L.S.,

Professor of Plant Physiology and Pathology, Imperial College of Science and Technology,

AND

E. J. WELSFORD, F.L.S.,

Research Assistant, University of Leeds.

With Plates LXX and LXXI.

OUR knowledge of the details of ascocarp development in the Pyrenomycetes, when compared with that of other groups of the Ascomycetes, is extremely scanty. Only a few forms have been investigated in full cytological detail, such as *Aspergillus* (7), *Gnomonia* (6), and the forms examined by Dangeard (3). An examination of *Polystigma* seemed then particularly desirable not only on this ground, but also from the fact that the earlier investigations of Fisch (5) in 1882 and Frank (6) in 1883 suggested that this form was of particular interest. Their observations indicated the existence of well-marked, coiled, multicellular ascogonia with trichogynes, and also of spermatia of peculiar form. Furthermore, Frank believed that he had obtained evidence of a fusion between spermatium and trichogyne indicating the occurrence of a normal sexual process. It seemed then possible that a knowledge of the cytology of this form might throw considerable light on the general question of the sexuality of the Ascomycetes and of the Lichens in particular, for the problem which apparently faces us in the Lichens, that of the fertilization by a spermatium of a *multicellular* ascogonium, has in no case been completely solved.

With these hopes, which were, however, doomed to disappointment, some tentative observations were made as far back as 1905, but material in any quantity was not available till 1908. Difficulties in obtaining complete stages and in elucidating the behaviour of the complicated ascogonia, together with a change of posts, have delayed the completion of the work.

Polystigma rubrum is a fungus parasitic on *Prunus spinosa* and *P. insititia*, and on the cultivated plum. Its attack is confined to the leaves, on which it produces orange-yellow sclerotial patches. These patches are each the result of a separate infection and they only spread to a limited extent; with the fall of the leaf in autumn the host plant is freed from the disease. The life-history is almost identical with that of the leaf-scorch fungus (*Gnomonia erythrostoma*) of the cherry, but while the affected leaves of the cherry remain on the tree during the winter, the leaves attacked by *P. rubrum* fall at the usual time. This difference is no doubt related to the fact that in *Polystigma* there is a sclerotium, in which the perithecia develop as the leaves lie upon the ground, while in *Gnomonia* this structure is absent, so that if the leaves fell and rotted on the ground there would remain no basis for perithecial development.

In this country *P. rubrum* does not seem at all abundant. Though it is found in small quantities in various places the only locality known to us in which it occurs in any abundance is at Palling-on-Sea, Norfolk; our attention was first drawn to the fungus in this locality by Mr. George Massee.

Mycelium. The stages of actual infection of the leaf by a germ-tube from the secondary spore, which develops from the germinated ascospore, have been sufficiently investigated by Fisch (5) and Frank (6), and were not studied. The mycelium in its early stages shows thin-walled hyphae with cells containing a small number of nuclei, usually one to three. The hyphae push their way between the host cells (Pl. LXX, Fig. 1) gradually, forcing them apart and bringing about their disorganization. In a mature sclerotial patch the host tissue is reduced to a few isolated cells with tannin-like contents which stain deeply; the rest of the cells having been completely absorbed (Fig. 2).

The walls of the hyphae are at first thin (Fig. 1), but early in development the thin walls are modified into thick, gelatinous membranes which encroach on the cell cavity of the hyphae; these membranes usually show fine pits (Fig. 3). The gelatinous wall is no doubt of the nature of reserve material, for it appears to be in part absorbed during the later development of the perithecium after the fall of the leaf. No storage of reserve material in the form of special cell contents was to be observed.

In many well-developed sclerotial patches the hyphae form a continuous mass between the upper and the lower epidermis, the only remains of the mesophyll being the few scattered cells already mentioned. The hyphae generally contain in the fresh state an orange pigment which gives the bright colour to the sclerotial patches; it is easily soluble in alcohol. It is to be noted that in the early stages of mycelial development the hyphae congregate, especially in the intercellular spaces beneath the stomata, and often push their way through the stomatal pore (Figs. 4 and 5).

Spermogonia. These arise from a group of interwoven unthickened hyphae found usually beneath a stoma. From this mass there develops the flask-shaped spermogonium (Fig. 6), which is often large enough to extend across the leaf from one epidermis to the other. The periphery of the spermogonium is formed of densely interwoven hyphae and is lined internally by the spermatia-bearing hyphae. The spermatia are borne terminally on these hyphae, which, like the spermatia, are uninucleate; but while the nuclei of the special hyphae are only slightly elongated, those of the spermatia become very long and narrow (Fig. 8 *c*). The spermatial nucleus appears at maturity as a narrow band, staining nearly homogeneously and occupying the lower half or two-thirds of the cell (Figs. 8 *a* and 8 *b*). The spermatia narrow at their free ends and show the peculiar curvature which has been described by earlier workers (Figs. 7 and 8). The nucleus appears in many cases to undergo early disorganization, for it may show a nodulose appearance (Fig. 8 *a*) while the spermatia are still enclosed within the spermogonium. The spermatia are carried out of the spermogonium by a mucilaginous material which oozes from the mouth of that organ, and thus the spermatia become distributed over the surface of the leaf.

No relation of any kind was observed between the spermatia and the female reproductive organs, and attempts to bring about the germination of the spermatia ended, like those of Fisch, in failure. The spermatia must, then, be considered *functionless* structures, like the similarly named structures in the Uredineae.

Ascogonia.¹ These structures develop from the rapidly growing ends of ordinary hyphae; they were multinucleate in the earliest stages observed (Fig. 9). This hypha soon becomes curved and septate (Fig. 10), and gradually assumes the more or less closely coiled appearance of the mature ascogonium (Figs. 11, 12, and 13). Surrounding each ascogonium is a mass of small-celled hyphae, which are uninucleate, and with walls slightly thickened. There is a great variety in the length of the ascogonia and their degree of 'coiling' (Figs. 12 and 13). One end of the ascogonium, the base, usually can be traced into a vegetative hypha, while the other ends freely in the mycelial mass (Figs. 12 and 13). A simple slightly coiled ascogonium is shown highly magnified in Fig. 12, and a more complicated one is drawn on a smaller scale in Fig. 13.

The ascogonia are usually found in the neighbourhood of a stomata (Pl. LXX, Fig. 11, and Pl. LXXI, Fig. 14), and the stoma shows the

¹ Owing to the abortive nature of these coiled structures designated ascogonia by Fisch, it is impossible to say whether, primitively, they were wholly ascogonial in nature, or whether they represent archicarps of which only a portion was fertile, i. e. gave origin to the ascogenous hyphae. Under these circumstances the older name, ascogonium, may be retained, although by analogy with other cases (e. g. Lichens) we should expect the terminal portions of the coil to be sterile in nature, when the term archicarp would more fittingly describe them as a whole.

projecting hyphae already described, but in no case could the ascogonial hypha be followed through the stoma in the form of a specially differentiated trichogyne, as described by Fisch and Frank. As already stated, the apex of the ascogonium usually ends blindly in the tissues (Pl. LXX, Figs. 12 and 13) some distance from the stoma. In fact, of all the hundreds of ascogonia examined, in only three or four cases could the ascogonium be traced upwards towards the stoma, and even then it did not project as a differentiated trichogyne. In one of these cases the ascogonium lost itself in an ordinary hypha a little below the stoma (Fig. 11). In another case (Pl. LXXI, Fig. 14) the ascogonium was clearly abnormal, for it was much branched towards the epidermis, and gave origin to several slightly differentiated hyphae which could be traced upwards towards the hyphae projecting from the stoma. The projecting hyphae were unusually long, but were of ordinary vegetative nature and not comparable with the trichogynes described by Fisch. Only in one case was a broad hypha of a trichogyne-like nature seen projecting from the stoma, and then there was no evidence of its connexion with an ascogonium. In all other cases the projecting hyphae (Pl. LXX, Fig. 5) were clearly of vegetative nature, and in no case was a spermatium found attached to any of them.

The number and size of the cells which make up the ascogonium is very variable, but the majority of the cells are multinucleate, a few uninucleate cells being occasionally found. The basal cell, which connects the ascogonium with an ordinary vegetative hypha, is commonly larger than the others, and contains a large number of small nuclei (Pl. LXXI, Fig. 15); the majority of the other cells contain about four nuclei. The nuclei usually show a chromatin network and a well-marked nucleolus, but the nuclear membrane is not generally to be distinguished. In a few of the cells of each ascogonium there is generally to be found—either alone or with other ordinary nuclei—a nucleus without a distinct chromatin network, but with a huge nucleolus (Pl. LXX, Fig. 12, and Pl. LXXI, Fig. 16 *b*). The origin of these special nuclei could not be traced. No convincing evidence of fusion of ascogonial nuclei could be obtained, though the common close association of the nuclei in pairs and the difference in the size of the nuclei of a single cell (Fig. 16) suggest that such fusions may still take place in spite of the abortive nature of the ascogonia.

In some cases two ascogonia may develop together, but this occurrence was not nearly so common as Fisch's description would lead one to expect.

The outgrowths of the large cells of the ascogonium figured by Fisch and described as ascogenous cells were not observed. Our observations show that the cells of the ascogonia do not become emptied of their contents, as in the functional ascogonia of *Ascobolus*, *Humaria*, &c., but retain their contents during the process of disorganization, and so appear as darkly staining masses; this is well seen in Figs. 17 and 18 and particularly clearly in Fig. 19.

Perithecium. This structure, though not in structural connexion with the ascogonium, arises in its neighbourhood, one perithecium being usually found in association with each ascogonium. The perithecium is first to be distinguished as a group of special hyphae which arise from the small-celled hyphae surrounding the ascogonium. These special hyphae are characterized by their long finger-like shape; together they soon take the form of a conical mass with its apex pointed towards the lower epidermis (Figs. 17 and 18). Their cells may have the nuclei arranged in pairs (Fig. 18). This conical mass increases in size and develops into the flask-shaped perithecium (Fig. 24). During the early stages of development the disorganizing cells of the ascogonium can be clearly seen at its periphery (Figs. 17, 18, and 19).

At a stage a little later than that shown in Fig. 18, ascogenous hyphae become differentiated towards the base of the young perithecium. They have no connexion with the ascogonia, but arise by differentiation from the perithecial hyphae, which are of vegetative origin as described above. The ascogenous hyphae are at first not very sharply marked, but later they are easily distinguished by their larger size, denser contents, and larger nuclei (Fig. 19). If a section be taken through the base of the perithecium at a time when the ascogenous hyphae are differentiating there may be seen (Figs. 20 and 21), besides the nuclei in pairs mentioned earlier, larger nuclei. Nuclei in close contact are also seen, and in one case what appeared to be a stage of nuclear fusion (marked thus * in Fig. 20). There are thus indications that at this stage a nuclear fusion occurs which replaces a normal sexual fusion now lost.

The details of the formation of the asci and the ascospores were not followed, since for such work this form is not a favourable object, but a few stages were observed showing that the ascus is formed in the normal way with fusion of nuclei in the penultimate cell of an ascogenous hypha (Figs. 22 and 23).

CONCLUSION.

Polystigma rubrum possesses well-marked, coiled, multicellular ascogonia. The ascogonia disorganize without producing ascogenous hyphae. The spermatia also are functionless, and appear in some cases to show signs of nuclear disorganization while still within the spermogonia. The ascogenous hyphae arise near the ascogonia by differentiation from vegetative hyphae. There is a nuclear fusion in the ascus, and some evidence for an earlier nuclear fusion in the ascogenous hyphae at the time of their differentiation. Vegetative hyphae push through the stomata, but there are no trichogynes.

The divergence from the results obtained by Frank and Fisch are no doubt to be explained by the deficiencies of the primitive technique employed by earlier investigators.

P. rubrum is to be added to the already long list of Ascomycetes in which the normal sexual process is absent. It is, however, to be distinguished from the majority of such forms by the fact that well-marked male and female reproductive organs are produced, but *both* are abortive. It resembles *Gnomonia erythrostoma* in this respect, but the ascogonia are much more clearly marked than in that form. It is probable that *Xylaria* is similar to *Polystigma*, for in that form according to Fisch the ascogonia degenerate later. In *Poronia*, Miss Dawson (4) finds at the base of the young perithecium 'a group of stouter deeply-stained hyphae, presumably the remains of the coil, and now representing the young ascogenous hyphae'. It is clear from this quotation that a reinvestigation of *Poronia* might show that the ascogenous hyphae really arise independently of the ascogonia, as in *Polystigma*. In *Claviceps*, which requires, however, further investigation, there are no ascogonia, according to Fisch (5).

The evidence to be drawn from a study of *Polystigma*, though not very strong, gives no support to the contention of Claussen (2) that there is only one nuclear fusion in the Ascomycetes, that in the ascus.

The expenses of this investigation were mainly defrayed by grants from the Government Grant Committee of the Royal Society.

Observations on *Asarum europaeum* and its Mycorrhiza.

BY

E. J. SCHWARTZ, M.A., B.Sc., F.L.S.

King's College, London.

With Plate LXXII.

A *SARUM europaeum*, the Asarabacca, is said to form our sole native representative of the Natural Order Aristolochiaceae; it is, however, questionable as to whether its claims to be indigenous are justifiable. The plant was formerly cultivated for medicinal purposes, a volatile oil, asarol, being extracted from it, and it is probable that the few plants found wild in this country are either 'escapes', or the descendants of 'escapes', from plants so cultivated. The plant, which in its wild state grows in woods and damp, shady places, consists of a branched rhizome which creeps along or near to the surface of the ground, each branch bearing annually two kidney-shaped green leaves with long petioles. These leaves are protected in the bud by a few scale leaves also borne by the rhizome. From the under surface of the rhizome spring a number of adventitious roots, which with their branch roots form the root-system of the plant. The roots penetrate the soil to a depth of from six to eight inches. The flowers resemble those of other members of the Aristolochiaceae in having a three-lobed calyx and twelve stamens, the latter being united to the style to form a gynostemium, thus showing some similarity to a monocotyledon, the similarity being heightened by the existence in the roots of an endotrophic mycorrhiza, of a character somewhat resembling that described by Groom (2) as being found in the roots of *Thismia Aseroë*. The plant, however, is an undoubted dicotyledon, as is evident from the anatomy of its rhizome, and from the possession of two cotyledons by the seedling plant. The affinities of the order are, however, very obscure; it has been placed with the Santalaceae, Loranthaceae, and Rafflesiaceae to form the class Hysterophyta.

The material used in this investigation was obtained from a small group of plants growing in the garden of my home at Sevenoaks. These plants were uprooted in the early autumn of 1911, and portions of the roots

and stems were fixed in Bouin's picro-formol solution. The plants were growing in dense shade, being overshadowed by taller herbaceous plants in the immediate vicinity. The soil was a loam in which clay predominated. In spite of the dry summer it had remained somewhat damp; it was not particularly rich in humus.

Microtome sections of the rhizome and root were cut, and were stained, some with Erlich's haematoxylin and orange G, others with Benda's iron-haematoxylin and orange G, and a few with anilin safranin.

STRUCTURE OF THE RHIZOME. A transverse section of the rhizome showed the usual dicotyledonous structure. The ring of vascular bundles was of typical appearance, and both fascicular and interfascicular cambium were well differentiated; the hard bast was lacking. The cortical and pith cells were many of them filled with starch grains, although a few of the cells contained oil, presumably the 'asarol'.

No fungus was to be seen in any of the cells, nor were calcium oxalate crystals present either in the cells of the rhizome or of the leaf.

STRUCTURE OF THE ROOT AND ITS MYCORHIZA. In transverse section the root showed either a diarch or triarch stele; one such section with a diarch stele is shown in Pl. LXXII, Fig. 1. The endodermis had thickened walls, and showed the usual 'radial dot' on the side walls of its cells. The cortical cells of the root contained a lot of reserve starch, which, however, was lacking from the first two or three outer layers, and also from the innermost layers which formed the home of the 'mycorrhizal' fungus. In roots free from the fungus, however, all the cells of the cortex contained starch grains except the few outer layers.

Although the cortex of roots containing the mycorrhizal fungus may be said to consist of three differentiated portions outside the endodermis—viz. (1) the outer cell layers, two or three in number, free from starch; (2) the median three or four layers of starch-containing cells; and (3) the innermost two or three layers with the mycorrhiza and containing but little starch—these portions are, however, not sufficiently well differentiated and separated to admit of division into exocortex, mediocortex, and endocortex.

In *Thismia Aseroë* these divisions are well differentiated, and Groom observed in the exocortex a number of sacs containing crystals of calcium oxalate in the form of raphides. Neither these nor any other form of calcium oxalate is to be seen in *Asarum*. Outside the endodermis the first two or three layers of cells are occupied by the mycorrhizal fungus, the cells of the layer abutting on the endodermis containing irregular-shaped masses of fungoid matter as shown in Figs. 1, 2, and 3. These masses are highly refractive and are composed of dead portions of fungus, only slender portions of hyphae being as a rule distinguishable in them. The cells are mostly devoid of starch, and are of normal shape and appearance; their nuclei, when visible, show no signs either of hypertrophy or degeneration.

The appearance presented suggests that the fungus, on entering this layer of cells, has encountered some substance which has caused its death and disorganization, and probably partial digestion by the plant, the irregularly shaped mass left in the cells being composed of portions of fungus, which the plant is incapable of absorbing. Cells of this nature are to be seen in Figs. 2 and 3. Starch grains, when present in these or other cells of the plant, stain blue with iodine solution, and not red, as was the case in *Thismia*.

The cells of the two or three layers external to that described above are for the most part filled with the coiled hyphae of the fungus, as is shown in Figs. 2 and 3. The fungal hyphae mostly run in a longitudinal direction, as illustrated in Fig. 2, and coil round and round the cell, which finally becomes filled with fungus; the hyphae may infect the neighbouring cell by penetration of the cell-wall (see Fig. 6). Intercellular hyphae also occasionally occur; these run a straight course between the cells and send branches into them which give rise to the coils mentioned above.

The hyphae are very irregular in shape. Sometimes they are swollen out into bladder-like forms, as is shown in Fig. 4; at other times they resemble ordinary fungal hyphae. The bladder-like swellings occasionally found on them bear no relation to the cell nucleus, which when visible in mycorrhizal cells is of normal size and appearance; on the other hand, the nuclei of cells in portions of roots which are free from the mycorrhizal fungus have sometimes been observed to be considerably enlarged and of abnormal shape.

The fungal hyphae, which are densely filled with granular protoplasm, are non-septate and contain numerous small nuclei, which stain well with Benda's iron-haematoxylin.

The hyphae, unlike those of the fungus in *Thismia*, do not make straight for the cell nucleus, but, as stated above, form coils in the cells. The fungus is confined entirely to these few cortical layers in the vicinity of the stele, and shows no inclination to spread into the outer region of the cortex with its cells rich in reserve starch. Portions of fungal hyphae are shown in Figs. 4, 5, and 6.

On some hyphae may be seen intercalary or terminal swellings of a spherical or a pear shape. These swellings, which are thick-walled, contain dense granular protoplasm and are multinucleate. They doubtless, if belonging, as I believe they do, to the mycorrhizal fungus, represent its resting or reproductive stage. They are not very commonly met with, and it is just possible that they belong to a parasitical fungus which has also obtained an entrance into the root. When met with, however, they are invariably found in the inner cortical layers with the mycorrhiza, although the hyphae bearing them are somewhat different in appearance, owing to their staining at times rather more deeply than those of the undoubted

mycorrhiza. These swellings are illustrated in Figs. 7 and 8. In the former figure the swelling is giving rise to a tube which is penetrating a neighbouring mycorrhizal cell containing undigested fungal matter.

For the purpose of comparison, the roots of plants of *Asarum europaeum* obtained from the Chelsea Physic Gardens and from the garden of Mr. E. M. Holmes, at Sevenoaks, were examined. But in both cases these were free from mycorrhiza, as were also the roots of *Aristolochia Siphon* obtained from the same sources. It is, however, by no means unusual for a mycorrhizal fungus to be absent at times from a root, the general rule being that when the plant is growing in a soil rich in humus the fungus will be present, and that when the soil is poor in humus it will be absent. It may be added that the roots of plants possessing the mycorrhiza were found to possess comparatively few root-hairs, whereas in those which lacked the mycorrhiza the root-hairs were more abundant.

Endotrophic and ectotrophic mycorrhizas have long been known; the former are commonly to be found in the roots of the Orchidaceae, Ericaceae, and Epacridaceae, although the hyphae are never so deeply seated as in *Asarum europaeum*. The ectotrophic forms are to be found in the Cupuliferae and many of the Gymnosperms, not to mention numerous other orders in plants of which they have been observed.

The mycorrhiza of *Neottia Nidus-avis*, which bears points of similarity to that of *Asarum*, has been investigated by Magnus, in 1900 (3), who states that the fungus enters the root or rhizome, where it branches and fills up a series of concentric layers of cells. In some cells it kills the host protoplasm, while in others it is itself killed and partly digested by the plant, the indigestible residue aggregating into a ball in the centre of the cell and being covered by a membrane.

In 1904 Ternetz (6) isolated a fungus, which was presumably its mycorrhiza, from the roots of some of the Ericaceae and stated that it was an active agent of nitrogen-fixation from the atmosphere.

In 1909 Osborn (8) described a fossil mycorrhiza found in the lateral roots of *Amyelon radicans*. According to this authority, the hyphae are non-septate, and they are found in the inner cortical layers of the root, and are apparently very similar to those found in *Asarum*. He states that some of the cortical cells are filled with coils of fungal hyphae, whereas others, which he designates 'digestive cells', contain irregular masses of fungoid matter. The fungus, like that of *Asarum*, is limited to the inner cortical layers of branch roots, and is absent from the tissue of the main roots. On some of the hyphae thickened terminal dilatations were found, evidently representing a resting stage of the fungus. These dilatations correspond with the thick-walled swellings observed by me on some of the hyphae in *Asarum*, and lend support to the view that these swellings belong to the mycorrhizal and not to some other parasitic fungus.

Weiss (5) has also described a mycorrhiza from the Lower Coal Measures; it, however, does not bear so many points of resemblance to that of *Asarum* as does the one on *Amyelon radicans*.

SIGNIFICANCE OF THE MYCORRHIZA. It is difficult, if not impossible, to assign the exact rôle played by a mycorrhiza in the nutrition of the plant. It may be, as stated by Ternetz (6), that some mycorrhizas have the power of fixing atmospheric nitrogen. Starting from the fact that plants possessing mycorrhiza are to be commonly met with in soils rich in humus, Stahl (4) suggests that the fungus aids the plant in the absorption of the ash constituents from the soil. He thinks that the numerous Fungi to be found in a soil rich in humus are severe competitors with any Phanerogams for the available plant food in the soil, and is of opinion that the Phanerogam probably benefits in some way by association with a fungus which might yield up the ash constituents to it. This might conceivably apply to the case of plants possessing an ectotrophic mycorrhiza, but certainly is no explanation of such a deeply seated mycorrhiza as is found in the roots of *Asarum*. Moreover, the soil in which the *Asarum europaeum* was growing was not very rich in humus, nor was it crowded with Fungi.

Stahl also suggests that the fungus may prepare and transform the raw nutritive salts (as absorbed from the soil) into products of assimilation ready for the use of the plant, as for example asparagin. He notes the absence of any form of calcium oxalate, a substance which is usually associated with the assimilation of nutritive salts. As I have stated, calcium oxalate crystals are not found in *Asarum*. This hypothesis seems to fit in with the facts so far as they are known.

According to Gallaud (7) the Fungi of the endotrophic mycorrhiza are 'saprophytes internes', which by means of highly developed haustoria borrow some non-living nutritive material from the cells in which they live. The plant cells finally kill the haustoria, digest, and partially absorb them. The cells, he thinks, defend themselves from the attack of the fungus by their digestive power, and consequently the fungus is but little harmful. Against this view, in the case of *Asarum*, is the fact of the fungus being confined to the innermost cortical layers and not straying from them. One would expect a parasitic fungus to attack the whole of the cortex and the soft bast of the stele. Gallaud doubts whether any true mycorrhizal fungus has been grown isolated from the root of its host plant.

RELATIONSHIP BETWEEN THE PLANT AND THE FUNGUS. The question whether the fungus found in the roots of *Asarum* be a parasite, or whether the relationship existing between the plant and the fungus be a symbiotic one, is of considerable interest.

From a purely morphological point of view, the signs of parasitism may include destruction or hypertrophy of tissue, hypertrophy of cells or nuclei, degeneration of nuclei, unhealthy appearance and poor growth of

the plant, at times giving rise to its death, and a poor store of reserve food such as starch.

On the other hand, in the case of symbiosis, plants with a symbiotic partner ought to, and do, flourish better than those in similar situations without a symbiont. This is the case in the Leguminosae, in which plants bearing plenty of root nodules, containing the nitrogen-fixing Bacteria, thrive better than those with fewer or no nodules on their roots. Again, the host plant may provide a special home or region for the use of its symbiont; this, however, may likewise be the case in parasitism, as for example oak-galls. We may compare also the root nodules of the Leguminosae with those of the Juncaceae, the former being a case of symbiosis and the latter one of parasitism. With regard to *Asarum*, there is neither hypertrophy nor destruction of tissue, and the cell nuclei when visible in mycorrhizal cells are in most cases of normal size and appearance. On the other hand, a special region of the root, viz. the innermost cortical layers abutting on to the stele, is set apart by the plant for the habitation of the fungus, which for its part makes no attempt to stray from this region. In the cell layer outside the endodermis, the cells were seen to be filled with dead fungoid matter, suggesting that either the fungus was providing food for the plant, and the cells contained the undigested residue left after the absorption of the digested portion into the stele, or that the fungus was a parasitic one which had been killed by this innermost cell layer to prevent its entrance into the stele. The position of the fungoid layers close to the conducting stele, the similarity of the fungus with its coiled hyphae in some cells and irregular dead masses in others to the mycorrhizal Fungi of *Thismia Aseroë*, *Neottia Nidus-avis*, and other roots, are all facts which favour the former interpretation. The shade-loving nature of the plant, and the presence of humus in the soil, also point to the same conclusion.

It is evident from the deeply seated situation of the fungal home that the fungus obtains all its nutriment from the plant, although some of it may be in a raw state, unaltered by the plant since its entrance into the root from the soil. The carbohydrate is apparently supplied by the reserve starch of the root, which is mostly absent from the mycorrhizal cell layers, or the fungus may feed on the sugars supplied by the green leaves to the roots, these sugars being converted into starch in those cells of the root which are free from fungus. As far as the facts observed warrant the expression of an opinion as to the function of deeply seated endotrophic mycorrhiza, one is inclined to accept Stahl's hypothesis that the rôle of the fungus is to elaborate the raw salts absorbed from the soil into organic compounds such as asparagin, and in this connexion the lack of calcium oxalate crystals from *Asarum* roots is suggestive. The diminished numbers of root-hairs on mycorrhizal roots is difficult to explain when we have such

a deeply seated mycorrhiza as in *Asarum*. In cases of ectotrophic mycorrhiza root-hairs may be absent altogether.

In conclusion, my thanks are due to my sister, Miss Alice M. Schwartz, for her kind assistance with the drawings.

SUMMARY AND CONCLUSIONS.

1. The roots of *Asarum europaeum* are inhabited by a fungus which is limited to the cortical region abutting on to the steles of young roots.
2. This fungus is very similar to those found in *Thismia Ascroë* and *Neottia Nidus-avis*.
3. Thick-walled swellings are to be found on some of the hyphae, representing a resting stage of the fungus. These correspond with those on the fossil fungus on roots of *Amyelon radicans*.
4. The fungus forms an endotrophic mycorrhiza in most respects similar to those found in other roots.

Some Wound Reactions in Filicinean Petioles.

BY

H. S. HOLDEN, M.Sc., F.L.S.

Lecturer in Botany in the University College, Nottingham

With Plates LXXIII and LXXIV and one Figure in the Text.

INTRODUCTION.

THE healing of wounds in phanerogamic tissues is normally accomplished by the production of either a callus or of a wound periderm. This subject has, on account of its economic value, long occupied a prominent place in botanical research, especially among experts in forestry and arboriculture, in whose province the question is naturally an all-important one. For similar reasons one finds that the occurrence of disease due to fungal agency has also received close attention, with the result that a considerable amount of literature has been produced bearing on these problems and their treatment, of which the works of Prillieux (23), Sorauer (28), Hartig (13), and Tubeuf (35), and more recently those of Duggar (9), Massee (17), and Smith (26), may be regarded as typical. In the case of the vascular cryptogams the investigation of wound response seems to have excited little interest, since any economic value is, in their case, absent.

The Bonn text-book (33) says of wound response in these forms, 'The wounded cells die, and become brown and dry, whilst the walls of the underlying, uninjured cells become lignified' (pp. 150-1); it also briefly touches upon the formation of periderm in *Ophioglossum* (p. 148), a feature first noted by Holle (16), whose observation is also quoted by de Bary (8), and upon the formation of a pseudoperiderm in the Marattiaceae.

Incidental reference to a case of periderm formation is made by Chandler (4) for *Polypodium aureum*, while Stopes (30) and Seward (24) also refer to the healing of deep wounds in Calamitean axes.

Wound reactions of a somewhat different character are recorded by Strasburger (32), who describes the formation of tyloses in the carinal canals of *Equiseta* when the upper portions have been cut away, and by

Weiss (36), who regards the abnormal proliferation in a Stigmarian rootlet, described by him, as due to a fungal attack.

The writer was fortunate enough to discover a case of superficial wounding in a Medullosean petiole, which had been repaired by the production of a typical wound periderm (14), and this led to an investigation of the reactions of Filicinean petioles to wounding, with a view to ascertaining whether similar phenomena were exhibited by these.

An incidental study of two cases of surface wounds in Cycadean petioles, those of *Cycas circinalis* and *Bowenia serratula*, was also made in connexion with the present paper. These both showed the same type of response as the 'Myeloxylon' referred to, having to the outside a layer of dead, excised cortical tissue, immediately below which was a band of suberized cells, devoid of contents, and finally a mass of cambiform cells which merged into the typical cortical parenchyma (Pl. LXXIV, Fig. 21).

METHODS.

The investigations were commenced in the summer of 1909 at Manchester, where, owing to the kindness of Mr. Garnett, of Whalley Range, I was enabled to perform a preliminary series of experiments in his fern-house. I should like to express here my appreciation of his unfailing courtesy, and my thanks for the facilities he granted me during the earlier portion of the work. Further series of experiments were performed during the spring and summer of 1910 and 1911, and a considerably increased number of forms was examined.

For purposes of investigation the petioles, where possible, were divided into three regions, as follows: (i) the curled apical portion, (ii) the region of pinna insertion, (iii) the region below pinna insertion; where special sterile and fertile segments occurred, as in *Osmunda regalis* and *Allosorus crispus*, both segments were examined.

It was thought that the nature of response would in all likelihood differ in the still actively growing apices and the maturer parts below, and, as the former did not appear to have been investigated in this connexion, would possibly reveal some points of interest.

The wounds were made with a sharp scalpel in each of the regions indicated, and were of a purely superficial nature, a thin shaving being removed which penetrated below the sub-epidermal layer of sclerenchyma characterizing most fern petioles, but did not seriously disturb the vascular supply. In those cases where the vascular supply was, accidentally, interfered with to any appreciable extent, it was found that various parasitic Fungi and Bacteria caused the complete rotting of the injured member, thus rendering it of little use for further study for this purpose.

The petioles thus wounded were allowed to continue growth for periods varying between a fortnight and fifteen weeks, and were then cut and at

once preserved in chromo-acetic fixative, Perenyi, or Farmer's fluid. The number of forms examined in this way included the following species: *Adiantum Capillus-veneris*, *A. Edgworthii*, *A. fulvum*, *Allosorus crispus*, *Asplenium Belangeri*, *A. bulbiferum*, *A. fontanum*, *A. viride*, *A. viviparum*, *Aspidium thelypteroides*, *Athyrium Filix-foemina*, *Blechnum brasiliense*, *Cystopteris bulbifera*, *C. fragilis*, *Dennstaedtia punctilobula*, *Davallia polyantha*, *Faydenia prolifera*, *Lastraea dilatata*, *L. Filix-mas*, *L. reflexa*, *L. thelypteris*, *Lomaria chilensis*, *Microlepia anthurifolia*, *Osmunda regalis*, *Phegopteris hexonaptera*, *Phlebodium (Polypodium) glaucum*, *Polystichum angulare*, *P. proliferum*, *P. falcatum*, *Pteris aquilina*, *P. cretica*, *Scolopendrium vulgare*, *Struthiopteris germanica*, *Woodwardia orientalis*, *W. radicans*, *W. virginica*.

A large proportion of these were found to be much too hard in texture to microtome successfully, and consequently only sections of the apices of such were so prepared; some of the less resistant forms, however, offered little difficulty. The material was transferred from absolute alcohol, through pure cedarwood oil, to paraffin, as this method caused less shattering than when xylol was used. The harder forms were sectioned by hand. The best general results were obtained by double staining with carthamin and picric anilin blue, or safranin and Lichtgrün; for nuclear studies Heidenhain's iron-haematoxylin with a light erythrosin counterstain was satisfactory.

The microchemical investigation of the cell-walls and contents involved the use of special reagents, which will be dealt with in detail later.

RESULTS AND DISCUSSION.

The change in the external appearance of the affected surfaces, apart from a browning of the dead cells, was, as a rule, inconsiderable. In one or two cases, however, notably in *Pteris cretica*, the petiole became distorted and bent at the seat of injury (Pl. LXXIV, Fig. 23), and the explanation of this seems to be that the removal of tissue had caused a violent disturbance of the osmotic balance. This had resulted in the flexure of the petiolar strand and the consequent crushing of the cortical parenchyma on that side of the strand remote from the wound.

With regard to the details of internal modification a systematic survey of the results obtained serves to demonstrate that, although no rigid scheme of classification of the various types of wound response is possible, there are yet certain underlying broad similarities and differences, correlated with the region of the wound and the texture of the petiole. Thus an almost solid deposit of gummy matter in the cells at the seat of injury is of practically universal occurrence, whilst the more or less widespread thickening of the cortical tissue is also a very frequent feature.

It is a well-known fact that the tissues of many fern petioles are, even at maturity, of a comparatively delicate and parenchymatous character, a feature which is shared by all forms in their extreme apical portions, whilst others, such as *Osmunda regalis* and *Davallia polyantha*, are characterized, when mature, by an extremely tough, almost horny exterior, together with a highly developed sub-epidermal band of sclerized tissue, this rendering them very resistant. This tough character is doubtless a necessity in the large, upstanding forms, but is by no means confined to these, several of the small forms (e.g. *Adiantum* spp.) showing similar characters.

It appeared to the writer that, in this difference in the character of the more mature parts of the petiole, there occurred one of the features which lent itself to the grouping of the forms worked upon, and this proved to be the case, for it was only in what might be termed the softer bodied forms that any appreciable cell-growth, in response to injury of the maturer parts, occurred.

(i) Taking first the curled, apical region, it was found that practically the whole of the forms experimented upon showed attempts at cambium formation. This, in the most successful cases, resulted in the production of a complete wall of meristem in the injured area, and was found to occur in only a small number of the species examined, namely, *Asplenium Belangeri*, *A. bulbiferum*, *A. viviparum*, *Polystichum proliferum*, *Woodwardia orientalis*, and *W. radicans*. A reference to the figure (Pl. LXXIII, Fig. 1) illustrating the wound meristem produced in the case of *Polystichum proliferum* will serve to demonstrate the complete nature of the healing. Here the wounded area has been completely traversed by an entirely new growth, several cells in depth, of typically cambiform cells with delicately granular contents. This growth is due to the elongation and division of the layers of cortical parenchyma abutting upon the wound, and has, in a few cases, rendered the identification of these primary units difficult, though in most parts the outlines of the original parent cells can still be determined.

The result of this continued elongation and division has been, in favourable cases, to produce at the originally flat, or slightly concave wound surface, a distinct convexity or intumescence (Pl. LXXIV, Fig. 20). The mode of growth of the affected cortical cells is well shown in specimens which have been allowed to grow for some time (nine or ten weeks). In these it is clear that the elongation is accomplished by a process of sliding growth somewhat analogous to that obtaining in the development of prosenchymatous elements, and often results in the production of a row of cambiform cells, of which the terminal members are somewhat longer than their fellows, and are bluntly conical in shape, thus enabling them to dovetail into the spaces between the divergent ends of their neighbours (Pl. LXXIV, Fig. 19).

A peculiar feature with regard to the cambial cells which lie at the

actual surface of the injured area is that they show no traces of suberization upon their outer walls. They are, however, usually protected to a large extent by the scab-like remains of the cells originally injured when the wound was made, and it would appear that this has proved adequate. The brown appearance of the wound scar in most cases is due very largely to the remains of these tissues, though in the few petioles where suberization occurs the same effect is produced.

Immediately below the meristem proper there is a marked change in the character of the cells, which are much larger and possess abundant, coarsely granular contents. It will be seen that the most peripheral of these, that is, those which lie next to the cambial tissue, have also, in many cases, elongated somewhat, and have divided by a transverse wall suggesting an incipient attempt at cambium formation.

The features upon which I should like to lay emphasis in these specially active forms is, first, that there is an actual production of a complete pad of healing tissue, formed by the elongation and division of the cortical parenchyma, and second, that there is no evidence of the secretion of gummy matter in any of these species during the earlier stages of reaction.

It is a singular fact that the forms which exhibit the most successful attempts at the production of a healing tissue should be those in which the formation of bulbils for vegetative propagation is a characteristic feature.

It would seem that the production of these structures must necessitate the retention of a particularly mobile and responsive type of tissue, and this view receives strong support from the evidence afforded by the results obtained in other, non-bulbiferous, species of the same genera, in other soft-bodied forms, and by the nature of the response to injury in the maturer parts of the petioles of the same forms.

The young plantlets raised from the bulbils do not possess this power of regeneration to anything like so marked an extent as do the mature forms. In their case, in fact, an elongation of the cortical cells in the region affected, and the occasional division of these by a single transverse wall, suggesting cambial possibilities, seems to be the extent of their powers (Pl. LXXIII, Fig. 2).

This evident contrast with the bulbil-producing petioles also lends strong support to the view that the cambial activity and the formation of reproductive buds are correlated, since the immature forms lack this power.

The elongation of the cortical cells, and their subsequent division to produce two or three daughter cells, would seem to be the most general type of response, and is a feature of the majority of the remaining forms examined. Thus in *Lastraea Filix-mas*, in *Polypodium glaucum*, and in

Athyrium Filix-foemina there is a remarkable increase in the length and bulk of the cortical cells for a depth of from four to six cells, and these divide by one or more transverse walls, giving a distinctly meristematic character to the region, and affording a marked contrast to the cells which have not become secondarily active. Here, too, the suberization of the outer walls of the most peripheral cells has also taken place, thus affording adequate protection without interfering with their vitality (Pl. LXXIII, Fig. 3).

This stage of wound repair seems to be generally attained within three weeks of the infliction of the injury, but in the case of *Asplenium Belangeri* there was no trace of secondary activity in that period. Petioles of this species examined after three weeks showed a dry but in no way discoloured wound, and sections demonstrated that the collapse of the cells at the surface was the only response. In five weeks, however, the characteristic cambial development was perfectly obvious, and, apart from the slower rate of the early development, this species showed no striking points of difference from the remaining bulbiferous forms.

One form, *Cystopteris bulbifera*, however, appears to stand somewhat apart from the rest. The cortical cells of the petiole showed very little secondary activity either at the apex or below, but if a young, barely visible bulbil were cut off there was an appreciable cambial reaction. This is perhaps partially explicable in the comparative slenderness of the petiole, since this would be obviously more weakened by wounding than one of a more robust type, such as *Asplenium viviparum*.

The behaviour of *Scolopendrium vulgare* was also of some interest, as the cortical cells, for a much greater depth than the average, elongated, but on the other hand this was accompanied by a relative paucity of transverse divisions.

As the plant develops, and the originally curled portion becomes straight, secondary changes are involved. In one or two cases, however, plants of *Lastraea Filix-mas* which were wounded early, whilst they were still completely enveloped in ramenta, and collected eight weeks afterwards, before the spring period of rapid uncurling and growth had supervened, were found to show very little further modification. It is a noteworthy fact that all the hardy indigenous forms appear to show a more pronounced activity if wounded before the first great elongation of the petiole has taken place, the results with *Lastraea*, referred to above, with *Athyrium Filix-foemina*, and with *Pteris aquilina*, being specially marked (Pl. LXXIII, Fig. 3).

This second type of apical wound response, with its inadequate attempts at cambium formation and its inability to produce a really efficient cell-barrier, affords a striking contrast to the condition characterizing *Woodwardia radicans* and its allies.

A still further reduction is shown in the attempt at healing made by *Polystichum angulare*, *Pteris cretica*, *Lastraea reflexa*, and *Woodwardia*

virginica, in which only a single layer of cortical cells, namely, that consisting of the uninjured units immediately below the wound, exhibits any activity. This layer elongates quite appreciably, but generally shows no trace of cell-division (Pl. LXXIII, Fig. 4).

The superficial resemblance of these cells, both in *Polystichum angulare* and in the species which have previously been described, to the intumescences produced on the leaves of *Hibiscus* and other forms (Dale, 5, 6), led to a careful investigation of their cytology with a view to ascertaining whether there were any induced pathological nuclear phenomena. In a few cases cells were found to contain two nuclei, almost invariably in close proximity to one another, and in a considerable number of cells nuclei of abnormal shape, often showing a median constriction, were noticed (Pl. LXXIII, Fig. 10).

In *Osmunda regalis*, *Blechnum brasiliense*, and *Struthiopteris germanica*, which serve to illustrate the last gradation of wound response, there is very little or no elongation of the individual cells, and only very rarely a transverse division, but the outermost cells develop very early a strong suberization of their walls. These, and others of the hardest-bodied forms, also show a band of lignified tissue immediately above the vascular structures, which, though differing in structural detail from the sub-epidermal sclerenchyma, serves largely to replace this tissue as a protective sheath on the injured side (Text-figure).

TEXT-FIGURE. Transverse section, young petiole of *Osmunda regalis*. SCL., sub-peripheral sclerenchyma; V.B., vascular bundle; W.S., wound-surface; S.S., suberized cells; LIG., cortical cells, secondarily lignified.

From the foregoing examples it will be seen that a distinct and gradual series of forms is traceable, commencing with those producing a perfect pad of healing tissue such as *Asplenium Belangeri* and *Polystichum proliferum*, and passing through forms like *Lastraca Filix-mas*, with cell-elongation and the production of an incipient cambium, to forms like *Polystichum angulare*, with cell-elongation alone, and finally to types like *Osmunda regalis*, in which cell-elongation and division are very infrequent, and where these are replaced by an efficient suberization and lignification.

The secondary changes which occur in the wounded apical areas as these unfold and become mature were found to be extremely variable,

and to tend, in ultimate effect, towards the condition resulting from wounds of the second order, that is, those within the region of pinna-insertion.

In the bulbil-producing forms there were very marked changes: the cambiform cells had evidently ceased to divide and had become decidedly more thick-walled (Pl. LXXIV, Fig. 19), this thickening proving to be of a purely cellulose nature, whilst, in addition, the whole of the cortical tissues on that side of the stele adjacent to the affected surface had become filled with a gummy deposit (Pl. LXXIV, Fig. 20 *b*). This intracellular gum deposition was also a characteristic feature of all the remaining species, whether the cambial response had been still fairly strongly in evidence or not.

The gum, even in the fresh material before preservation, was extremely thick and viscous, especially in the outermost cells of the affected region, and on fixation and hardening in alcohol was found to have become quite solid. The slight shrinkage of the cell-contents had, in many cases, caused the solid gum to crack and furrow, so providing a ready means of recognition.

The process of secretion of this substance in the cells could be followed with ease, since the earlier stages were shown in the specimens which had only been allowed to grow for a comparatively brief period after wounding, and also in the deeper seated cells of the maturer specimens. From these it could be seen that the secretion was first produced as minute granules or globules in the cytoplasm, these gradually becoming larger and ultimately coalescing to produce an almost solid deposit.

This substance, which is presumably of a protective nature, gives the following reactions characteristic of wound gum:

1. It is insoluble in alcohol, chloroform, or benzol.
2. It is insoluble in hot or cold concentrated H_2SO_4 .
3. It is insoluble in hot or cold concentrated solution of KOH.
4. It stains deeply with alkannin, and with ruthenium red.

Treatment with thymol, orcinol, and phloroglucin gave, however, entirely negative results. It differs from wound gum also in the fact that it is intracellular, and does not appear to be due to any tissue degeneration, since even the cells in which the deposition is most complete show no traces of disintegration, and the nuclei do not appear to be adversely affected.

The cell-walls in the gum-secreting zone invariably increase in thickness, but this, in different forms, and even different specimens of the same form, varies considerably in its microchemical reactions.

In practically all species the outermost cells gave a pure cellulose reaction with chlor-zinc-iodine, and absolutely negative results with phloroglucin and HCl, and other lignin-demonstrating reagents. This is easily understood in those petioles where the cells show elongation and division,

as lignification would obviously interfere with their growth, but where the elongation is slight in amount or absent, the explanation does not seem at all clear.

The inner layers were also occasionally of cellulose, but more commonly showed distinct evidences of lignification, giving a pink colour with phloroglucin after acidification with HCl. The depth of the coloration indicates a very imperfect lignification, the walls being of a ligno-cellulose rather than a true lignin nature. In other cases the lignification had become much more pronounced, giving the typical bright red phloroglucin coloration and in some of the smaller petioles extending throughout the cortex.

The modified cells, especially in the immediate vicinity of the wound, were coloured yellow or yellow-brown by the deposition of tannin-like substances in their walls, and, as this interfered to a certain extent with the action of the various reagents, it was, as a rule, removed by gently warming the sections with eau de Javelle. Zimmermann (37, p. 143) cites Mangin as stating that treatment with this liquid causes lignified elements to give the cellulose reactions, but in the experience of the writer, if reasonable care is observed, this is certainly not the case in the Filicineae.

As a test of the reliability of the phloroglucin reaction after treatment of the tissues with eau de Javelle, several series of microtome sections of a wounded petiole of *Lastraca reflexa* were employed.

Half of these were acidified with HCl and then treated with phloroglucin solution, whilst the remainder were first decolorized with eau de Javelle and then similarly treated. The coloration, apart from the yellowness of the walls of the most peripheral cells, was identical in each case, the xylem elements being bright red, whilst the imperfectly lignified cortical tissue was stained pink. The walls of the modified cells are abundantly pitted, though the pits themselves are not large; they are shown very clearly on swelling with caustic potash (Plate LXXIII, Fig. 8).

(ii) With regard to the reactions of the tissues in the regions below the apex, the same variability is noticeable in the different forms, but to a less degree.

A section of a wounded area produced just below the curled apex in *Asplenium bulbiferum* exhibited a slight elongation of the cortical cells, accompanied by a large number of cambial divisions, this resulting here and there in the production of a small tabulate cell. There was not, however, any attempt at the production of a complete new growth. The cells at the periphery showed what seemed to be slight traces of suberization, but the tests for suberin gave results which could only be described as extremely inconclusive (Pl. LXXIII, Fig. 5).

Similar cambial activity, to a perhaps slightly less extent, was perceptible in the middle of the fully unfolded pinna-bearing region of all the

bulbiferous species examined with the exception of *Cystopteris bulbifera* and *Adiantum Edgeworthii*, but gum did not begin to make its appearance until the lapse of from four to five weeks (Pl. LXXIII, Fig. 6).

In one case, however, in which a plant of *Woodwardia radicans* had accidentally been kept without water, the gum deposit was abundant within a fortnight, and there were practically no traces of either cell-elongation or cambium formation.

Two specimens of *Woodwardia orientalis* were also somewhat exceptional in that for a considerable depth the affected tissues after division became suberized (Pl. LXXIII, Fig. 11).

That actual suberization and not merely a deposit of tannin in the tissues had occurred was amply demonstrated by the following reactions:

1. The cell-walls were insoluble in hot or cold concentrated H_2SO_4 .
2. They were only dissolved with difficulty by a strong solution of chromic acid.
3. They stained readily with cyanin, with alkannin, and with fresh chlorophyll solution after removal of the tannin with eau de Javelle.
4. They stained brown-violet with chlor-zinc-iodide after treatment with KOH solution.
5. They were doubly refractive with polarized light.

It was at first a source of difficulty to understand how the suberization could be so complete, and the cells yet retain their contents after three months apparently but little affected.

Staining with cyanin, alkannin, and chlorophyll, however, showed the presence of abundant pits in the walls, these showing especially well where the walls had been cut tangentially, and doubtless serving to ensure protoplasmic continuity.

An abundant deposit of gum was a general feature in all the remaining cases, but there were certain differences apparent in the mode of repair.

In *Athyrium Filix-foemina*, *Lastraca reflexa*, and most of the remaining species there was a certain amount of cell-elongation, with an occasional transverse division in a few forms, but this was seldom pronounced. It was always accompanied by an increase in the thickness of the walls, this usually being of a ligno-cellulose character.

The species of a more horny nature, such as *Pteris cretica*, *Blechnum brasiliense*, and *Polypodium glaucum*, varied somewhat, specimens occasionally showing some elongation, but more commonly contenting themselves with a thickening of the walls and a dense aggregation of gum. The modified walls in these also were often slightly lignified, and in one or two instances the lignification was strongly marked. In *Lomaria chilensis* and *Phegopteris hexonaptera* the lignification extended throughout the petiole in the wound area. *Osmunda regalis* and *Struthiopteris germanica* as a rule behaved similarly to the above forms, but in one or two instances, in the

large mature petioles, the reaction was quite different, and was similar to that constantly resulting in *Davallia polyantha* and *Adiantum* spp. Here the peripheral cells became brown and enormously thick-walled with large pits for protoplasmic connexions, the thickening becoming less pronounced as the cells became further from the wound until they merged into the normal cortical parenchyma (Pl. LXXIV, Fig. 12).

Microchemical investigation demonstrated that this thickening was also peculiar in consisting throughout of pure cellulose. As in previous cases, the outermost cells showed a solid deposit of gum, whilst those near the exterior also showed large quantities of granular matter.

The reaction produced in *Scolopendrium vulgare*, which is soft bodied and possesses an undivided leaf, was exceptional. The parenchymatous cells extending through fully half the diameter of the cortex, and in some specimens even partially round the vascular bundle, had, under favourable circumstances, without actually dividing, elongated to a very considerable extent, producing exaggerated intercellular spaces owing to the partial separation of adjacent cells (Pl. LXXIII, Fig. 9). The result of this lengthening is that a slight intumescence is formed, comparable to those produced as a consequence of traumatic stimulus in the case of many roots (Némec (20), Bayliss (1), Davis (7)).

No amitotic nuclear divisions were observed, though the majority of those in the cells affected were spindle shaped, and some showed a median constriction (Pl. LXXIII, Fig. 10). The number of cells which were completely filled with gum was exceptionally large, these extending inwards to a depth of six or more, and, as in previous cases, the cells below also showed abundant granules.

From these facts it will be perceived that there is in the pinna-bearing region a distinct loss of cambial activity, the bulbil-producing species of *Asplenium*, *Polystichum*, and *Woodwardia* being the only ferns among those examined which still show any marked efforts in this direction.

The tissues developed during the formation of 'pneumathodes' which characterize the rhizome and stipules of the Marattiaceous ferns as figured by Hannig (12), offer a remarkable analogy to those produced in the wounded areas in the pinna-bearing parts of the bulbiferous species referred to.

In the remaining species examined the general mode of response takes the form of local thickening, either of cellulose, ligno-cellulose, or lignin, of the tissues at the seat of injury, this being accompanied by a greater or less amount of cell-elongation and division, and an abundant deposit of gummy matter.

(iii) In the petiole below the region of pinna-insertion, the tissues of which may be regarded as quite mature, there is an almost uniform response to wounding. Here there is no elongation of the cortical elements in normal cases, thickening and the production of gum in large quantities

being general. In one case only, and that of a decidedly exceptional nature, was any secondary growth observed. This exceptional case occurred in the basal part of the petiole of *Woodwardia orientalis*, and was apparently due to bacterial infection.

The petiole showed a pronounced local dilatation in the wound area (Pl. LXXIV, Fig. 13), and on microscopic examination it was found that the uninjured cortical cells at the wounded surface had proliferated in a peculiar, irregular manner, giving rise to a well-marked intumescence (Pl. LXXIV, Fig. 14).

The cells had, in some cases, especially at the margins of the affected area, grown very long without dividing, whilst the remainder had divided up by transverse walls at varying intervals, and the resultant daughter cells had also grown. The appearance of these cells was very different from that produced by ordinary cambial division. The whole of the cells were filled with cytoplasm of a cloudy nature, and in addition contained minute rods, which were presumably the cause of the growth. Cells containing two nuclei were not uncommon, and in one or two of the largest cells three nuclei were detected (Pl. LXXIII, Fig. 10).

Strasburger (34) records somewhat similar instances of cells containing several nuclei in the case of graftings where tissues have been injured.

Hypertrophy as a result of infection by Bacteria is not uncommon, the root-nodules produced in Leguminosae, *Alnus*, and *Myrica* being typical instances, whilst Smith (27) has also described local swellings produced on the olive due to similar causes.

Immediately below the meristematic zone there was a large patch of tissue several cells in diameter which had become strongly impregnated with tannin, this cutting off the infected cells from the general mass of cortical tissue (Pl. LXXIV, Fig. 14).

Appearances point to this being of the nature of a protective wall since the rodlets were not detected in any of the cells within this zone.

The results obtained in the basal petiolar region are precisely what might have been anticipated from a comparative study of the effects of wounding in the younger parts. As the petiole becomes absolutely set and mature the stimulus causing anything but the simplest form of response, that is, local thickening, would have to be of a very unusual character, a condition fulfilled in the abnormal case recorded.

The description of the various reactions recorded has been confined to the results produced in the general mass of cortical parenchyma, and as the remaining tissues appear to each show considerable uniformity it has been thought preferable to deal with them separately.

- (a) *The epidermis* in the most freely reacting forms (e.g. *Asplenium Belangeri*) showed a certain amount of sliding growth in the wound area accompanied by one or more cell-divisions, this

resulting in a callus-like incurving at the margins somewhat similar in appearance to the early stages of repair seen in trees after a branch has been severed (Pl. LXXIV, Fig. 20). In the remainder the epidermal cells nearest the wound showed at the most an increase in general bulk rather than elongation in any particular direction, and were usually filled with gum (Pl. LXXIV, Fig. 16). The walls did not exhibit any additional growth in thickness in any case.

- (b) *The vascular bundle and bundle-sheath.* Whenever a bundle was cut into to any great extent, degeneration of the tissues and a general deposit of coarse, brown, granular matter seemed invariably to result. Where the bundle-sheath was not actually cut away the cells on the side adjacent to the wound showed a growth in length and also division, this often leading, where the sheath did not show radial thickenings, to loss of identity as a definite layer. Where radial thickenings were present the daughter cells resulting from the division also showed these (Pl. LXXIV, Fig. 20).

The endodermal cells of some forms (e. g. *Davallia*) are characterized by heavy brown thickenings, but these do not seem to be in any way affected by wounds, the bundle-sheath of parts remote from the wound showing an amount of thickening equal to those nearer to it (Pl. LXXIV, Fig. 15). With regard to the phloem and xylem, where the differentiation of these elements is already complete no traumatic effects are perceptible, but where, as in the apical portions, the lignification of the later-formed xylem elements has not begun, both this and the phloem show distinct elongation towards the affected part. The cells of the phloem and of the bundle parenchyma often show both elongation and transverse division; in the case of the large xylem elements elongation alone occurs. That this elongation is of the nature of traumatic response, and is not due to the disturbance of the bundle symmetry by the departure of a leaf-trace, is strongly supported by the fact that specimens wounded on the abaxial side of the petiole show this feature very markedly (Pl. LXXIV, Fig. 17).

From the foregoing it will be perceived that the more specialized tissues, such as the epidermis, the endodermis, and the vascular elements, are all responsive to a greater or less extent to traumatic stimuli, but that, as might be expected, the modification is of a much less pronounced character than that obtaining in the comparatively simple cortical parenchyma.

A first series of experiments such as these are almost of necessity incomplete, since the aim has been to obtain a general idea of the mode of response to wounding in the Filicineae as a group, rather than a detailed knowledge of the behaviour of one or more species. As a result the effect of varying physiological conditions has not been studied, except incidentally.

With the exception of a few of the hardest forms, such as *Pteris*

aquilina and *Lastraea Filix-mas*, the plants were grown under glass and under practically identical conditions. The writer hopes to make the physiological aspect of the paper the subject of a subsequent investigation.

SUMMARY.

1. When a fern petiole is wounded in the still meristematic apical zone, the plant attempts to protect the injured area by the production of a pad of cambiform cells, which arise by the subdivision of the cortical parenchyma.

2. In the most successful cases the wound-cambium completely covers the affected part with a typically meristematic tissue, as in *Asplenium bulbiferum*, *A. Belangeri*, *Polystichum proliferum*, *Woodwardia orientalis* and *W. radicans*.

3. More usually the cambial response is imperfect, consisting of the elongation of the cells at or near the seat of injury, with a greater or less number of transverse divisions of these (e. g. *Lastraea Filix-mas*, *Polypodium glaucum*, *Scolopendrium vulgare*). In *Polystichum angulare*, *Pteris cretica*, *Lastraea reflexa*, and *Woodwardia virginica*, elongation of the outermost layer alone occurs.

4. The cambium, whether well developed or imperfect, is supplemented by the scab-like remains of dead cortical cells on the outside.

5. As the petiole develops secondary changes take place, resulting in the thickening of the cell-walls by deposits of cellulose, ligno-cellulose or lignin, and in the deposit of an almost solid mass of intracellular gum.

6. Petioles wounded in the more mature 'region of pinna-insertion' produce cambium less readily, only those producing bulbils, of the forms examined, showing this mode of response in any marked degree.

7. It is suggested that the production of bulbils may demand a more adaptable type of tissue, this accounting for the readiness with which cambium is produced.

8. In other forms, elongation of the outer cells, together with an abundant deposit of gum, is the most general type of wound response. Transverse divisions of the modified cells are few in number or do not occur.

9. Occasionally, as in *Davallia polyantha*, there may be an extremely thick deposit of cellulose on the walls of the cells at the seat of injury, resulting in the production of a very resistant tissue. Gum is deposited as in the previous cases.

10. Plants wounded in the basal part of the petiole generally show no cell-elongation, but thickening of varying character together with a constant deposit of gum were constant features.

11. In only one case, an abnormal one, in which the wound was infected by Bacteria, was any secondary activity evinced. This resulted in the local

dilatation of the petiole, and the formation of a distinct intumescence by the irregular division of the infected cells.

12. Where cell-elongation occurs, pathogenetic, amitotic nuclear division, either complete or incomplete, may accompany this.

13. The epidermis in the most active species may show sliding growth comparable to that exhibited by the cortical cells, but usually, beyond an abundance of gum and an increase in the size of the cells, little sign of activity is shown.

14. The cells of the endodermis either enlarge or elongate, and may divide so that their identity as a definite layer is lost on the side nearer the wound, when this approaches the bundle at all closely.

15. There is some evidence that the phloem and xylem, when young, are influenced by wounding, and elongate towards the seat of injury.

In conclusion, the author's thanks are due to Professor Weiss for much encouragement and help; to Professor Carr, in whose department the major portion of the work has been done, and who has permitted his plant-house to be used for the experimental work; to Mr. S. Garside, M.Sc., lately of the Victoria University, Manchester, who kindly collected and preserved part of the material used; and to Miss Bancroft, B.Sc., who performed a series of control experiments on a number of the hardier forms, whilst studying at the University College, Nottingham.

A Bee-hive Fungus, *Pericystis alvei*, Gen. et Sp. Nov.

BY

ANNIE D. BETTS, B.Sc.

With Plates LXXV and LXXVI.

THE bee-hive Fungi, as a class, have been studied but little, though bee-keepers have long been aware of the occurrence of 'mould' in their hives, and some of the diseases to which the honey bee is liable are known to be of a fungous nature. An investigation was begun with the object of filling this gap in our knowledge of the economy of the hive; in the course of it, the species which is the subject of the present paper was met with.

Pericystis alvei is a common fungus, being in fact the principal constituent of the 'pollen-mould' prevalent in hives during the winter and early spring. It grows, as this name indicates, on the pollen stored in the combs (Pl. LXXVI, Fig. 11), and is not found, so far as is known, on any other substratum. The contents of cells attacked by the fungus tend to dry up ultimately into hard plugs, which often split into layers (see Pl. LXXVI, Fig. 12); they are permeated by mycelium, which is, however, most plentiful on the surfaces and especially on the top (that is, the surface exposed when the plug is in the cell).

This species may be readily distinguished from all others found in the hive by the character of its mycelium. Many of the hyphae have a large proportion of their cells converted into chlamydospores; this is sometimes carried so far as to give the appearance of an oidium-hypha (Pl. LXXV, Fig. 2, *b*). The remaining cells tend to lose their protoplasmic contents, so that the hyphae when mature break up readily (Fig. 2, *a*). Other hyphae are more or less devoid of spores, or only bear occasional lateral or intercalary ones (Pl. LXXV, Fig. 1, *a*).

The hyphae are $2-6\mu$ in diameter. As a rule, they assume their characteristic appearance when quite young (Pl. LXXV, Fig. 3, *a*, where chlamydospore is shown in course of formation on a young hypha).

The chlamydospores are of various forms (Fig. 3). In position they are terminal, lateral, or intercalary, or are borne on short lateral processes (Pl. LXXV, Figs. 1, 2). Their dimensions vary from $4-5\mu$ to $9.5 \times 7\mu$ or even

larger; $8.6 \times 7.5 \mu$ are average measurements.¹ The walls of these spores are thicker than those of the ordinary hyphal cell; this, together with their frequently isolated position, is felt to justify the use of the term chlamydospore rather than that of oidium-cell, although they resemble the typical oidium-cell in their capacity for immediate germination.

If a comb on which *Pericystis alvei* is present be examined in the early spring,² some cells will be found in which the fungus is no longer white, but grey. In May it is not unusual to find specimens of a dark slate-grey colour. This change is due to the formation of the cysts. These are subglobose or irregularly oval objects 20μ (occasionally less) to $40 \times 30 \mu$ (average about 30μ in diameter),³ and contain numerous spores. The cyst-wall is thin, smooth, and structureless, semi-transparent, and has a polished appearance when viewed by reflected direct sunlight. It is dark green in colour, appearing black by reflected light. Each cyst is borne on three to five short hyphal branches, also of a dark green colour. The general appearance of a culture with mature cysts is shown in Pl. LXXVI, Fig. 10.

The walls of the mature cyst and its supporting hyphae are not dissolved when placed in concentrated sulphuric acid on a slip, covered with a cover-glass, and heated till bubbles are expelled.

The cyst-spores are hyaline, spherical, and thick-walled (Pl. LXXV, Fig. 9); they are $3.7-4.7 \mu$ in diameter, average 4.3μ . The number present in a cyst is variable, depending on the dimensions of the cyst. So far they have not been observed to germinate. Possibly they require a resting period, or conditions different from those which are favourable to the germination of the chlamydospores.

The cyst arises as a swelling or lateral projection on a hypha. This puts out one or two (rarely three) processes, which fuse with a neighbouring hypha, usually bending through a right angle to do so (Pl. LXXV, Figs. 4, 5). The young cyst now increases in size, and its contents assume a vacuolated appearance (Pl. LXXV, Fig. 6). The wall presently begins to acquire a brownish tint; a culture at this stage is of a pale salmon or bone colour to the naked eye. The tint deepens, till finally the wall turns green; it almost attains its mature depth of colour before the spores begin to be visible within the cyst (Pl. LXXV, Fig. 7).

The fusing hyphae become septate at an early stage. Inspection of stained material reveals that there are three septa; one at the junction with the cyst, and two others close together further along the hypha (Pl. LXXV, Fig. 7). The contents of the young cyst are highly granular, and the septa are in consequence frequently invisible in unstained material.

¹ Measurements taken from honey-gelatine culture material.

² Possibly in mid-winter also. Grey specimens were plentiful on some material in January; but these combs were from hives where the bees had died, so that the conditions were not normal.

³ Measurements taken from honey-gelatine culture material.

The green colour, in the mature cyst, extends as far as the third septum ; the fusing hyphae can therefore be easily distinguished from the hypha bearing the cyst, by the septum near their distal ends (Pl. LXXV; Figs. 7, 8).

When several cysts form on one hypha, their processes often all fuse with the same neighbouring hypha (Pl. LXXV, Fig. 5). It has not been ascertained that this is invariably the case, so that any deductions from it as to a possible differentiation of the hyphae would be premature.

The cyst is indehiscent ; the spores are presumably set free by the breaking of the wall.

Pericystis alvei is not very easy to cultivate. It will germinate readily on most media, and produce mycelium and chlamydo-spores ; but cysts, if formed at all, are usually empty. The only satisfactory medium was found to be honey-gelatine.¹ On this the fungus developed normally and cysts containing spores were produced.

Cultures of the fungus have a distinctly alcoholic odour. Gelatine is liquefied, but slowly ; the process is often one of softening rather than of liquefaction.

Some rough experiments were made to test the effect of different temperatures on the germination of the chlamydo-spores. The results indicate that :

- (1) The chlamydo-spores will not germinate at 26°–38° C., but do so when transferred from this to 15°–18° C., so are not killed. The cultures were kept at 26°–38° for 13–16 days.
- (2) They germinate at 15°–18° C. in 1–5 days.
- (3) They germinate under outdoor conditions (mild winter weather) in about 11 days.

These facts are of interest in view of the probable life-history of this species. In the spring the bees clean out their combs, throwing the plugs of mouldy pollen out of the hive. Some of the spores will, however, be left in the hive, and will remain there during the summer. When the stock swarms, the bees of the swarm probably take with them some spores adhering to their bodies, and so transfer the fungus to the new colony. If this be so, we can see that the inability to germinate at high temperatures is of use to this species. The temperature of the bee-hive when the bees are active is 32°–34° C. ; were the spores to germinate under these circumstances, the bees would remove the fungus from the combs as fast as it grew. In the winter, on the other hand, the temperature does not usually exceed 12° C. ;² and the fungus is able to establish itself unmolested by the bees, which are hibernating in a cluster in the central part of the hive.

¹ Diluted honey (three or four parts of water to one of honey), 100 c.c.; gelatine (Gold Label), 10 grm. The medium was usually left acid.

² The consensus of opinion seems to point to this as the temperature of the cluster when quiescent. The outer combs, where the fungus usually grows, are of course colder.

Attempts to cultivate *Pericystis alvei* on bouillon, bee-pupa agar, &c., were not very successful ; and there is no reason to suppose that this species is ever pathogenic in the bee. It is, in fact, present alike in healthy and in diseased stocks ; if occasionally more plentiful in the latter, this is due to some secondary cause such as the weakness of the colony rather than to any direct connexion with disease.

As this fungus is undoubtedly a normal inmate of the healthy bee-hive, and is, so far as is known, confined to that habitat, I propose for it the name *Pericystis alvei*.

Pericystis, gen. nov. Hyphis repentibus vel suberectis, contextis, ramosis, septatis, multis cellulis in chlamydosporas se mutantibus, tandem saepe se dissolventibus. Chlamydosporis terminalibus lateralibus intercalariisque, subglobosis vel irregulariter ovalibus, membrana crassa, lēvi. Cystis subglobosis vel ovoidibus, tribus ad quinque ramis hyphalibus ferentibus, sporis numerosis repletis. Membrana cysti membranacea, simplice, lēvi, tandem fusca. Sporibus hyalinis, sphericis, membrana crassa, lēvi.

P. alvei, sp. nov. Characteres ut supra. Mycelium album. Hyphis 2-6 μ (saepissime 5 μ diam.). Chlamydosporis 9.5-4.5 \times 7-4.5 μ . Cysts 40-20 \times 30-20 μ ; membrana cysti tandem atroviridi. Sporibus 3.7-4.7 μ (saepissime 4.3 μ diam.).

Hab. ad pollinem in favis *Apis mellificae*.

Pericystis, gen. nov. Hyphae creeping or suberect, interwoven, branched, septate, having many cells converted into chlamydo-spores, ultimately breaking up. Chlamydo-spores terminal, lateral and intercalary, subglobose or irregularly oval, thick-walled, smooth. Cysts subglobose or ovoid, borne on three to five hyphal branches, containing numerous spores. Cyst-wall membranaceous, structureless, smooth, ultimately dark-coloured. Spores hyaline, spherical, thick-walled, smooth.

P. alvei, sp. nov. Characters of the genus. Mycelium white. Hyphae 2-6 μ (average 5 μ diam.). Chlamydo-spores 9.5-4.5 \times 7-4.5 μ . Cysts 40-20 \times 30-20 μ ; cyst-wall ultimately dark green. Spores 3.7-4.7 μ (average 4.3 μ diam.).

Hab. on pollen in the combs of the honey bee.

In conclusion, I wish to express my thanks to Miss A. Lorrain Smith for her kindness in giving me much helpful advice.

SUMMARY.

A new fungus, *Pericystis alvei*, prevalent in bee-hives, is described, and its probable life-history discussed.

EXPLANATION OF PLATES LXXV AND LXXVI.

Illustrating Miss Betts's paper on *Pericystis alvei*.

The magnification is uniform for Plate LXXV, and is approximately $\times 700$. The figures were drawn with the aid of a camera lucida from unstained material. All the specimens (with the exception of those figured in Plate LXXV, Fig. 2, *a*, and Plate LXXVI, Figs. 11 and 12) were taken from cultures on honey-gelatine.

PLATE LXXV.

Fig. 1. Hyphae and chlamydospores from a young culture. *a*, hypha with few spores; *b*, spores on lateral processes.

Fig. 2. Hyphae and chlamydospores from an older culture. *a*, an old hypha, cells between spores have lost their contents; *b*, an oidium-hypha (from comb).

Fig. 3. Chlamydospores. *a*, spore germinating, and a chlamydospore forming in the resulting hypha.

Fig. 4. Young cyst; early stage, before fusion.

Fig. 5. Two young cysts on one hypha, after fusion.

Fig. 6. Young cyst; shortly before wall changes colour.

Fig. 7. Cyst; wall has turned green, but spores not yet visible.

Fig. 8. Mature cyst.

Fig. 9. Cyst-spores.

The Formation and Physiological Significance of Root Nodules in the Podocarpineae.

BY

ETHEL ROSE SPRATT, B.Sc., A.K.C.

Demonstrator in Botany at King's College, London.

With Plates LXXVII-LXXX.

THE assimilation of atmospheric nitrogen by plants, belonging to families other than the Leguminosae, which possess structures on their roots known as nodules, has long been recognized in the Cycadaceae, Elaeagnaceae, *Alnus*, and *Podocarpus*. Quite recently, too, Bottomley has shown that the root nodules of *Myrica Gale* are intimately associated with the fixation of free nitrogen.

Nobbe and Hiltner, in 1899, demonstrated that the nodules of *Podocarpus* were active agents in the utilization of atmospheric nitrogen. In their experiments it was found impossible to cultivate plants of *Podocarpus* in the absence of the fungus which caused the nodule formation, but plants possessing nodules were grown for five years in quartz sand from which nitrogen was entirely absent, and during this period they remained perfectly healthy and grew well.

The earlier observers failed to demonstrate the presence of Bacteria in the nodules of these non-leguminous plants, but they found numerous hyphal-like structures in them, which they considered to be the hyphae of a mycorrhizal fungus forming a symbiotic association with *Podocarpus*. Shibata described a mycelium, composed of non-septate hyphae possessing numerous nuclei, as being present in the cortical cells of the nodule. His investigations showed that these hyphae are eventually disorganized and absorbed, through the agency of a proteolytic ferment, by the host cells. These and similar observations in connexion with *Alnus*, *Elaeagnus*, and *Myrica* led to the idea that the formation of the nodules of non-leguminous plants was caused by the presence of an endophytic mycorrhiza. More recent investigations, however, have shown this idea to be erroneous in some cases. Bottomley, in 1909, isolated and grew the nitrogen-fixing organisms *Pseudomonas radicola* and *Azotobacter* from *Cycas* tubercles,

and, in 1912, he has shown the nodules of *Myrica Gale* to be bacterial in origin. The author has described the root tubercles of *Alnus* and *Elaeagnus* as being caused by the infection of the root with a species of *Pseudomonas radicola*, which afterwards flourishes in the cortical cells of the nodule.

The first part of the present series of investigations was carried out with material of *Podocarpus Totara*, *Podocarpus elongata*, and *Podocarpus chilina* obtained from the Royal Botanical Gardens, Kew, at various seasons of the year. At the suggestion of Professor Bottomley, however, the observations were extended to comprise the whole of the group Podocarpaceae; and through the kindness of the Director of the Royal Botanical Gardens, Kew, roots of *Microcachrys tetragona*, *Dacrydium Franklini*, *Saxegothaea conspicua*, and *Phyllocladus trichomanoides* were obtained.

In all the genera of the Podocarpaceae numerous nodules are present on the small roots, along the sides of which they are arranged in two very definite rows, thus producing a beaded appearance (Pl. LXXVII, Figs. 1-5). In the four species of *Podocarpus* examined, *P. Totara*, *P. elongata*, *P. chilina*, and *P. alpina*, the nodules are almost spherical in shape, attaining a diameter of 0.8 to 1 mm., and are very symmetrically disposed along the two sides of the root (Fig. 1). The nodules are very numerous, occurring quite close to one another along the whole length of the roots, which branch relatively infrequently. In general appearance the roots of *Dacrydium Franklini* resemble those of *Podocarpus*, but they branch somewhat more frequently; the nodules are smaller, only attaining a diameter of 0.54 to 0.68 mm., and although they occur in two rows along the sides of the roots they are less regularly arranged (Fig. 2). The roots of *Microcachrys tetragona* are very fibrous, numerous very fine branches being produced, and along two sides of all these numerous small rootlets, minute nodules, with a diameter of 0.25 to 0.35 mm., are arranged side by side in close proximity with one another (Fig. 5). In *Saxegothaea conspicua* the roots present a coralline appearance, being quite small, but so repeatedly branched that dense clusters are produced, and the roots bear two very closely packed rows of nodules, which are 0.4 to 0.5 mm. across (Fig. 3). *Phyllocladus trichomanoides* has a much more straggling root, and the nodules are less numerous than in the other genera, but are present upon the small roots, where there are two rows, thus presenting the characteristic beaded appearance. In this genus they appear to be more widely separated from one another, and attain a diameter of about 0.5 mm. (Fig. 4).

The roots and nodules of all these plants being quite small, it was found convenient to mount some of them whole for examination under the low power of the microscope, which immediately revealed the fact that the nodules in all the genera are endogenous in origin and each possesses a small but well-defined vascular strand, which is connected with the root-

stele. In the material of *Podocarpus* obtained during the autumn and winter the surface of the nodules was always quite smooth, whilst in *P. chilina*, *P. elongata*, and *P. Totara* obtained in the spring the epidermal cells in a few nodules were growing out into hairs, and a few were covered with numerous fine non-septate hairs about the same length as the nodule. In *P. alpina* gathered in February a very large number of the nodules were clothed with a thick mantle of long hairs, some of which were quite three times as long as the nodules. The hairs were most abundant on nodules which were one year old, and which were, in many cases, attached to the roots in, or near, the regions where they themselves were producing root-hairs, but they were also sometimes present on the nodules, which were two, three, or even four years old. In *Microcachrys tetragona* the surface of the nodules was generally quite smooth (Fig. 8), but occasionally small protuberances from the surface cells were visible. In *Dacrydium Franklini*, *Saxegothaea conspicua*, and *Phyllocladus trichomanoides* the production of hairs, in the spring, is a constant feature of all nodules which have completely emerged from the cortex of the root. It is, therefore, usually in the beginning of the second season's growth that practically all the surface cells of the nodules are capable of growing out to produce hairs, which radiate in all directions from the nodule (Figs. 6 and 7). In *Dacrydium* they attain a length about equal to that of the nodule in many cases, but sometimes they are longer; in *Saxegothaea* a thick mass of relatively long hairs covers the nodules, whilst in *Phyllocladus* they are very long and straggling.

These hairs are evidently comparable to root-hairs; they are non-septate structures produced by the epidermal cells of the nodules, which are themselves modified roots. Like other root-hairs they are produced abundantly in the spring, whilst later in the year, in the autumn and winter, they collapse and eventually disappear. Any nodule which has reached maturity seems to be capable of producing these structures, but since they persist for very varying periods of time, nodules of diverse ages may be seen to possess hairs on their surface. When the nodule is more than two years old, however, they can distinctly be seen to be portions of the old hairs, which have remained attached to the nodules. They are evidently produced in response to certain environmental conditions in *Podocarpus* and *Microcachrys*, where it is only some of the nodules which produce these outgrowths, but in *Dacrydium*, *Saxegothaea*, and *Phyllocladus* there is a much greater tendency for the formation of hairs, their presence in the spring being characteristic of these genera. The frequent presence of root-hairs, not only on the roots but also on the nodules in all the genera of the *Podocarpaceae*, precludes their association with a mycorrhizal fungus.

In order to ascertain whether there were any Bacteria present in the nodules, some were removed from the roots, carefully washed with distilled

water, then crushed on a slide, and the material so obtained allowed to dry. This was then stained with Ziel's carbol fuchsin or aniline gentian violet, and subsequent microscopical examination revealed the presence of numerous small rod-shaped Bacteria. These organisms were apparently identical with the *Pseudomonas radiculicola* found in the root nodules of leguminous plants and also the Cycadaceae, Elaeagnaceae, *Alnus*, and *Myrica*. Many of them contained two or three minute, spherical, densely staining bodies, which are so characteristic of that organism.

For further investigation with regard to the nature and growth of this organism, the exterior of some nodules from the *Podocarpus* roots was sterilized by placing them for about two minutes in a sterilizing fluid of the following composition :

2.5 c.c. concentrated hydrochloric acid,
1 gram. mercuric chloride,
500 c.c. water.

They were then removed and thoroughly washed in distilled water, precautions being taken that all the instruments used were quite sterile. The nodules were then crushed, and their contents placed in a nutrient medium of the following composition :

1 gram. saccharose or glucose,
0.5 gram. acid potassium phosphate,
0.02 gram. magnesium sulphate,
0.1 gram. calcium carbonate,
100 c.c. distilled water.,

The solution was then incubated at a temperature of 28° C. for two days, at the end of which period it had become quite cloudy owing to the rapid development of the rod-shaped Bacteria.

Pure cultures of this organism were also obtained on solid media, prepared by adding 2 per cent. agar-agar to the above nutrient solution. The colonies produced, after two days' incubation at 28° C., were ovoid to circular in shape, entire, raised, shining, and viscous, with a diameter of 0.75 to 1 mm. They were apparently characteristic colonies of *Pseudomonas radiculicola*.

Since this organism so closely resembled, in its appearance and growth on nutrient media, species obtained from the nodules of legumes and the non-leguminous plants mentioned above, which are known to assimilate atmospheric nitrogen, 100 c.c. of the above nutrient solution containing saccharose was placed in each of four Erlenmeyer flasks, 300 c.c. capacity. To two of them, the controls, was added 2 c.c. of a liquid culture of the organism, obtained, as described above, from *Podocarpus* nodules. All the flasks were then sterilized by autoclaving, at a temperature of 140° C. and

a pressure of two and a half atmospheres, for ten minutes. After cooling, 2 c.c. of the same culture as had been added to the controls was used to inoculate each of the other two flasks. All were then incubated at 28° C. for ten days. During this period the contents of the control flasks remained quite clear, whilst the others had become cloudy owing to the presence of a growth of a very slimy nature. The nitrogen content of the flasks was determined by the Kjeldahl method of analysis, with the following results :

<i>Nitrogen found in the control.</i>	<i>Nitrogen found in the culture.</i>	<i>Gain in nitrogen due to organism.</i>
1.06 m.grm.	3.72 m.grm.	2.66 m.grm.
0.93 m.grm.	3.46 m.grm.	2.53 m.grm.

The increased nitrogen content of the solution in which growth took place can only have been produced by the activity of the living organisms obtained from the *Podocarpus* nodules and introduced into the media, and must have been caused by the utilization of the free nitrogen of the atmosphere by these organisms during the processes of metabolism. Hence it becomes evident why Hiltner was able to grow *Podocarpus* plants in pure sand, containing no nitrogen, provided nodules were present on the roots. The Bacteria in the nodules assimilate atmospheric nitrogen, and thus render it available to the *Podocarpus* plants.

Material used for sectionizing was fixed in either Flemming's or Bouin's fixative, or absolute alcohol. Microtomed sections were stained with Flemming's triple, Heidenhain's iron-haematoxylin, Ziel's carbol fuchsin, or Kiskalt's amyl gram stain with very satisfactory results.

The nodules of *Podocarpus*, *Microcachrys*, *Dacrydium*, *Saxegothaea*, and *Phyllocladus*, as of other non-leguminous plants, are modified lateral roots, being developed from the pericycle immediately opposite the protoxylem of the diarch root (Pl. LXXVIII, Figs. 10 and 11), and possessing a central stele (Pl. LXXX, Fig. 17). Owing to some cells of the pericycle becoming meristematic (Pl. LXXVIII, Fig. 10, *a*, *b*), a small swelling is produced beneath the endodermis of the root. These cells continue to develop, and as the protuberance increases in size aplerome becomes differentiated (Fig. 10, *c* and *d*), which later produces a vascular strand directly connected with the vascular cylinder of the root (Pl. LXXVIII, Figs. 11 and 12, and Pl. LXXIX, Figs. 13 and 14). This structure gradually pushes its way through the cortex of the root and may become a lateral root, but very frequently, as indicated by the enormous number of nodules present on the roots, its growth is arrested, with the result that it produces a small almost spherical structure known as a nodule. This arrest in its development is caused by the infection of the young cells with the nitrogen-fixing organism *Pseudomonas radicola*, before it emerges from the cortex of the root (Fig. 10).

The Bacteria enter the cortex of the root by means of the root-hairs, in which they have frequently been seen, particularly in some young roots of *Phyllocladus* (Fig. 9). Having once penetrated the cell-wall and entered the hair, they multiply rapidly, producing a zooglea thread, exactly comparable to the infection threads of the Leguminosae. The thread passes into a neighbouring cell, and subsequently numerous zooglea threads are produced which pass from cell to cell of the cortex (Figs. 9 and 16). When, however, a meristematic region arises in the neighbourhood of the Bacteria, they appear to be stimulated to further and more rapid development, and chemotactically attracted by the meristematic tissue, so that some of the infection threads penetrate into the young tissue (Fig. 10). Having once entered this new structure the Bacteria divide repeatedly, and the zooglea threads so produced ramify through the young cortical cells, causing their expansion, but arresting their further division, and consequently the immediate growth of the nodule.

A mature nodule possesses a small stele (Fig. 17), surrounded by a definite endodermis, the cells of which are slightly thickened on the outer side, although there is no evident radial dot, and many of them, as in the endodermis of the root, contain a deposit of tannin which renders them more apparent. In all the species of *Podocarpus*, where the nodules attain the greatest size in the group Podocarpaceae, the nodular stele becomes distinctly diarch (Fig. 17); so also in *Saxegothaea* it usually becomes thus differentiated, but in *Microcachrys* and *Phyllocladus* the vascular strand is frequently very rudimentary, the xylem only consisting of two or three tracheides, around which are two or three layers of parenchymatous cells, and then an endodermis. The stele is continuous with that of the root and traverses about half the length of the nodule. The remaining nodular tissue is composed of parenchymatous cells, in which there is no differentiation of a meristematic zone, all the cells are similar, but the outermost layers after the nodule has emerged from the root for some time become slightly more compressed, and their walls become a little thicker, the outer ones eventually becoming slightly suberized (Figs. 11 and 17). The outermost layer of cells of a mature nodule, like the epidermal cells of the roots, have the capacity of growing out to form hairs (Figs. 6 and 7). This they characteristically do in *Dacrydium*, *Saxegothaea*, and *Phyllocladus* in the spring of their second year, and it sometimes also occurs in *Podocarpus* and *Microcachrys*.

The cortical cells of both roots and nodules in all the genera appear to be traversed by numerous very narrow filaments. These, however, when stained with Kiskalt's amyl gram stain are seen to be composed of numerous rod-shaped Bacteria, obviously *Pseudomonas radicola*, which are embedded in a mass of slime, forming a zooglea, and thus giving the appearance of a network of hyphae (Figs. 15 and 16). These threads are capable of pene-

trating the cell-walls of the host tissue, and where the zooglea thread comes in contact with the cell-wall it widens out somewhat before passing through into the neighbouring cell. Expansion in this area is characteristic of infection threads produced by *Pseudomonas radicola* in leguminous nodules. In the interior of the host cell some of the Bacteria become isolated from the infection threads and divide independently, forming groups of organisms. The threads vary considerably in width, even in the same nodule, sometimes being only a single chain of organisms, at others, especially in *Podocarpus*, as many as five, six, or even more are arranged across side by side, so as to form apparently one thread. The Bacteria are quite evident in the cells when the sections are treated with Flemming's triple stain or Heidenhain's iron-haematoxylin. They also respond, in the manner described by Harrison and Barlow as being characteristic of *Pseudomonas radicola*, to treatment with alcohol after Gram's method of staining, that is, the aniline gentian violet is rapidly removed by ethyl alcohol, but not by amyl alcohol.

The zooglea threads are undoubtedly analogous to those present in leguminous nodules, and like them they appear to have an affinity for the nucleus of the host cell. Shibata described the nuclei of the cortical cells of *Podocarpus* nodules, which he said contained mycorrhizal hyphae, as assuming an amoeboid form, and subsequently dividing directly until as many as eight nuclei were present in a single cell. The nuclei appear to be stimulated to activity when they become surrounded by a large number of Bacteria, for many instances have been seen, especially in *Podocarpus*, where more than one nucleus has been present in the cell containing Bacteria. The increased number is evidently produced by amitosis, no karyokinetic figures having been observed in such cells, but numerous elongated nuclei, and others in which the elongated structure is constricted in the centre and about to form two nuclei (Fig. 15). This effect of the presence of Bacteria around the nucleus of the host cell is quite comparable with that seen in the root-nodules of *Elacagnus*, where the nuclei have been described by the author as becoming amoeboid and very irregular in shape, and then in some cases disintegrating.

As the season advances towards autumn further changes occur in the cortical cells of both root and nodules in all the genera. The cytoplasm and nuclei are gradually used up in the deposition of numerous cellulose bars on the walls of the cells, which gives them a scalariformly striated appearance, and assists in keeping them distended. The Bacteria tend to migrate from these cells, which appear first in isolated positions and thus become quite devoid of living contents. Gradually, however, almost the whole of the parenchymatous cortex, except the two or three outermost layers, becomes transformed into this water-storage tissue, and here the Bacteria continue to live in a quiescent state through the winter, until

environmental conditions are again favourable for their activity, and also that of the host plant (Figs. 11, 12, and 16).

The following spring, in the nodules of all the genera of the Podocarpineae examined, some of the cells immediately below the endodermis at the apex of the vascular strand of the nodule become meristematic (Fig. 12). A rapid formation of new tissue ensues in the centre of the nodule, pushing out and crushing the old water-storage tissue, which now readily collapses. The formation of new tissue beneath the endodermis causes the rupture of the latter, but later, when the rapid cell division ceases, a new endodermis is differentiated around the apex of the stele (Fig. 13). The Bacteria resume their activity and are stimulated to produce numerous infection threads, which penetrate into the newly formed cortical cells (Fig. 13). In this way living, active cortical cells are produced inside the old tissue of the nodule, which now forms a protective covering around the new nodule. This formation of a meristematic zone at the apex of the vascular cylinder, and the consequent production of new internal tissue, recurs year after year, so that a number of successive protective layers are formed around the active cortical cells by the annual displacement and collapse of the tissue formed the previous year (Fig. 14). The outermost zone in all the nodules always remains intact, being composed of a few layers of cells which are part of the first year's growth. It is this zone which has the capacity for producing hairs if occasion arises. The tissue produced in succeeding years becomes very crushed, and often, as in *Microcachrys* and *Saxegothaca*, almost obliterated, except at the base, just around the vascular strand, where the annual additions are always apparent.

In *Saxegothaca conspicua*, where the branching of the root is extremely prolific and the nodules are produced side by side in very close proximity to one another, the nodules have frequently been observed to branch (Figs. 7, 18, and 19). In the spring, when the meristematic zone arises at the apex of the vascular strand, bifurcation of the zone takes place (Fig. 18), with the result that the nodule at first appears to have a branched stele; but later a distinct zone of cortical cells is produced by the apex of each branch of the stele. In this way two new cortical zones centred round a portion of the stele are produced inside the original nodule (Fig. 19), and these, at first, compress the tissue formed the previous year or years, and by their united activities eventually break through it. The tissue of the original nodule thus becomes ruptured and later is cast off; the two nodules produced in its place are each complete, independent structures, which subsequently develop according to the usual method described above. The capacity which the nodules in this genus have for branching gives the root its characteristic coralline, rather than beaded, appearance, a very large number of nodules being produced around the root eventually by their

bifurcation. The rupture and subsequent shedding of the old outer nodular tissue when two nodules are produced in place of the old ones also adds to the possibilities of hair production by the surface cells. The old protecting layers having disappeared, the outer cells of the new nodules can, on reaching maturity, grow out into these structures. This explains the apparently more constant appearance of hairs on the nodules of *Saxegothaea* than on those of the other genera, because, on any portion, this method of branching makes it probable that there will be many nodules present which are only one year old, and which will probably be sending out hairs.

In their method of growth the nodules of the Podocarpaceae differ from all other root nodules with which they are associated. The leguminous nodules are annual structures and are not modified roots, and the non-leguminous nodules of the Cycadaceae, Elaeagnaceae, *Alnus*, and *Myrica* are modified roots with a perennial habit, each possessing an apical meristematic region, by means of which their growth is continued from year to year. The nodules of the Podocarpaceae, although perennial modified roots like the latter, are unique in having no persistent meristematic zone, the tissue definitely functioning for one year only. The formation of new tissue is always endogenous in this group, a new nodule being formed inside the old one year after year, whilst in the other non-leguminous nodules the growth is continued at the apex.

The nodules of the Podocarpaceae are typically simple structures, whilst those of other non-leguminous plants are characteristically branched. The bifurcation of the nodule which occurs in *Saxegothaea*, as described above, recalls the branched nodules of the Cycadaceae, Elaeagnaceae, and *Alnus*, but in these there is no breaking through of old tissue; this latter occurs in *Myrica*, when the stele continues its growth and eventually penetrates the nodule, emerging as a small root. There is, however, no other known case where the original nodule, by branching, becomes replaced, as it does in *Saxegothaea*, by two apparently simple nodules.

The outer zones of dead empty cells in the old nodules provide a suitable substratum for the development of various Fungi, and in *Podocarpus* one sometimes finds true fungal hyphae in these cells. Some of these have probably been described by other observers, and may, indeed, as they suggest, be of a mycorrhizal nature, forming a symbiotic association with the roots of the plant, but they are evidently not concerned with the formation of the nodules. This conclusion is supported by the production of root-hairs on the nodules at the beginning of their second year's growth, which sometimes occurs in *Podocarpus Totara*, *Podocarpus elongata*, *Podocarpus Chilina*, and *Microcachrys tetragona*, usually occurs in *Podocarpus alpina*, and always occurs in *Dacrydium Franklini*, *Saxegothaea conspicua*, and *Phyllocladus trichomanoides*. Shibata, however, does not suggest that the fungus he describes causes the formation of the nodules, because he remarks

that they may attain their full size even when they are not infected with it.

In the old roots there is a formation of periderm (Fig. 14), the phellogen arising immediately outside the endodermis, so that when this takes place the whole of the cortex is thrown off, amongst which are some cells containing Bacteria. This, however, does not usually occur until the root is two or three years old, by which time the formation of new nodules has ceased in this region, and the old ones already have a supply of organisms for the infection of their new cells.

These investigations entirely support the theory that the root nodules of *Podocarpus* are actively concerned in the assimilation of atmospheric nitrogen, not, however, primarily owing to the presence of a mycorrhizal fungus, but to their symbiotic association with a nitrogen-fixing bacterium. This not only occurs in all the species of *Podocarpus* examined, but also in *Microcachrys*, *Dacrydium*, *Saxegothaea*, and *Phyllocladus*, four other genera of the Podocarpaceae. The production of nodules on the roots is thus a constant feature throughout the Podocarpaceae, their development and morphology being in every case of the same characteristic type, and they are always inhabited by apparently the same organism. This organism is morphologically and physiologically identical with *Pseudomonas radicola* found in the nodules of the Leguminosae, Cycadaceae, Elacagnaceae, *Alnus*, and *Myrica*. This organism enters the roots of plants of the Podocarpaceae, and the infection of the meristematic cells of a young lateral root causes its transformation into the structure known as a nodule. In this tissue the Bacteria multiply very rapidly, and in their growth they have been shown to utilize the free nitrogen of the atmosphere, so that by their development in the nodules attached to the plant they are rendering that vast store of food material available, and enabling the plant to grow even under circumstances which exclude all other nitrogen supply.

The division of the Coniferales known as the Podocarpaceae are inhabitants of the southern hemisphere, principally Australia. The dominant genus *Podocarpus* has been considered related to the Araucarineae, through *Dacrydium* and *Saxegothaea*, on certain morphological grounds, and this association is supported by the common and peculiar geographical distribution of the two groups. Tison supports this idea, from the behaviour of the two systems of vascular bundles found in the megasporophyll, but he also says that *Podocarpus* and *Saxegothaea* are very definitely related through *Microcachrys*. There are many arguments against a union of the Podocarpaceae and the Araucarineae, but all the morphological work on the various parts of the plants indicates that *Saxegothaea* and *Podocarpus* are the most widely separated of all the genera placed in the Podocarpaceae, and *Dacrydium* and *Microcachrys* form connecting links between them. This conclusion is supported by the morphology of the root nodules in this

group, those of *Podocarpus* and *Microcachrys* being most nearly alike, differing only in size, whilst *Dacrydium* resembles *Saxegothaea* in the characteristic prolific formation of hairs, and *Saxegothaea* differs from all the rest in the extremely frequent branching not only of the root but also of the nodules.

The genus *Phyllocladus* has led to considerable discussion as to its relationships, since it possesses some of the characters of both groups of the Taxaceae, namely, the Taxineae and the Podocarpineae, and consequently may belong to either of these groups, or it may be an intermediate group between them. Young has summarized the characters which it possesses that are common to these groups respectively, and has decided that the features which relate it to the Podocarpineae are more fundamental than those relating it to the Taxineae, and are also too fundamental to admit of its being placed in an intermediate group. The presence of root nodules, indicating the capability of the root to form a symbiotic association with the nitrogen-fixing organism *Pseudomonas radiculicola*, in *Phyllocladus*, as well as in all the other genera of the Podocarpineae, is an additional character relating *Phyllocladus* with this group.

In conclusion, I wish to thank the Director of the Royal Botanic Gardens, Kew, for supplying the material necessary for my work, and also Professor W. B. Bottomley for his suggestions and kindness during the progress of these investigations, which have been carried out in his laboratory at King's College, London.

SUMMARY.

1. Root nodules are present in all the genera of the Podocarpineae examined, namely, *Podocarpus*, *Microcachrys*, *Dacrydium*, *Saxegothaea*, and *Phyllocladus*.

2. The nodules are modified lateral roots. They are perennial unbranched structures, except in *Saxegothaea*, where bifurcation frequently occurs.

3. The outer layer of cells in the nodules is capable of producing non-septate hairs at the beginning of the second year's growth in all the genera, but their presence is characteristic of the nodules *Dacrydium*, *Saxegothaea*, and *Phyllocladus*.

4. The nitrogen-fixing organism *Pseudomonas radiculicola* penetrates a root-hair and from thence enters the cortex of the root, where it propagates itself.

5. The nodules, in all the genera, are produced by the infection of the meristematic tissue of the young root, before it emerges from the cortex of the parent root, by *Pseudomonas radiculicola*.

6. A mature nodule is traversed for about half its length by a small

stele. In *Podocarpus* and *Saxegothaea* the stele is diarch; but it may remain more rudimentary, as in the small nodules of *Microcachrys*, where frequently only two or three tracheides are present. There is always an endodermis.

7. There is no differentiation of a meristematic zone in the cortical tissue. In this respect the nodules of the Podocarpaceae differ from the nodules of all the other non-leguminous plants with which they associated.

8. The majority of the cortical cells of the root and nodules eventually become water-storage cells, and in some of these the Bacteria remain quiescent during the winter.

9. The Bacteria produce a very definite zooglea in the cells, and in these slime threads pass from cell to cell.

10. The nuclei of the host cells, in *Podocarpus*, are stimulated by the presence of the zooglea around them to elongate and then divide amitotically, so that several nuclei are frequently present in one cell.

11. In the spring the cells immediately below the endodermis at the apex of the nodular stele become meristematic and produce new cortical cells in the interior of the old nodule.

12. Successive zones of collapsed tissue surround the new cortical cells of the nodule year by year.

13. In *Saxegothaea* the meristematic tissue at the apex of the nodular stele frequently bifurcates before producing the new cortical cells, with the result that there are two centres of tissue formation and two new nodules are produced inside the old one, which is eventually ruptured and cast off.

14. The outer empty cells in *Podocarpus* are sometimes inhabited by fungal hyphae, which may be of a mycorrhizal nature.

15. The Bacteria isolated from the nodules are found to be identical in structure, and growth in pure cultures, with *Pseudomonas radiculicola* obtained from the root nodules of the Leguminosae, Cycadaceae, Elaeagnaceae, *Alnus*, and *Myrica*.

16. When isolated from the nodule the organism is capable of assimilating atmospheric nitrogen when grown on suitable media, and consequently its presence is undoubtedly beneficial to the plants of the Podocarpaceae, with which it is associated.

17. The morphology of the nodules, supports the theory that *Podocarpus* and *Saxegothaea* are the most widely divergent of the genera in the Podocarpaceae, and that they are connected through *Microcachrys* and *Dacrydium*.

18. The presence of root nodules in *Phyllocladus* is additional evidence for regarding it as a member of the Podocarpaceae rather than of the Taxineae, or a group intermediate between these two.

DESCRIPTION OF PLATES LXXVII-LXXX.

Illustrating Miss Spratt's paper on the Root-nodules of the Podocarpaceae.

In Figs. 6-8, *r* = root, *n* = nodule, *st* = stele, *h* = hairs, *a* = young nodule, *b* = nodule one year old, *c* = nodule two years old, and *d* = nodule several years old.

In Figs. 10-19, *x* = xylem, *ph* = phloem, *p* = pericycle, *e* = endodermis, *c* = cortex, *b* = Bacteria.

PLATE LXXVII.

- Fig. 1. Root of *Podocarpus Chilina* with nodules. × 2.
- Fig. 2. Root of *Dacrydium Franklini* with nodules. × 2.
- Fig. 3. Root of *Saxegothaea conspicua* with nodules. × 2.
- Fig. 4. Root of *Phyllocladus trichomanoides* with nodules. × 2.
- Fig. 5. Root of *Microcachrys tetragona* with nodules. × 2.
- Fig. 6. Root and nodules of *Dacrydium Franklini*. × 60.
- Fig. 7. Root and nodules of *Saxegothaea conspicua*. *e* = branched nodule. × 60.
- Fig. 8. Root and nodules of *Microcachrys tetragona*. × 60.

PLATE LXXVIII.

Fig. 9. Root-hair and cortical cells of *Phyllocladus trichomanoides*, showing the infection with *Pseudomonas radicola*. *b* = Bacteria, *if* = infection thread, *r.h.* = root hair, *e* = epidermal cell of root. × 730.

Fig. 10. Longitudinal section of a root of *Podocarpus Tetara* with young nodules A, B, C, and D. *if* = infection thread, *pl* = plerome, *w* = water-storage cell. × 105.

Fig. 11. Transverse section of a root of *Podocarpus chilina* with a mature nodule attached. *p.x.* = protoxylem, *s.x.* = secondary xylem. $\times 105$.

Fig. 12. Longitudinal section of a root of *Podocarpus elongata* with a nodule at the beginning of its second year, showing the meristematic zone, *m.z.*, which will produce the new cortical tissue of the nodule. $\times 105$.

PLATE LXXIX.

Fig. 13. Longitudinal section of a root of *Podocarpus elongata* with a nodule in the second year of its growth, when the new cortex has been formed. *n.c.* = newly formed cortex, *o.c.* = old cortex. $\times 105$.

Fig. 14. Longitudinal section of a root of *Podocarpus chilina* with a nodule several years old. 1 = new tissue, 2, 3, 4, 5 = layers of tissue which formed the cortex of the nodule in preceding years, *c* = cork. $\times 105$.

Fig. 15. Cortical cells of the nodule of *Podocarpus Totara* with Bacteria. *i.t.* = infection threads, *n* = nucleus of the host cell; *a*, *c*, and *d* are nuclei in stages of direct division. $\times 730$.

Fig. 16. Cortical cells of the root of *Podocarpus Totara* with Bacteria. *i.t.* = infection threads, *n* = nucleus of host cell, *w* = water-storage cell. $\times 730$.

PLATE LXXX.

Fig. 17. Transverse section of the root nodule of *Podocarpus elongata*. $\times 120$.

Fig. 18. Longitudinal section of the root nodule of *Saxegothaea conspicua*, showing the branching of the meristematic zone. *c* = cortex formed last year, *a* = tissue formed the first year, *st* = stele, *m.z.* = meristematic zone, *h* = hair. $\times 120$.

Fig. 19. Longitudinal section of the root nodule of *Saxegothaea conspicua*, showing two new nodules produced as the result of the branching of the meristem formed in the original nodule. *n* = cortex of the new nodule, *st* = stele, *a* = old nodular tissue being cast off. $\times 120$.

§ 1. INTRODUCTION.

IN Warming's 'Pflanzengeographie', published in 1896, occurs the following passage¹: 'Das Ideal der wissenschaftlichen Behandlung der einzelnen Vereine muss der wissenschaftliche Nachweis dafür sein, wie jedes einzelne seiner Mitglieder (Lebensformen) im morphologischen, im anatomischen und im physiologischen Einklange mit den verschiedenen ökonomischen und geselligen Verhältnissen, worunter es lebt, ist.' We are as yet far from the attainment of this ideal in respect of even a single plant-

¹ Warming ('96), p. 119.

association. But in the meantime it is probable that light may be thrown on many ecological problems by the intensive study of the ecology of selected species.

The present paper, which is intended as a further contribution to our knowledge of 'swamp xerophytes',¹ is an attempt to see how far the study of a single species may help towards an explanation of xeromorphy in marsh plants. The species chosen for this purpose is the common Meadow-sweet, *Spiraea Ulmaria*, Linn., the leaves of which, as is well known, are covered beneath by a dense white felt of hairs. In this paper special attention is devoted to this characteristic pubescence, which is usually regarded as a device for depressing transpiration.

§ 2. HAIRINESS IN MARSH PLANTS.

Though aquatic phanerogams, as a class, are remarkable in being for the most part devoid of hairs, the latter are by no means uncommon on the leaves or stems of marsh plants. Indeed, I have noted the presence of a greater or less degree of hairiness in upwards of thirty of the commoner British species of marsh plants. No doubt even this list could be considerably augmented. In some cases the aerial parts are only slightly hairy, e.g. in *Angelica sylvestris*, *Hydrocotyle vulgaris*, *Valeriana sambucifolia*, *Phragmites communis*, *Molinia coerulca*, &c. In others the hairiness is more pronounced, as in *Epilobium hirsutum*, *Cnicus pratensis*, *Lysimachia vulgaris*, *Mentha aquatica*, &c. In a few cases the lower surface of the leaves is covered with a dense felt of hairs: such is the case in *Spiraea Ulmaria*, *Salix* spp., &c.

It may be remarked here that hairiness occurs most frequently in those species of marsh plants which either grow in the drier parts of marshes,² or else have their aerial parts more or less exposed to the effects of drying winds.³

§ 3. DISTRIBUTION OF CERTAIN HAIRY SPECIES OF *SPIRAEA*.

The genus *Spiraea*⁴ comprises some 127 species, which are spread over the temperate and colder regions of the northern hemisphere. Of these, the majority appear to be glabrous or nearly so, though others are hairy to a greater or less degree. A few species have dense pubescence on the under surface of their leaves; these fall naturally into two groups. In the first, which belongs to the § *Ulmaria*, are *Spiraea Ulmaria*, L., *S. palmata*, Thunb., and *S. vestita*, Wall. These are closely allied Old

¹ Cf. Yapp ('08, two papers), ('09), and ('10).

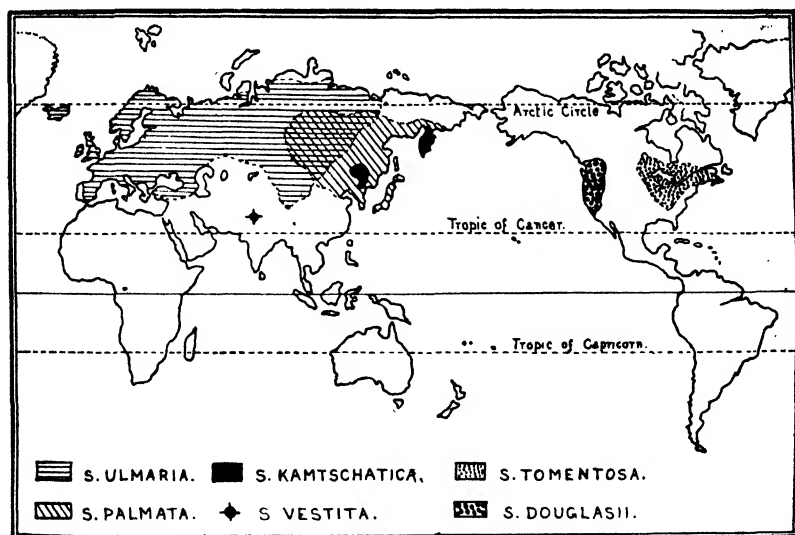

² e.g. *Spiraea Ulmaria*.

³ e.g. *Phragmites communis*, *Viburnum Opulus*, *Salix* spp., &c.

⁴ In the sense used by Linnaeus, Bentham and Hooker, and others, cf. Wenzig ('88). Other authors, probably rightly, separate the several sections of *Spiraea* as distinct genera, e.g. Focke ('94).

World forms, with pinnate leaves and exactly the same type of pubescence, i. e. their leaves are 'subtus albo-tomentosa'. The second group includes several N. American species with entire leaves, belonging to the § *Euspiraea*. Their pubescence is more or less similar to that of the first-named species,¹ e. g. *S. Douglasii*, Hook., *S. tomentosa*, L., &c.

It is interesting to note that most of these densely pubescent species have closely allied glabrous forms. Thus *S. Ulmaria* has the nearly glabrous variety *denudata*;² *S. palmata* has the varieties *tomentosa* and *glabra*; and *S. vestita* is practically indistinguishable, except in respect of

TEXT-FIG. 1. Map showing distribution of certain species of *Spiraea*.

hairiness, from the glabrous *S. Kamtschatica*, Pallas. Again, the two N. American species mentioned above are allied not only to each other, but also to the widely distributed glabrous *S. salicifolia*, L. For the general distribution of these species see Text-fig. 1.

§ 4. HABIT AND HABITATS OF *SPIRAEA ULMARIA*.

S. Ulmaria (= *Filipendula Ulmaria*, Max.) is a perennial herb with a sympodial rhizome which creeps on or just below the surface of the soil (Text-fig. 2). The aerial parts die back in autumn, leaving the persistent

¹ Densely downy leaves, similar to those of the species mentioned above, are apparently not very common in the Rosaceae, though they are met with in various genera, e. g. *Rubus*, *Prunus*, *Cornus*, &c.

² In Rouy et Camus ('00), p. 151, var. γ , *S. unicolor*, Nob. (= *S. denudata*, Presl.), is stated to be glabrous, except for pubescence on the veins below; while var. δ , *glaberrima*, Nob., is entirely glabrous.

rhizome with its winter buds. The plant thus belongs to Raunkiaer's class of 'hemicyptophytes'.¹ The winter buds begin to unfold during March, and each produces several radical leaves. In a vigorous adult plant such a bud may subsequently form an erect flowering shoot, with cauline leaves. In young plants, or buds of less vigour, however, the shoot does not elongate, but remains prostrate. In the latter case it continues to form radical leaves till September. These two kinds of shoot will be referred to in this paper as the *erect flowering shoots* and the *non-flowering shoots* respectively.

Text-fig. 1 shows that *S. Ulmaria* is widely spread over the north temperate and colder regions of the Old World. In Great Britain it is a com-

TEXT-FIG. 2. Sympodial rhizome of *Spiraea Ulmaria*, showing four years' growth. The winter bud has unfolded (April), but has not yet formed the erect flowering shoot. Leaves are numbered in order of age. About $\frac{2}{3}$ natural size.

mon plant, being found in the whole of Watson's 112 counties,² whilst its altitudinal range is from the coast to some 2,700 feet above sea-level.³

Itself a characteristic plant of the drier parts of marshes and fens,⁴ the habitat of *Spiraea Ulmaria* is usually where the water content of the soil is considerable rather than excessive. It prefers soils with a high water capacity, such as peat or clay. Provided that its needs in respect to soil moisture are satisfied, it will grow almost anywhere: at the edges of marshes and rivers; in the damper parts of meadows; in roadside ditches; on the sea-coast;⁵ in damp hollows between sand-dunes;⁶ and even in woods, if

the shade is not too dense.¹ It readily colonizes moist ground which has been recently disturbed; and hence frequently establishes itself at the foot of railway embankments, &c.²

§ 5. THE DISTRIBUTION OF PUBESCENCE ON THE LEAVES.

The various British Floras state that the type form of *Spiraea Ulmaria* has pinnate leaves covered with white down beneath. Consequently, in September of 1906 I was surprised to find that the Spiraeas at Wicken Fen varied markedly in this respect. Some leaves were completely hairy on the lower surface; others were glabrous, while all possible transitions were to be found (see Pl. LXXXII). The reasons for this extreme variability were by no means obvious, so a large number of specimens were grown for some years. It was hoped that if any explanation for such a marked phenomenon were forthcoming, it might throw light on the general problem of xeromorphy in marsh plants.

The experiments (confirmed by many field observations) revealed the existence of a regular periodicity in the production of hairs. The rules governing hair formation may now be stated. It should be borne in mind that all the following descriptions refer to the hairy type form of *S. Ulmaria*, and not to its glabrous variety, *denudata*.

(a) *Seedlings*. In all cases the seedlings are glabrous. This applies to every leaf formed during the first year. The plant, if small and weak, may remain in this juvenile glabrous condition for two or more years; though if under favourable conditions, it may form normal hairy shoots in the second year.

(b) *Erect flowering shoots of adult plants*. When a winter bud opens early in the year (about March), the first leaves unfolded are juvenile in type, i.e. they are small and glabrous. After a variable number (usually from 3 to 5³) of these glabrous radical leaves have unfolded, they are followed, about the end of April or the beginning of May, by one or two leaves which are partly hairy. The latter are in turn succeeded, as the flowering shoot elongates and becomes erect, by leaves which are completely covered with hairs on the lower surface.⁴ The pubescence becomes more dense as the erect stem is ascended. (Pl. LXXXI shows all the successive leaves formed on one flowering shoot. Leaves 1-7 are radical, and leaves 8-16 cauline. Hairy parts show white, and glabrous dark.) The plant

¹ Adamson ('12), pp. 358, &c., gives a good account of various *S. Ulmaria* societies in a Cambridgeshire woodland.

² At least some of the other species of *Spiraea* mentioned in § 3 are also swamp plants: e. g. *S. salicifolia* and *S. tomentosa*. See Britton and Brown ('97), p. 196.

³ I have seen as many as twelve, but this is quite exceptional.

⁴ The flowering shoot usually begins to elongate about the middle of May, by which time most plants already show some hairy leaves.

generally flowers towards the end of July (or earlier on drier soils), by which time all the leaves on the shoot are unfolded.

Thus the leaves of the erect flowering shoots vary markedly in hairiness, according to both their time of unfolding and their position on the stem.¹

(c) *The non-flowering shoots of adult plants* exhibit an even more remarkable periodicity in hair formation. They commence about March by unfolding glabrous leaves in precisely the same way as the erect flowering shoots. Similarly, too, as the season advances, the successive leaves are *increasingly hairy*. This goes on till about midsummer (the actual time appears to vary, possibly with the kind of season, from about the middle of June to the middle of July), when the process is reversed. The new leaves unfolded are now *decreasingly hairy*, until finally glabrous leaves are once more produced on the approach of autumn. The actual number of hairy or partly hairy summer leaves formed on a given shoot appears to depend on its size and vigour. If a shoot is fairly large and vigorous, it may form only a few glabrous leaves, but a number of nearly or completely hairy ones. On the other hand, a small, weak shoot may produce only one or two slightly hairy leaves; all the rest formed during the year being glabrous.²

To sum up, the successive leaves on an erect flowering shoot exhibit a continually rising curve of hairiness, the spring leaves being glabrous and the summer leaves hairy. On the other hand, the non-flowering shoots have glabrous spring and autumn leaves, and (if the plants are sufficiently vigorous) more or less hairy summer ones. In other words, the curve of hairiness rises from zero in spring-time to a maximum about midsummer, once again falling to zero towards autumn.

(d) *Distribution of hairs on the partly hairy leaves.* The series of leaves shown on Pl. LXXXII and LXXXIII, selected from various non-flowering shoots, serves to illustrate the rules governing the localization of hairs on leaves which are not completely hairy. In each leaf, taken as a whole, it is readily seen that *hairiness decreases from above downwards*. Out of many hundreds of leaves examined, I have only met with one or two partial exceptions to this rule. If individual partly hairy leaflets are considered, it is equally obvious that the distribution takes the form of a *marginal band of hairs* (Pl. LXXXII, leaves 2, 3, 5, 7, 11, &c., and Pl. LXXXIII, leaves 1 and 2); with sometimes, but by no means always,

¹ Ascherson and Graebner ('00-'05), p. 438, state that the radical leaves are less hairy than the cauline in certain varieties of *S. Ulmaria*.

² Curious cases are sometimes met with in which a fairly vigorous shoot shows no sign of elongating to a flowering shoot at the usual time. It proceeds to behave like a non-flowering shoot, showing first increasing, then decreasing, hairiness. A few weeks later it suddenly alters its behaviour again; the leaves once more exhibit increasing hairiness, and a belated flowering shoot is formed.

additional bands running inwards from the margin, between the main veins (Pl. LXXXII, leaves 4, 6, 9; also Pl. LXXXIII, leaf 3).¹ The partly hairy leaves on the erect flowering shoots also follow the same rules (Pl. LXXXI, leaves 6, 7, and 8). All the leaves photographed (Pl. LXXXI-LXXXIII) are mature. The hairs would not spread subsequently from the margin over the entire surface.

Broadly speaking, the rule followed in every case is that when a leaf or leaflet is only partially hairy, the hairs are localized principally at those points which are most remote from the main water supply. This point will be dealt with later.

§ 6. COMPARISON WITH OTHER HAIRY PLANTS.

Spiraea Ulmaria is not unique in this curious periodic production of hairs, though it is the most striking case I have seen. Specimens of *S. vestita*, Wall.,² a species quite distinct from *S. Ulmaria*, though closely allied to it, were examined in the Cambridge University and Kew Herbaria. The upper leaves are downy, but in both herbaria specimens exist which show that the lower leaves are only partly hairy. In one or two cases the lowest leaf of all is glabrous. Thus this species apparently follows much the same rules as *S. Ulmaria*. I have also grown *Spiraea tomentosa*, L., from specimens kindly sent me by Professor H. C. Cowles, of Chicago, and Professor J. B. Pollock, of Michigan. This is a shrubby form, with small downy leaves. Here, too, as the buds open in the spring-time, there is a similar succession of glabrous, partly hairy, and hairy leaves.

A number of other marsh herbs resemble these species of *Spiraea* in forming small glabrous leaves in spring-time, followed, as the season advances and the erect flowering shoots are formed, by a steadily increasing production of hairs on the later leaves.³ Such are *Epilobium hirsutum*, *Lysimachia vulgaris*,⁴ *Mentha aquatica*, *Valeriana sambucifolia*, *Scabiosa succisa*, *Eupatorium cannabinum*, *Lycopus europaeus*, &c.

But the phenomenon is not confined to marsh plants. I noticed a specimen of *Rubus discolor*, W. and N., growing partly shaded by trees in the New Forest, in which the proximal leaves on the lateral shoots were invariably much less hairy than the distal ones. Again, I examined the cultivated Raspberry (*Rubus idaeus*, L.), without finding any trace of

¹ The distribution is not always quite so regular as shown in the series of leaves photographed; though it is so in most cases. Sometimes an interveinal band is incomplete: in this case its innermost portion is often present as a group of hairs in a fork where two veins meet (Pl. LXXXIII, leaf 2). It will be shown later that hairs are developed also on the main veins themselves. Cf. Renner ('08), p. 128, who states that in many leaves in which the lamina is folded in the bud, both on the midrib and lateral veins, hairs are developed especially on the veins and the edges of the leaf, e.g. *Fagus sylvatica* and *Carpinus betulus*.

² *S. vestita*, Wall. MSS. = *S. Kamtschatica*, var. *himalensis*, Lindl. Cf. Lindley ('41), t. iv, and Hooker ('79), p. 323.

³ Yapp ('08), p. 691.

⁴ Yapp ('09), Text-fig. 1, p. 278.

diminished hairiness in the lower leaves. But Mr. E. J. Salisbury informs me that in the wild Raspberry, when the canes are growing in thick clumps, the lower leaves are considerably less hairy. Specimens kindly sent by Mr. Salisbury confirm his observation.

Thus we are evidently dealing with a widespread phenomenon.

§ 7. SEASONAL DIFFERENCES IN LEAF STRUCTURE.

Various authors have called attention to the periodicity of growth exhibited by shoots.¹ The leaves increase in size and the internodes in length (and also in the length of their cells) from below upwards. Such increase is followed by a corresponding decrease after the maximum is reached (cf. Pl. LXXXI and Text-fig. 5). It has been shown above that a similar periodicity of hairiness obtains in the non-flowering shoots of *Spiraea*

TEXT-FIG. 3. Sections of (A) a 'sun' leaf, and (B) a 'shade' leaf of *Spiraea Ulmaria*. $\times 350$.

Ulmaria. The leaves of the erect flowering shoots, on the other hand, exhibit a more or less continually rising curve of hairiness. It will now be shown that corresponding seasonal differences of structure occur in the successive leaves formed on these erect flowering shoots.²

The possible range of structure may first be indicated. Text-fig. 3 shows sections taken through extreme 'sun' and 'shade' leaves. A is from a cauline leaf of a fully exposed plant, and B from a radical leaf of a plant grown in deep shade and a constantly humid atmosphere (under a bell-glass).³

¹ Moll ('76), Pfeffer ('03), Tammes ('08), Groom ('08), &c.

² The method of investigation was as follows: The successive leaves on selected shoots were preserved in alcohol, care being taken not to remove any leaf from the plant till it was fully mature and several later leaves had unfolded. Sections were taken from corresponding portions of the terminal leaflet. Another portion of the same leaflet was cleared in eau de Javelle and mounted in water as a transparent object. In this state the size and relations of the epidermal, palisade, and other cells could be studied, and the number and size of the stomata ascertained. The cells remain of approximately the same size as during life. The latter point was determined by taking a contact print of a living leaf on photographic paper. The leaf was then treated as above, when it was still found to correspond in size with the photographic print. Thus the number of stomata per unit area given later may be taken as practically the same as in a living leaf.

³ Cf. the figures given in Hesselman ('04), p. 419.

TEXT-FIG. 4. Three leaves from one erect flowering shoot of *S. Ulmaria*, var. *denudata*. The months indicate time of unfolding. Below each leaf are shown successively (a) part of its upper epidermis, superposed on palisade cells, (b) part of lower epidermis, with stomata, and (c) section of leaf lamina. Intercellular spaces are black. Shaded cells are at a somewhat different level to the others. Leaf outlines \times about $\frac{2}{3}$; all other drawings \times 350.

We have seen that two types of leaf (glabrous and hairy), with intermediate transitions, occur on each shoot. As was perhaps to be expected, the glabrous low-growing leaves were found to possess a more or less definite 'shade' structure; while the upper, exposed hairy leaves approximated to the 'sun' type. There is a gradual transition (often fluctuating as regards individual leaves) in structure between the two extremes.

The glabrous radical leaves, which are unfolded about March, have large epidermal cells, with more or less sinuous lateral walls (especially those of the lower epidermis). The cuticle is thin. The stomata are large and relatively few in number. The mesophyll is composed of large, loosely arranged cells, with large and abundant intercellular spaces (Text-fig. 4, leaf 2). As more leaves are unfolded the following progressive changes may be observed. The epidermal cells (both upper and lower) of the successive leaves become gradually reduced in size, and their lateral walls less sinuous. The cuticle of the upper epidermal cells is thicker, though in this plant it is always fairly thin. The stomata become progressively smaller, and at the same time considerably more numerous per unit area.¹ The lower surface of the leaves is more and more hairy. The mesophyll is more compact (especially the upper palisade layer), its cells are smaller, and the intercellular spaces are gradually reduced to a minimum (Text-fig. 4, leaves 10 and 18).

The general question of relation of structure to environment will be discussed later. It may, however, be remarked here, that while the above relative differences were found in the successive leaves of each shoot examined, the actual structure of any given leaf depends partly on its position on the shoot, and partly on the general nature of the habitat. Thus the most lacunar leaves, with the fewest stomata, &c., are the radical leaves of plants grown under conditions of extreme humidity and shade. The converse also holds true (cf. Text-fig. 3). Again, the observed differences depend only to a certain extent on the actual size of the leaf lamina. Thus, a 'shade' leaf has not only a larger surface area, but also larger epidermal cells, fewer stomata per unit area, &c., than a *corresponding* leaf from a plant grown under fully insolated conditions (see Text-fig. 5). On the other hand, if the leaves formed on a single shoot are considered, a curve showing the periodicity in size of lamina would exhibit a very distinct rise and subsequent fall (both sides of this curve are steeper in shade than sun plants, cf. Text-fig. 5). But a curve showing the progressive changes of structure would be a continually rising one. Thus two leaves from opposite ends of a shoot may be approximately equal in size, yet possess a totally different structure (Text-fig. 4).

¹ Dufour ('87), p. 407, states that stomata are more numerous on leaves grown in sun than in shade, while Eberhardt ('03), pp. 151-2, says that in humid air the size of epidermal cells is increased, and the number of stomata decreased, as compared with the effect of dry air; cf. Fig. 4. p. 81.

Some of the more important features may now be dealt with in detail.

(a) *The stomata.* These are slightly raised, even in the more exposed leaves of *S. Ulmaria*, var. *denudata* (Text-figs. 3 and 4). They are for the

TEXT-FIG. 5. Selected leaves from two flowering shoots, to show (a) periodicity of leaf size, (b) difference in actual size of 'sun' and 'shade' leaves, and (c) narrowing of leaflets of upper leaves. Certain leaves of each series have been omitted (see numbers of those selected). In each case the largest and smallest are shown. All $\times \frac{1}{2}$.

most part confined to the lower surface of the leaf. The only exceptions to this are (1) a few at the sides of the larger veins, and (2) groups of very small stomata, which are crowded on the upper surface of the leaf-teeth, immediately above the endings of the more important veins. On determin-

ing the numbers of stomata per unit area, it was at once apparent that an increase occurred in successive leaves. Unfortunately, while the numbers on the glabrous leaves are readily ascertainable, the dense pubescence of the majority of leaves renders accurate counting impossible. Many methods of surmounting this difficulty were tried, but none proved really successful.¹ Finally, the var. *denudata* was used, though this is also hairy to a certain extent. It is from this plant that the only complete series of counts were obtained. A few actual examples may be given.

SHOOT A² (Type form). A 'shade' plant, i. e. grown in ordinary garden soil, under currant bushes, and sheltered by a high wall on the south side. The shoot produced a total of 24 leaves. Of these, the first two were quite glabrous. A few extremely short hairs appeared on the main veins of the *third* leaf. The hairs gradually increased in number and length until the eighth leaf, when it was difficult to count the stomata; above this it was impossible.

Leaf No.	1	2	3	4	5	6	7	8
No. of stomata per sq. mm. ³	221	221	224	226	240	255	302	about 348

SHOOT B (Type form). Grown under distinctly drier and sunnier conditions than A. In all, 14 leaves were produced. Very short hairs again began on the *third* leaf. The stomata could not be counted beyond the sixth leaf

Leaf No.	1	2	3	4	5	6
No. of stomata per sq. mm.	239	283	273	350	360	372

SHOOT C (var. *denudata*).⁴ Grown in a garden, fully exposed to sun. In all, 21 leaves were produced. A very few short, straight hairs appeared on the main veins of the *fifth* leaf. These slowly increased in number and length on the remaining leaves. In this variety, however, the leaves never become densely hairy, though in a few cases stomata counting was somewhat difficult.

Leaf No.	1	2	3	4	5	6	7	8	9	10	11
No. of stomata per sq. mm.	393	303	313	322	313	352	482	440	543	678	807
Leaf No.	12	13	14	15	16	17	18	19	20	21	
No. of stomata per sq. mm.	776	856	945	934	928	1095	1188	1293	1083	1090	

Thus there is a gradual though fluctuating rise in the number of stomata through the successive leaves of the entire shoot. The numbers themselves are worthy of comment. Not only are the absolute numbers of

¹ Hesselman ('04), p. 419, states that he, too, was similarly baffled by this same species.

² The same shoots will also be referred to later as Shoots A, B, and C.

³ The stomata counts, in this and the following cases, were taken from the terminal leaflet, cleared as previously described. As a rule, the numbers represent the mean of ten counts taken from different parts of the leaflet (lower surface only). The larger, and as far as possible even the smaller, veins were avoided.

⁴ The leaves used for Text-fig. 4 are from this shoot.

stomata on the upper leaves extraordinarily high,¹ but the range from about 300 to nearly 1,300 per sq. mm. for different leaves of the same shoot is equally remarkable. It may be that *Spiraea Ulmaria* is exceptional in the latter respect. But it would be worth while comparing the successive leaves of a number of other plants, for if the phenomenon is at all general, the numbers already published for a large number of species² might need considerable revision. The highest number previously recorded appears to be 1,000 per sq. mm. in *Psidium Guyava*, which Parkin and Pearson³ mention as being very remarkable in this respect.

The glabrous autumn leaves resemble the glabrous spring leaves in structure as well as appearance. Thus the number of stomata in the former is usually between 200 and 300 per sq. mm. Further, in the case of tall radical leaves, there is often considerable difference between the upper and lower leaflets, the latter possessing a more pronounced 'shade' structure than the former.⁴ Thus the lower leaflets may be less hairy, and have fewer stomata and more lacunar mesophyll. E. g. the sixth leaf of Shoot A had 255 stomata per sq. mm. on the terminal leaflet, and only 213 on the lowest leaflet. Again, in a partly hairy leaf (the fourth on the shoot) collected at Wicken Fen, the terminal leaflet had 395 stomata per sq. mm.; the second pair of leaflets, 333; the fourth pair, 269, and the lowest pair of all, only 176. In other cases, however, the differences were less than these.

TEXT-FIG. 6. Stomata from different leaves. For description see text. $\times 535$.

But the number of stomata is not the only thing to be considered. From the point of view of transpiration, the size of the stomata, and more particularly of their pores, is as important as their number. Text-fig. 6 shows stomata taken from three different leaves. A is from a radical leaf of a plant grown in deep shade, under a bell-glass, i. e. in saturated air and weak illumination. The pore is widely open. The leaf had an average of 255 stomata per sq. mm. B is from the second leaf of Shoot C, with 303 stomata per sq. mm. Here the pore is smaller, but still much larger than that of C, which is taken from the eighteenth leaf of the same shoot (C),

¹ Shoot C was not unique in possessing such numerous stomata. In all, three shoots of var. *denudata* were examined, and in each case the stomata on the upper leaves exceeded 1,000 per sq. mm. In one shoot 1,252 were recorded, and in another, grown in shade, but otherwise exposed, 1,112.

² Cf. Morren ('63), Weiss ('65), and other authors. Miss Delf ('11), p. 500, has recently recorded a similar rise (from 97.5 to 236.25 per sq. mm.) in the number of stomata on successive internodes of *Salicornia annua*.

³ Parkin and Pearson ('03), p. 443. Jost ('07), p. 38, states that in extreme cases there may be as many as 625 (*Olea*) or 716 (*Brassica rapa*) per sq. mm.

⁴ Boodle ('04), pp. 663-4, records an instance in which the upper, exposed pinnae of a leaf of *Pteris aquilina* had marked xerophytic characters, which were absent in the lower, sheltered pinnae.

with 1,188 stomata (cf. Text-fig. 4). Many of the stomata on the upper leaves had even smaller pores than C. Moreover, abortive stomata, or what appear to be such (Text-fig. 6, D), with no actual pore at all, are very frequently found. These are much more common on the leaves with numerous stomata than on the lower leaves, and have been included in the countings given above.

The question at once arises, so far as the stomata alone are concerned, will the transpiration from the numerous small stomata of the upper leaves be greater or less, per unit area of leaf surface, than that from the fewer but larger stomata of the lower leaves? If very much greater, it would seem possible that any economy of water effected by the production of hairs and other xerophytic devices in the upper leaves might be rendered nugatory by the numerical increase of stomata. Appended below are rough calculations,¹

¹ Unfortunately, the only measurements available at the time of writing this paper are taken from the stomata of leaves fixed and cleared in the manner described above. As, however, the several leaves were treated in exactly the same way, it is probable that the respective sizes of the stomatal pores bear much the same relations to each other as when fully open in nature. Still, the measurements, &c., given must be taken as approximations only.

Regarding the stomatal pores as ellipses, the areas of the pores shown in Text-fig. 6, B and C (i. e. from the second and eighteenth leaves), are 0.0000136 sq. mm. and 0.0000036 sq. mm. respectively. As the second leaf has 303 stomata per sq. mm. of leaf surface, the total area of the stomatal openings amounts to about 0.00412 sq. mm., i. e. 0.41 % of the whole lower surface of the leaf. In the eighteenth leaf, however, which has 1,188 stomata per sq. mm., a considerable number of the stomata are abortive. Moreover, the pores of many of the remainder are smaller than the one figured (see Text-fig. 6, C and D). It has been estimated (roughly) that the number of effective stomata on this leaf may amount to about 80 % of the whole. On this assumption, the total area of stomatal openings would be about 0.00342 sq. mm., or 0.34 % of the lower leaf surface; that is, actually less than in leaf 2.

For calculating the amount of water vapour which could be transpired through the stomata of the two leaves respectively, the formula given by Brown and Escombe ('00, p. 276) for the absorption of CO₂ may be used. It is assumed that the air in the intercellular spaces of the leaves is saturated with water vapour, and the free air outside the leaves two-thirds saturated. The measurements are calculated at 18° C. and 760 mm. The formula in question is:

$$Q = \frac{k p \cdot A \cdot y \cdot 3,600}{l + x}$$

where Q = the amount of water vapour (in c.c.) transpired per hour per sq. cm. of lower leaf surface, and

(1) in the case of leaf 2:

k = diffusivity of H₂O vapour at 18° C. in C.G.S. units = 0.248.

p = difference of pressure of H₂O vapour inside and outside leaf, in atmospheres = 0.0067.

A = area of pore of stoma = 1.36×10^{-7} sq. cm.

y = number of stomata per sq. cm. = 30,300.

l = length of stomatic tube = 0.0010 cm.

$x = \frac{2}{3}\pi \times$ diameter of circle of same area as elliptical pore of stoma = 0.00016 cm.

Hence, $Q = 21.2$ c.c. of water-vapour transpired per hour per sq. cm. of lower leaf surface.

(2) For leaf 18, the differences will be:

$A = 3.6 \times 10^{-8}$ sq. cm.

y (reckoning 80 % of the total number as effective) = 95,000.

$l = 0.000714$ cm.

$x = 0.000084$ cm.

In this case, $Q = 25.4$ c.c. of water vapour transpired per hour per sq. cm. of leaf surface.

It will be seen that there are several possible sources of error in such a calculation as the above.

from which it seems probable that the difference is not great. Thus, considering the stomata alone, and under certain specified conditions (the same for the two cases), it is calculated that for Shoot C transpiration from the second leaf (Text-figs. 4 and 6, B) might amount to 21.2 c.c. per hour per sq. cm. of leaf surface. From the eighteenth leaf (Text-figs. 4 and 6, C) the corresponding amount would be 25.4 c.c. per hour per sq. cm. The difference is not very pronounced; so as the upper leaves possess a dense covering of hairs, more compact mesophyll, &c., it may safely be asserted that, in spite of the numerous stomata, they are, on the whole, distinctly more xerophytic than the lower leaves (see § 13). The argument here is from leaf structure alone; the ultimate test is of course the measurement of actual transpiration (see § 12).

(b) *Thickness of leaves, &c.* The leaves of *Spiraea Ulmaria* are fairly thin, varying in total thickness (excluding the hairs) from about 78 to 140 μ . Curiously enough, the thickest leaves on a shoot are invariably the glabrous spring leaves. In these the individual cells are large and loosely arranged. On passing up the stem, the successive leaves show a gradual shrinkage in the size of these cells,¹ which at the same time become more tightly packed together (see Text-fig. 4). The leaves thus exhibit a progressive reduction in thickness. The upper leaves, in fact, may almost be said to be shrunken miniatures of the lower. This of course applies to structure, not to surface area of the lamina. It is chiefly in this variation in size of the individual cells that the plasticity of the leaves of *Spiraea* consists, rather than in any marked change in the number of layers comprising the leaf, or the proportions assumed by the various tissues. There are, however, some changes in these proportions, which may now be instanced, and a few average measurements given (in μ).

		Total thickness of leaf, between veins.	Depth of cells of upper epidermis.	Depth of cells of lower epidermis.	Depth of palisade.	Depth of spongy mesophyll.	Ratio of palisade to spongy mesophyll.
SHOOT A (referred to above)—grown in shade:							
Leaf No.	2	138.0 μ	22.0 μ	15.5 μ	54.5 μ	46.0 μ	1.2 : 1.0
"	18	78.0	15.5	8.0	31.0	23.5	1.3 : 1.0
SHOOT B—grown in light of moderate intensity:							
Leaf No.	2	140.0	19.5	15.5	60.0	45.0	1.3 : 1.0
"	12	104.0	18.0	8.0	47.0	31.0	1.5 : 1.0
SHOOT C—fully insolated:							
Leaf No.	2	135.0	19.5	15.5	57.0	43.0	1.3 : 1.0
"	18	80.5	17.0	8.0	31.0	24.5	1.3 : 1.0

These figures illustrate the general shrinkage referred to above. Further, the lower epidermal cells decrease in depth in the upper leaves,

But it is probable that the difference in transpiration could not be very much greater, and might even be considerably less than that calculated here.

I am indebted to Professor G. A. Schott for assistance in making this calculation.

¹ This has already been noted for the epidermal cells and stomata.

much more than those of the upper epidermis (cf. also the sections and surface views in Text-fig. 4). The latter cells remain relatively large in the upper, exposed leaves, especially at the leaf margins.

(c) *Palisade tissue*. The above table shows that the ratio of the total depth of the palisade *tissue* to that of the spongy mesophyll is remarkably constant. The variation, however, in the ratio of the length of a palisade *cell* to its breadth is considerably greater. As one would expect, the palisade cells of 'shade' plants tend to be relatively shorter and broader than those of 'sun' plants. In addition to this, in an individual leaf, those palisade cells which are most remote from the larger veins are relatively longer and narrower than those situated near to the veins. Again, taking a lower and an upper leaf from each of the three shoots previously used, we get the following average measurements (expressed in μ):

	<i>Length of palisade cell.</i>	<i>Breadth of palisade cell.</i>	<i>Ratio of leng to breadth.</i>
SHOOT A—shade:			
Leaf 2 (a) near vein . . .	30.0 μ	15.5 μ	1.9 : 1.0
(b) remote from vein	32.0	11.5	2.8 : 1.0
Leaf 22 (a) near vein . . .	19.0	9.5	2.0 : 1.0
(b) remote from vein	18.5	6.5	2.8 : 1.0
SHOOT B—moderate sun:			
Leaf 4 (a) near vein . . .	27.5	9.5	2.9 : 1.0
(b) remote from vein	35.5	8.0	4.4 : 1.0
Leaf 10 (a) near vein . . .	24.0	8.5	2.8 : 1.0
(b) remote from vein	31.0	7.0	4.4 : 1.0
SHOOT C—full sun:			
Leaf 2 (a) near vein . . .	30.0	12.5	2.4 : 1.0
(b) remote from vein	36.5	10.0	3.6 : 1.0
Leaf 18 (a) near vein . . .	20.0	9.5	2.1 : 1.0
(b) remote from vein	24.0	7.5	3.2 : 1.0

This table shows clearly (1) that the actual dimensions of the palisade cells are less in the upper than the lower leaves; (2) that the palisade character is best developed at some distance from the larger veins;¹ and (3) that the palisade character is least marked in shoots grown under shade conditions.

§ 8. DEVELOPMENT OF THE LEAVES, AND TIME OF ORIGIN OF THE HAIRS, PALISADE CELLS, &c.

In order to appreciate the effect of environment on the production of hairs, it is necessary to follow to some extent the development of the leaves themselves. Comparatively little appears to have been written on the later stages of leaf development.² A brief account will therefore be

¹ Stahl ('83), p. 35, records the same fact for the sun leaves of the Beech and the Bilberry. This is analogous to the development of the interveinal bands of hairs in partially hairy leaflets.

² Goebel ('05), p. 302 et seq., and others have described the distribution of growth during development, &c. The former points out (p. 305) that 'in general, parts which have the earlier functions to perform appear the earliest'. Mer ('83), p. 111, has given a very brief account, unaccompanied by figures, of the order of development of the tissues of the lamina itself.

given of the order and time of appearance of certain of the tissues of which the lamina is composed.

If a winter bud of *Spiraea Ulmaria* be examined about November, it will be found that the stipular bud-scales are well developed. The most advanced foliage leaves (the glabrous ones of the following spring), however, have only reached a stage approximately equivalent to that shown in Text-fig. 7 (this figure is taken from a hairy leaf). The leaves remain practically in this condition throughout the winter, and are little further developed by the following March, when the bud begins to expand. Multicellular mucilage hairs are abundant, especially on the upper surfaces of the veins. But the long cutinized hairs¹ which form the characteristic pubescence of the later leaves are at this stage absent from the entire bud. It is

TEXT-FIG. 7. Section through part of a young developing leaf, while in the bud. The still meristematic portions (i. e. the interveinal parts of lamina) are shaded. $\times 360$.

important to notice that *few, if any, of these cutinized hairs are developed in the bud until after the first foliage leaves have expanded and become functional.*

The development of one of the hairy leaves may now be followed. In every case the larger veins are the first parts of the lamina to develop, and are relatively large and well differentiated at a time when the rest of the lamina is still meristematic (see Text-fig. 7). On a leaf such as this, which is destined to become hairy, the first hairs are formed early. They appear

¹ At least three kinds of hairs occur on the leaves of *Spiraea Ulmaria*: (1) capitate mucilage hairs, which appear to function mainly in the bud (in *Spiraea* they wither soon after the leaf expands); (2) short bristly hairs found scattered on the upper surface and at the margins; and (3) the long, unicellular, twisted, cutinized hairs, of which the pubescence clothing the lower surface of the leaves is composed. It is the last kind which is to be understood when 'hairs' are referred to in the remainder of this paper.

on the larger veins at approximately the same time as the protoxylem, and while the leaf is still completely enclosed in the bud (Text-fig. 7). At this time the remainder of the lamina is meristematic, though the upper and lower epidermis and several layers of mesophyll are distinguishable.

A somewhat later stage is diagrammatically represented in Text-fig. 8, A. The first seven leaves of the shoot had expanded, but the leaf figured was still completely enclosed in the bud. The interveinal parts of the lamina

TEXT-FIG. 8. A, transverse section through part of an apical bud, showing several leaflets of a single developing leaf. Meristematic portions shaded black. B, a single leaflet just emerged from the bud. C, a still later stage. All $\times 16$.

are developing, and in consequence assuming a looped appearance. They are still meristematic, and as yet bear no hairs. The mesophyll is undifferentiated, and there are neither stomata nor intercellular spaces. The smaller veins have not yet been formed. In the main veins the protoxylem alone is lignified, but the veinal hairs are now so numerous that they form a fairly dense packing below and between the veins.

Text-fig. 8, B is taken from the terminal leaflet of the ninth leaf of the

same shoot as 8, A. This leaf had emerged from the bud, and so was in contact with the outer air. It was a little further expanded than leaf 6 in Text-fig. 2. By this time more xylem tracheae have matured, and many of the finer veins, also bearing hairs like the main veins, have been differentiated. Many stomata have appeared, and also intercellular spaces in the mesophyll, but the latter are small, and few of the former quite mature. The uppermost layer of mesophyll has begun to take on the character of palisade tissue (this is most marked at the tops of the loops), and in places even a second row of palisade cells has begun to form. Thus at this stage, i. e. very soon after the leaf emerges from the bud, and before it is fully expanded, all the chief tissues are recognizable. But the leaf has not as yet attained either its full size or thickness.

A still later stage is seen in Text-fig. 8, C, which represents a section through the lowest leaflet of the same leaf as 8, B. (N.B.—The leaflets, like the leaves, develop and unfold in regular acropetal succession; see Text-fig. 2, leaf 5.) The leaf has now nearly reached its final thickness. The smallest veins are present, also the cuticle and two layers of palisade. The stomata are more mature and the intercellular spaces larger.

The ultimate degree of expansion of the cells and tissues, and also the question of whether the lamina shall become flat or remain more or less crinkled or folded, depends chiefly on the external conditions.

The general distribution of pubescence on the leaves has been discussed earlier in this paper. It is now clear that the earliest hairs appear on the main veins, while the leaf is still in the bud. Subsequently, when the leaf is emerging, or has just emerged from the bud, the next hairs to be formed are those on the finer veins at the leaf margins or between the main veins; that is, on those parts most remote from the main veins, and which are the first to be exposed to the air as the leaf unfolds.¹ Development of the pubescence may now be arrested, as in the partly hairy leaves or leaflets; or it may proceed further until even the finest veins are covered with hairs. In many cases hairs are even formed on the ultimate parenchyma 'islands' bounded by the finest veinlets.

To sum up, the main veins of the lamina, together with the hairs they bear, reach a high state of development in the bud. On the other hand, the hairs on the finer veins, and those which occur over the parenchyma 'islands', only appear when the leaf has emerged from the bud; i. e. when some parts of it are already in direct contact with the outer air. This is also true of the palisade tissue, the intercellular spaces of the mesophyll, the cuticle, and the stomata.

We are now in a position to discuss :

¹ In the case of the interveinal bands of hairs, it is the *upper* surface which is most exposed, while the hairs are actually developed on the *lower*. Cf. Text-fig. 8, B.

§ 9. THE EFFECT OF ENVIRONMENT ON THE PRODUCTION
OF HAIRS AND PALISADE CELLS.

(a) *Historical.* Many of the older observers noticed that plants not infrequently varied in hairiness according to habitat. Thus Linnaeus¹ mentioned *Plantago Coronopus* as being 'in humido foliis glabris integris, in sicco hirsutis dentatis'.¹ De Candolle² said that lymphatic (i. e. non-glandular) hairs 'are in general rare in plants which grow in the shade, or in rich and moist places'; while 'they are more abundant, generally, in those which grow in warm and dry places, much exposed to the sun'. Kraus³ instanced potato shoots as being less hairy or even glabrous when grown in very moist air than in dry air.

During the last thirty years a considerable literature has arisen, dealing with the influence of external factors, not only on the development of epidermal structures such as hairs, stomata, &c., but also on the differentiation of the mesophyll, and especially of the palisade tissue. One of the earlier works of this period was the classic paper by Stahl,⁴ published in 1883, in which the action of light is regarded as the factor determining the structure of 'sun' and 'shade' leaves.

In the same year Mer⁵ found that light and also dry air favour the production of palisade tissue, while shade and humidity produce the reverse effect. The same is true also of hairs on aerial stems.⁶ A well-watered soil hindered the formation of both stem- and root-hairs, while both were produced if the soil were drier.

Vesque and Viet⁷ proved that light, accompanied by more or less dry air, increases the development of palisade tissue, and the number and length of hairs on leaves. In a later paper, Vesque⁸ says that the result of a large number of cultural experiments shows that a marked development of palisade tissue can always be referred to the action of transpiration.

Kohl⁹ stated that changes of relative humidity in the atmosphere surrounding growing organs are capable of inducing the formation or suppression (as the case may be) of palisade cells. Again, he found¹⁰ that in the case of hairy species of Compositae or Labiatae, not only the number of hairs, but also their length, is determined to a great extent by the amount of transpiration from the organs themselves. The less the transpiration, the fewer and shorter the hairs.

Dufour¹¹ found that the dimensions of leaves developed in light of high intensity are greater in all respects (and the palisade tissue is more pronounced) than those of leaves grown in shade.

Eberhardt¹ showed that plants grown in dry air tend to be more hairy, and their leaves thicker (in consequence of the great development of palisade), than those grown either in normal or in very humid air.

Zinger,² in an interesting paper on some European species of *Camelina*, shows that in *C. microcarpa* and the different varieties of *C. sativa*, a gradual transition from a xerophytic to a hygrophytic type can be traced, with marked differences in respect of palisade tissue, hairiness, &c. These differences are strictly correlated with the conditions of illumination and moisture in the respective natural habitats.

Lesage³ found that when plants were grown in a saline soil, or solutions in which the salts reached a certain concentration, they developed more palisade than when grown in ordinary soil or very dilute salt solutions. Later⁴ he subjected growing plants to periodic variations of atmospheric pressure. Those which had been exposed to the periodic lowering of pressure had (if leaves of the same age, &c., were compared) more marked palisade than the control plants grown under ordinary air pressure.

Similar results to those of the above-mentioned authors have been obtained by other experimenters.⁵

Although the question of root-hairs scarcely comes within the scope of this paper, it may be mentioned that their formation also is largely dependent on the water supply. Schwarz⁶ found that no root-hairs were formed in very wet soil. Further, that as the water content of the soil decreased, root-hairs increased correspondingly. Finally, however, when the soil attained a certain degree of dryness, root-hairs were again suppressed.

If the above results be analysed, it will be noticed⁷ that *in general*,⁸ both palisade cells and the epidermal hairs of aerial shoots (and to some extent at least, root-hairs) are most fully developed under conditions which either promote transpiration or hinder absorption; namely, under conditions which impose on the plant some necessity for increased economy of water.

The results of the writer's own work on *Spiraea Ulmaria* and other marsh plants may now be given.

(b) *Field observations on Spiraea*, &c. It has been stated above that even the type-form of *Spiraea Ulmaria* produces both glabrous and hairy

⁸ Of course plants vary much in plasticity. Stahl ('83), pp. 5-10, instances cases of pronounced shade and sun plants which have little or no power of adapting themselves to sunny and shady habitats respectively.

leaves. As a rule, these occupy in nature the more shady and humid, and the sunnier and drier positions respectively. This is true as regards both time and space; i.e. whether we consider the leaves in relation to the annual march of the seasons, or the vertical distribution of humidity and light in the vegetation. The curves in Text-fig. 9 represent the mean evaporation and light intensity for several years. Both curves rise to a maximum in July and then fall steadily towards autumn. Further, I have shown that in marshes there is a rapid rise in the average evaporation as the

TEXT-FIG. 9. Curves of mean evaporation [continuous line] and light-intensity [broken line]. The former shows the mean monthly evaporation for twenty-five years in London [see Mill ('10), p. 56]. The latter represents the mean maximum light-intensity at Vienna for three years only [taken from Wiesner ('07), p. 52].

successive strata of the vegetation are ascended.¹ Lately, I have also determined by experiment that the same is true of light-intensity.

If the degree of hairiness could be conveniently represented by means of curves, it would be found that the curves of actual hairiness in *Spiraea Ulmaria* follow very closely the mean curves of evaporation and light-intensity, both in space and time. Thus, (1) in the erect flowering shoots, the glabrous spring leaves are formed near the ground, at a time of

¹ Yapp ('09), p. 287 et seq. Dachnowski ('11), p. 146, has recently confirmed my evaporation results, in the case of the bog vegetation of Cranberry Island.

year (about March) when the average evaporation is slight and the light-intensity low. As the season progresses and the curves of evaporation and light rise steeply (Text-fig. 9), and further, as the shoot itself grows upwards into drier and lighter strata, the leaves exhibit continually increasing hairiness (Pl. LXXXI, and Text-fig. 10). (2) The curve of hairiness of non-flowering shoots rises steadily to June or July; subsequently falling till glabrous leaves are once more reached in autumn. This corresponds very closely indeed to the curves in Text-fig. 9. Finally, (3) the same general relations obtain even in the case of individual partly hairy leaves. Just as

TEXT-FIG. 10. Diagrammatic section through a group of plants of *Spiraea Ulmaria*, showing relation of glabrous and hairy leaves to strata of varying humidity. Glabrous leaves, black with white veins; hairy leaves, white with black veins. (June.) \times about $\frac{1}{2}$.

successive leaflets occupy higher and less humid levels, so they exhibit increasing hairiness from below upwards (Pl. LXXXII and LXXXIII, and Text-fig. 10).

The same relations are broadly true of other hairy marsh plants,¹ and also for the structural variations described earlier in this paper. These field observations are at once seen to agree with the general experimental results quoted above. They suggest considerable responsiveness, on the part of *S. Ulmaria* and other plants, to even slight variations in the environment.

¹ See § 6; also Yapp ('08), p. 691.

(c) *Experiments on Spiraea, &c.* In the first instance I was easily able to confirm the researches of Vesque and Viet, Kohl, and others,¹ on the effect of humidity on hair production in certain plants. E. g. in *Epilobium hirsutum* and *Mentha aquatica*, the formation of hairs was completely inhibited by growing the plants in a damp atmosphere; the converse being true of a dry atmosphere. The case of *S. Ulmaria*, however, proved to be somewhat different. A large number of plants of this species were grown, some at the Cambridge Botanic Garden (through the kindness of Mr. R. I. Lynch), and others at Aberystwyth. A wide range of habitats was secured by varying the following factors: (1) soil, (2) soil-moisture, (3) humidity of air, (4) light-intensity, and (5) degree of exposure or shelter.²

The experiments extended over a period of four years, so that while the same individual plants were used, several generations of shoots were observed.

On the whole, the effect of varying habitats on the hairiness of *Spiraea Ulmaria* was less than had been expected, the character being apparently one of a certain degree of fixity. Differences of soil, soil-moisture, light-intensity, and exposure produced no effect whatever on the normal periodicity of hair formation. Under no conditions could the normally glabrous spring or autumn leaves be induced to become hairy,³ while in all cases the upper leaves on the flowering shoots produced hairs.

But though external conditions had comparatively little controlling effect on the actual formation of hairs, in certain instances they exercised considerable influence on the frequency, and especially on the length of the hairs. This was the case with shoots grown under glass shades, i. e. in still, humid air. When (a) these were exposed to full sunlight,⁴ the effect was

¹ Vesque and Viet ('81), Kohl ('86), &c.

² At Cambridge the plants were potted in either (a) pure peat, (b) loam, or (c) a mixture of peat, loam, and sand. The pots were then divided into two sets. One set was placed in a fully insulated part of the garden, the other in a shady spot, never reached by the direct rays of the sun. Soil-moisture was varied by submerging (partly or completely) certain pots in water. Others had good drainage, but were copiously watered, while a third set were only watered at infrequent intervals. A final differentiation of habitat consisted in placing glass shades over some of the drained and also undrained pots. The aerial shoots were thus developed in a still, humid atmosphere, under varying conditions of light, soil-moisture, &c.

At Aberystwyth plants were grown in various situations in a garden, some in deep shade, others in the open, &c. Others were kept in the laboratories, and also on the roof of the College, which is situated close to the sea, and exposed to great gales of wind.

³ Cf. Vesque ('84), p. 21, who says that he had never succeeded in inducing a single hair to form on a really glabrous plant: though theoretically he thought it should be possible, as 'les plantes glabres ont dû précéder historiquement'.

⁴ As determined by experiment:—

(1) The shade plants (b) were grown under light-intensity = 1.0

(2) " sun " (a) " " " " " = 4.5

(3) In the free air outside the glass shade (a) " " " " " = 4.9

Thus, a little light is cut off by the glass shade, or by the moisture which condenses on its

comparatively slight; the leaves appearing to be nearly as hairy as those grown in the open. The hairs, however, were distinctly shorter. *The greatest diminution of hairiness was induced when low light-intensity was superadded to stillness and humidity of the air.* Thus (b) flowering shoots grown in weak light under glass shades still produced more or less hairy leaves, but the hairs were straight and very short. The lower cauline leaves appeared to be more easily influenced than the upper.

A curious inhibition of hairs occurred on plants which had been protected from cold, &c., during the winter. A number of plants were kept indoors continuously for some years, in the Cool Fern House and the Cool Pit at Cambridge, and the Laboratories at Aberystwyth. In all cases the rhizomes of these plants remained horizontal, and each year produced a crop of radical leaves of the glabrous spring or autumn type.¹ In a few instances patches of hairs occurred on a leaf, but for the most part the leaves were entirely glabrous. On the other hand, plants brought indoors towards the close of the winter produced normal erect flowering shoots with hairy leaves.

Another experiment which resulted in decreased hair formation is recorded on p. 847.

Spiraea Ulmaria, var. *denudata*, Boenn., like the type form, commences in spring-time by forming glabrous leaves. These are followed by increasingly hairy leaves as the erect flowering stem elongates. But here the hairiness begins somewhat later, and is chiefly confined to the larger veins of the leaves; the general pubescence, so characteristic of the type, being absent. In nature I have found many transitional forms intermediate between *S. Ulmaria* and its variety *denudata*.² Thus individuals are sometimes found with an unusual number of glabrous radical leaves. In others, one, two, or even more of the cauline leaves may also be glabrous. Finally, plants occur in which only the leaves at the extreme top of the flowering shoot are markedly hairy. But in all cases, whether in the type, or its var. *denudata*, or in any of the numerous intermediate forms, the lower leaves are glabrous. On the other hand, the cauline leaves are (in varying degrees) increasingly hairy as the flowering shoots are ascended.

inner surface. The method used was based on the following: If a solution of potassium iodide be mixed with dilute sulphuric acid, and exposed to light in the presence of oxygen, the iodine liberated is a measure of the total light received during the time of exposure (see Manchester ('93), p. 88 et seq.). This method, to which Professor Weiss called my attention, has the advantage of recording the *total light received*, and not merely the intensity at a given moment. Like other photometric methods, it has the disadvantage of recording only the chemically active rays. For a discussion of the utility of such methods for botanical researches, see Rübél ('08), pp. 5-7.

¹ Gates ('10), p. 677, similarly found that the internodes of *Oenotheras* grown in a tropical greenhouse did not elongate, the plants thus remaining (for the entire time of the experiment, i.e. twenty months) in the rosette condition. Cf. also the experiments of Klebs ('10), p. 552 et seq., on *Sempervivum*.

² Trow ('11), p. 58, also states that *S. denudata* occurs in Glamorganshire, together with many intermediate forms connecting it with the type.

The var. *denudata*, as well as several intermediate forms, has been grown for some years. The results show that the individual, in its successive generations of shoots, retains to a considerable extent its peculiar characteristics, even under varying habitat conditions. For example, *S. denudata* has never been induced to become really hairy, even when grown in dry, sunny, exposed situations.

The results recorded in this section show that (1) the production of glabrous and hairy leaves in *Spiraea Ulmaria* and certain other marsh plants closely follows in nature the mean curves of evaporation and light-intensity; but that (2) *S. Ulmaria* possesses a more limited plasticity, in respect to hairiness, than that exhibited by such species as *Mentha aquatica*, &c.

§ 10. THE LOCALIZATION OF WITHERING IN LEAVES EXPOSED TO WIND, ETC.

Before discussing the causes of hair formation, certain parallel phenomena must be mentioned. As stated above (p. 820), the partially hairy leaves and leaflets of *Spiraea* exhibit a definite localization of the hairs (cf. Pl. LXXXII and LXXXIII). It was early noticed¹ that when *Spiraea* plants with glabrous leaves were exposed to winds sufficiently strong to cause partial withering, the distribution of the withered parts coincided very nearly with the distribution of hairs on the partly hairy leaves of the same species. Exposure withering thus begins round the margins of the leaflet, and sometimes, though not always, extends inwards in the form of bands between the main veins. Subsequently observations were made on the localization of withering in the leaves of many other plants. These, which for the most part confirm the results of Schröder,² published in 1909, may now be summarized (cf. Text-fig. 11).

Leaves which are allowed to wither naturally in still air lose their colour gradually, and either more or less uniformly or else irregularly. On the other hand, the effect of exposure to strong winds, &c., is to cause first a marked withering of projecting apices, e.g. the apex in linear leaves,³ &c., leaf-teeth, or the various tips of lobed leaves (see Text-fig. 11, A, B, and E). Next, in other than linear leaves, the withering extends round the margin of the leaf, and sometimes, though by no means always (even the same species may vary in this respect, cf. Text-fig. 11, C and D), between the larger veins (Text-fig. 11, B-G).⁴ The process may now stop, or it may

¹ Yapp ('08), p. 691.

² Schröder ('09), pp. 85, &c. Apart from this paper the literature on the withering of leaves is scanty. Hansen ('01), p. 32, and ('04), p. 34, calls attention to the withering of leaf apices and margins through wind. Hasenclever ('79), and Oliver ('93), p. 22, show that acid gases will cause discoloration of the apices and margins of leaves. Cf. also Stahl ('09), pp. 134-5.

³ Cf. Yapp ('08, second paper), p. 65.

⁴ My attention was called by Professor F. W. Oliver to the exceptional case of *Polygonum*

TEXT-FIG. 11. To illustrate localization of withering in leaves exposed to wind, &c. Withered portions, black with white veins; uninjured parts, white with black veins. A, *Plantago lanceolata*; B, *Quercus Robur*; C and D, *Fagus sylvatica*; E, *Crataegus Oxyacantha*; F, *Populus* sp.; G, *Rosa* sp.; H and J, *Polygonum cuspidatum*. J is a section through an unfolding leaf: the black parts here are not yet withered, though they may wither later. A-H, $\times \frac{2}{3}$; J, $\times 4\frac{1}{2}$.

continue until only the tissue immediately surrounding the larger veins remains green;¹ finally this too may wither and die.

Further, a similar localization is seen in other connexions. Thus anthocyan in young leaves in spring-time is frequently confined to the tissues at the apex of the leaf, round the margins, and between the larger veins.

Lidforss² figures leaves of *Viburnum Tinus*, in which certain portions have been killed by frost. These portions are the margins, and to some extent the interveinal regions. On one occasion the present author noticed an autumn leaf of *S. Ulmaria* which had been injured by frost. Not only did the frozen portions show a similar localization in the individual leaflets, but the different leaflets exhibited decreasing injury from above downwards (cf. the hairiness described on p. 820).

Again, Professor T. H. Machbride, of Iowa, told me in 1909 that *Myxomycetes* often confine their attacks to just these same regions of a leaf.

It is obvious that those regions of the leaf lamina which show a special tendency to form hairs (in *Spiraea*), to wither on exposure to strong winds, &c., &c., are physiologically different from the remaining parts. So far as their water supply is concerned, it may be pointed out that they are usually thinner and more exposed than the parts immediately surrounding the larger veins. They are thus more liable to lose water. Further, they are themselves just the regions of the lamina which are most remote from the water supply coming up from below and passing along the main veins.

§ II. THE CAUSES OF THE FORMATION OF HAIRS AND PALISADE CELLS.³

Hairs on aerial shoots and palisade cells have a good deal in common. Both are elongated in a direction more or less at right angles to the surface of the organ which bears them. The production of both is favoured (at least in many cases) by the same external conditions (see § 9). Root-hairs

cuspidatum. If in exposed situations, the leaves of this plant are often marked in the spring-time with red bands, parallel to the midrib, and therefore crossing the larger lateral veins. Later, these red bands may disappear, or, if windy weather ensues, the tissue may wither and actual lesions occur (Text-fig. 11, H). This and other Polygonaceae (e.g. *Rumex* spp.) are the only instances I have seen in which the withered areas cross the larger veins, instead of lying between them. It is to be noted that the injury occurs in those parts which are exposed during the unfolding of the revolute leaves (Text-fig. 11, J). If withering is delayed until the leaf is mature, it is then localized round the margins in the normal manner.

¹ In certain cases, e.g. leaves of *Acer*, *Populus*, &c., fallen leaves may be found with the larger veins dead and brown, and the interveinal tissues green. This is the exact converse of exposure withering. It is due, so Mr. G. Massee informs me, to the action of certain parasitic Fungi, which attack only the leaf veins.

² Lidforss ('07), Taf. I.

³ A short paper on this subject was read at the Portsmouth meeting of the British Association. Yapp ('12), p. 565.

also may to some extent be included in the parallel. Probably all three elements play an important part in relation to the water supply of the plant (cf. § 12). They may therefore be considered together, though the main concern of this paper is with the leaf-hairs of *Spiraea*.

In the first place, in so far as the plant is plastic, is it possible to determine the nature of the stimulus to which the plant responds by the development of these special elongated cells?

Kraus¹ explained the formation of hairs on potato stems in dry air by supposing that decreasing humidity hindered growth in length. In consequence, said he, turgor increases in the transverse direction, and the epidermal cells grow out in the form of hairs.

Mer² supposed that the appearance of both stem- and root-hairs is due to the accumulation of nutritive substances caused by a slowing down of growth. Vesque³ adopted Mer's view, though he thought it complicated matters to include root-hairs in the hypothesis.

Jungner⁴ suggested a theory respecting the formation of hairs on certain xerophytes of alpine regions, extending it to include those of deserts and salt steppes. Although acknowledging that the plants are exposed to strong evaporation, he assumed that transpiration is depressed during the early stages of leaf development. Consequently the pressure of turgor in the cells is high, and, the air outside being rarified, the turgid cells grow out in the direction of least resistance.

Turning now to theories of palisade formation, Stahl⁵ supposed that intense light retarded the growth in length of the veins of developing leaves. The young assimilating cells then expand in the only direction possible (i.e. that perpendicular to the leaf surface), and in consequence assume the form of palisade cells.

Mer⁶ attributed a marked development of palisade cells to active nutrition resulting from the action of light in dry air.

Vesque⁷ regarded transpiration as the chief factor inducing the formation of palisade tissue. Kohl,⁸ who held the same view (and applied it also to hair formation), further pointed out that transpiration affects turgescence, and turgescence regulates the growth of cell membranes.

Of these theories, that of Kohl (and of Vesque so far as palisade cells are concerned) agrees best with the known facts (cf. § 9). All the evidence available suggests that any marked development of these peculiar elongated elements is in some way associated with *decreased turgor* rather than the *increased turgor* postulated by Kraus and Jungner. This evidence is as follows:

1. *The experiments of many observers*, which show that in general these

¹ Kraus ('76), p. 153.

⁴ Jungner ('94), pp. 233-4.

⁷ Vesque, l. c., p. 489.

² Mer ('83), p. 115.

⁵ Stahl ('83), p. 34.

⁶ Mer, l. c., p. 112.

elements are developed especially under conditions which either promote transpiration or hinder absorption (see p. 835). For *S. Ulmaria*, &c., in particular, we have seen that in nature the curves of hairiness follow very closely the mean curves of evaporation, &c. It is obvious that such external conditions can only act by inducing internal changes in the cells themselves. Kohl (l. c.) has already suggested that changes of turgor may be important in this connexion.

2. *What may be termed topographical evidence.* It has been shown (§§ 5 (d) and 10) that under certain conditions the margins of leaves and the thinner areas between the main veins exhibit phenomena which the other parts of the leaf do not. Also that these parts are not only especially liable to lose water, but are situated furthest from the water supply coming up from below. Thus it is easy to understand that any shortage in the supply of water to the leaf will affect these regions first and most severely. That such is the case is evidenced by the localization of withering from exposure to wind.¹ These considerations suggest that the marked localization of hairs (and to some extent palisade cells, see p. 830) in the same regions of the leaf may also be connected with a diminished water supply. This is, of course, especially so in view of the known effects of certain external factors (see 1 above).

3. *Evidence derived from leaf-development in Spiraea.* As regards the hairs, we must distinguish between those formed in the bud and those formed during the unfolding of the leaf (see § 8).

It has been shown that, while the earliest leaves are entirely glabrous, the later ones become progressively more hairy, the hairs on the larger veins being formed while the leaf is still in the bud (see Text-figs. 7 and 8). This increasing hairiness of the larger veins of the developing leaves occurs *pari passu* with the general increase of transpiration from the shoot. The latter is of course due partly to the increase of transpiring surface as more leaves are unfolded, and partly to the march of the seasons. Knowing the effect in general of a dry habitat on hairiness, it is difficult to avoid the suggestion that this increase of hairiness may be connected with a diminution of the water supply to the apical bud. This may readily be brought about by a partial deflexion of the water current into the continually increasing number of mature leaves. In this way the cells of the young developing leaves will find it increasingly difficult to maintain themselves in a complete and constant state of turgor. If this be so, it may be regarded as another case of what Wiesner² has called 'correlative transpiration'. Under this term he includes all cases in which strongly transpiring organs deprive others (which transpire little or not at all) of water. Such displacements of water not infrequently bring about striking results. Thus

¹ Hansen ('04), p. 43, &c., discusses the withering of leaves as a result of withdrawal of water by wind.

² Wiesner ('05), p. 477 et seq.

Wiesner (l. c.) observed the production of anisophylly in *Aesculus* under the influence of correlative transpiration. Again, Schimper,¹ Haberlandt,² and others found that the lower leaves of certain plants yielded up their water to the younger leaves when subjected to drought. Two cases which approach that of *Spiraea* very nearly are recorded by Smith and Balls. Smith³ produced evidence to show that during the day-time transpiration from adult bamboo culms may be so great as to draw off the supply of water from the growing culms, thus slowing down their rate of growth. Similarly, Balls⁴ found that in summer-time in Egypt the growth of the stem of cotton plants and others (e. g. *Helianthus*) was completely arrested whenever direct sun was shining on the plant. This he showed to be due to the consumption of all the available water in transpiration from the already unfolded leaves. The water supply was thus the limiting factor in stem growth. These instances add to the probability that a similar disturbance of the supply of water to the apical bud takes place in *Spiraea Ulmaria*, and that this disturbance affects the production of hairs in the bud.

But most of the leaf hairs, as well as the palisade cells, actually elongate after the leaf emerges from the bud, and while it is unfolding in direct contact with the outer air (p. 833). At this stage cuticular transpiration must be an important factor.⁵ Owing to its veneration, the parts directly exposed to atmospheric influences when the leaf first emerges from the bud are the larger veins (which are already covered with hairs) and the delicate leaf margins (cf. Text-figs. 8 and 2, leaf 6). Naturally, therefore, the loss of water by cuticular transpiration will be most severely felt by the latter. As the leaf still further unfolds, and if the transpiration is sufficient, the next parts to experience a shortage of water will probably be the interveinal areas, because it is here less easily replenished. It is precisely in these regions that the hairs are localized in the partly hairy leaves. Finally, when the water supply is still further diminished, the lower surfaces of the unfolding leaves become completely covered with a dense pubescence.

Thus the formation of both the hairs on the larger veins, as well as those on the smaller veins and other parts of the lamina, may be correlated with a diminished water supply to the developing leaves. In the former it seems probable that correlative transpiration plays the most important part. In the latter, loss of water by cuticular transpiration comes into play, coupled with (as before) a strictly limited supply of water from below.

Further, the fact that all the cells of the upper leaves are much smaller than those of the lower (cf. Text-fig. 4) suggests development under conditions in which there is a partial deficiency of water. In other words, it is

¹ Schimper ('88), pp. 37-8.

² Haberlandt ('09), p. 368.

³ Smith, A. M. ('06), p. 325.

⁴ Balls ('10), p. 6, and ('11), pp. 229-30.

⁵ F. von Hoene ('78) showed that very young developing leaves actually transpire more than mature ones. This he attributed entirely to cuticular transpiration.

probable that the upper part of a normal *Spiraea* shoot has, during development, a less constantly maintained turgor than the lower,¹ and that the water supply is the limiting factor in the growth in size of the cells.

But now arises a difficulty. Although turgor is no longer regarded as the direct cause of the stretching growth of cell-walls,² it is none the less a condition of such growth.³ It is difficult to conceive how either hairs or palisade cells can elongate unless they are turgid. And yet we have seen that they are most strikingly developed under conditions when turgor may be expected to be at a minimum. The difficulty, however, is more apparent than real. In nature the external conditions are never constant. No matter how active transpiration may be at certain times, periods frequently recur (e.g. at night-time or on still, humid days) when turgor is fully restored.

The course of events then is probably somewhat as follows: transpiration during the day-time, increasing with the number of leaves unfolded, and (at least until midsummer) with the march of the seasons, gives rise to a diminished turgor in the cells of the developing leaves. This disturbance of the water supply to the yet plastic cells acts to certain of them as a stimulus (merely, of course, an initial or proximate one), in response to which the cells assume an elongated form.⁴ But the actual stretching growth of the cells can only take place when they once more become turgid. This occurs when transpiration falls at night-time, &c.⁵

Boodle,⁶ in his suggestive paper on the Bracken Fern, has made a similar suggestion with regard to the factors determining leaf structure. He says 'it may possibly be some such factor as strong periodic fluctuations in the turgescence of the cells of the leaf (due to scarcity of water when transpiration is most active) which determines in the immature leaf of the Bracken whether the leaf shall be xerophytic or not; and the same may apply to other plastic species'.

The case seems clearly one of stimulus and response, and the somewhat mechanical theories referred to above appear to be inadequate.

¹ Cf. Pfeffer ('03), p. 120. Miss Delf ('11), p. 501, states that the upper internodes of *Salicornia* had not only more numerous stomata than the lower, but also much smaller epidermal cells. This she regards as indicating that neither they nor the guard cells had attained their full size; and this notwithstanding the fact that the stomata were fully formed and open. Whatever the case may have been in *Salicornia*, the upper leaves described for *Spiraea* were certainly mature, in spite of the small size of their cells.

² As Wortmann ('89), p. 293, &c., and others supposed it to be. Cf. the discussion of this question in Sokolowa ('98), p. 179 et seq.

³ Cf. Pfeffer ('03), p. 118 et seq.; also Sachs ('87), p. 565.

⁴ In this case the stimulus appears to induce the cells to assume a special *form*. In many of the cells of these upper leaves it is chiefly the *size* of the cell which is affected, owing to the stretching growth of the cell-walls being less.

⁵ It seems certain that such fluctuations in the moisture content of leaves do actually occur, at least in mature leaves. Cf. Thoday ('09), p. 19 et seq., also Livingston and Brown ('12).

⁶ Boodle ('03), pp. 665-7.

There yet remains, however, one factor to be briefly considered, i.e. *light*. We have seen that in *Spiraea* a humid atmosphere has relatively little effect in preventing hair formation unless coupled with light of low intensity. Many observers have regarded light as the determining factor, especially in the formation of palisade tissue. In practice it is extremely difficult to satisfactorily control habitats in such a way as to distinguish clearly between the effects of light and relative humidity: two factors very closely associated in nature. Critical researches in this direction are much needed. In the absence of these it is impossible to say anything definite as to the mode of action of light. Failing evidence to the contrary, the writer somewhat inclines to the view of Vesque and Viet:¹ i.e. that light acts by influencing transpiration. Even in a still, humid atmosphere, intense light would certainly tend to increase transpiration, by reason of its heating effect. This view makes it less difficult to understand why the combined effect of two such apparently different factors should be greater than when either acts alone. At present, however, the possibility cannot be excluded that light may act either as a direct, independent stimulus, or that we may be dealing with a case of 'associated stimuli'.²

So far the case has been made out most clearly for hair production in *Spiraea Ulmaria*. But in the light of our knowledge of the conditions which favour the formation of hairs (including root-hairs) and palisade cells in other plants (cf. §§ 6 and 9), it would seem not improbable that similar factors are at work in these also. In other words, that we are dealing with a more or less general phenomenon.³

An interesting apparent exception to what seems to be the general rule regarding the hairiness of successive leaves of a shoot is the case of certain South-west African plants recorded by Schinz.⁴ In a number of species of *Pseudobarleria*, &c., the first-formed leaves are markedly hairy; the later ones, however, are much less hairy. This is the converse of *Spiraea*. But the more hairy leaves are apparently unfolded towards the close of the hot, dry season; the less hairy ones during the cooler period of rains. So that here, too, hair production shows a dependence on external factors similar to the cases described in this paper.

4. Acting on the assumption that hair formation in *Spiraea* is affected by the amount of water supplied to the apical bud, some experiments were tried on growing shoots. When a number of leaves had been unfolded and were vigorously transpiring they were all cut off, subsequent leaves being also removed as soon as mature. It was thought that the removal of the transpiring surface, after a vigorous water current from the roots had been

¹ Vesque and Viet ('81), p. 175.

² Cf. Darwin ('06).

³ It is of course possible that in special cases the stimulus may be different, either in nature or degree: e.g. when palisade cells are formed in aquatic plants.

⁴ Schinz ('94), pp. 67-70.

established, might result in at least a temporary increase in the supply of water to the apical bud. This, by preventing the stimulus of decreased turgor, might perhaps bring about the formation of glabrous leaves. The results were not uniform, but this was to be expected, as we are dealing with a complex of variable factors. In each experiment, however, one or more glabrous leaves were sooner or later produced high up on an erect flowering shoot, where normally only hairy leaves are found.

One example may be given. A normal shoot was selected, which on May 21, 1907, possessed seven unfolded leaves. Of these, leaves 1-3 were glabrous, leaves 4 and 5 partly hairy, and leaves 6 and 7 completely hairy. These seven leaves were then removed from the plant. At this date leaf 8 (a hairy one) was unfolding. Subsequently, leaves 9 and 10 showed decreasing hairiness, while leaf 11 was quite glabrous. Leaf 12 had marginal hairs, leaves 13 and 14 exhibited increasing hairiness, while leaves 15-17 (the last produced on this shoot) were hairy, though not densely so.

It is difficult to say exactly what the reason is for this abnormal production of glabrous leaves. It may be that it is partly due to nutritive difficulties, for cutting off the leaves removes the assimilating as well as the transpiring surface. But if so, one would scarcely expect the return of hairiness described above. Taken in conjunction with the evidence previously given, the experiments, so far as they go, certainly suggest that the explanation may be, in part at least, the one already offered.¹ Some additional support of this view (i. e. that cutting off the transpiring surface may increase the supply of water to the apical bud) is furnished by an experiment of Balls's.² This author's observations on the cessation of growth of the cotton plant during sunshine have been already cited. He further found that removal of about one-third of the total leaf area in full sunshine caused the terminal shoot to resume growth at once, owing apparently to the decreased loss of water from the plant.

The causes which determine the presence or absence of hairs in *Spiraea Ulmaria* may now be summarized as a whole. Several distinct factors appear to be involved, i. e.:

(a) *Heredity*. It is difficult to assign exact limits to the part played by this. The inherent tendency to form hairs in the first instance is certainly hereditary. But how far the degree of hairiness in var. *denudata* and the

¹ Although the experiments were undertaken more or less with the expectation of arriving at the results actually obtained, there is reason for caution in interpreting these results. On several occasions I found plants in the field, the stems of which had been injured an inch or two above the ground, apparently at an early age. In each case two or three of the cauline leaves immediately above the injury were less hairy than the normal, and in some instances even glabrous. Thus it would seem possible that the abnormal production of glabrous leaves described in the text is in some way connected with the injury caused by the removal of the leaves, rather than with the water supply as suggested.

² Balls ('10), p. 9.

intermediate forms is determined by heredity, or how far it is attributable to individual variation, is at present problematical.

Goebel, in his interesting researches on the various forms of leaves in *Campanula rotundifolia*,¹ found that leaf form depended largely on illumination. In nature the seedling leaves, as well as the first leaves formed on the lateral runners, are always of a petiolate, rotund type. Linear leaves, on the other hand, are only formed on the erect flowering shoots. By lowering the light-intensity, rotund leaves could be induced to form on the flowering shoots in the place of linear ones. But the converse did not hold. Even the strongest illumination, whether continuous or intermittent, was powerless to hinder the formation of rotund leaves on either the seedlings or the runners. Goebel regarded the rotund form of the leaf in these cases as hereditarily fixed.²

Now the glabrous leaves of *Spiraea Ulmaria* are formed in nature under precisely the same conditions as the rotund leaves of *C. rotundifolia*, and the hairy ones correspond in position, &c., to the linear leaves of *Campanula*.³ Further, all attempts to induce the formation of hairs either on seedling *Spiraeas* or on the early spring leaves of mature plants have been unsuccessful. It is therefore probable that glabrousness is a character hereditarily fixed in these leaves, just as Goebel supposes roundness to be in the corresponding leaves of *Campanula*.

(b) *Individual variation.* One of the most obvious expressions of this is seen in the variable number of glabrous leaves formed on a shoot. Usually the number varies from three to five, though in exceptional cases as many as twelve glabrous radical leaves have been observed. Again, in most cases one or more hairy radical leaves are produced before the erect flowering shoot begins to elongate. But individuals are sometimes found (see p. 839) in which even the lowest one or two cauline leaves are glabrous or nearly so.⁴ As these plants occur side by side with normal ones, it seems probable that it is simply a case of individual variation.

(c) *Effect of external conditions.* This has already been discussed at length, and the conclusion arrived at that hair production is promoted by marked periodic fluctuations in the turgor of the hair-producing cells. It has also been shown that *Spiraea* is plastic only to a limited extent in regard to hairiness. Marked changes in the external conditions are required before any visible response can be obtained. This plasticity is less than that of *Campanula* in respect of leaf form, or than the plasticity with regard to hairiness in such plants as *Mentha aquatica*, &c. The stimulus, then, which

¹ Goebel ('96), ('08), and other papers.

² Goebel ('96), pp. 8-9.

³ There is frequently a slight approach even in the matter of form; see Text-fig. 5 and Pl. LXXXI, which show the tendency in *Spiraea* to form rounder leaflets below and narrower ones above. This is a common phenomenon in plants.

⁴ And this in localities in which var. *denudata* does not occur, so that it can scarcely be a case of hybridization.

decreased turgor appears to afford to the hair-producing cells is probably more of the nature of an accelerating stimulus than an actually determining one.

Further, different parts of the plant vary in plasticity. As mentioned above, the lowest leaves are not plastic, but are persistently glabrous. The upper leaves on the erect flowering shoots, on the other hand, are fairly persistently hairy. The most plastic leaves of all appear to be those occupying an intermediate position, i. e. the lower hairy ones. Many plants are more plastic than *Spiraea* in regard to hairiness; but in all cases hairiness appears to be associated with relatively dry, and glabrousness with relatively humid conditions. Taking these facts into account, it would seem that *Spiraea Ulmaria* is retaining a certain degree of plasticity in regard to hairiness. But at the same time it is tending to become fixed in the direction of response to the average conditions, to which the upper and lower leaves of the species, respectively, have been exposed in nature for many generations.

§ 12. THE PHYSIOLOGICAL EFFECT OF THE HAIRS, ETC.

Most authors agree that a dense covering of dead, cutinized hairs depresses transpiration. This is said to be due to the retarding of gaseous interchange on the transpiring surface, and also, in some cases, to the hairs acting as a screen against intense insolation. According to the distribution of the hairs on the respective surfaces of the leaf, one or other effect will be more marked. But, as Haberlandt¹ has pointed out, there is an absence of critical researches on the subject. At first sight, *Spiraea Ulmaria*, with its glabrous and hairy leaves, would seem to be admirably adapted for such critical researches. But, as we have seen, the progress towards hairiness in the leaves of this species is accompanied by other structural changes. These also cannot but exert an influence on transpiration. The whole question of the relation between leaf structure and transpiration is in a somewhat chaotic condition, different experimenters having obtained diametrically opposed results. Thus, von Hoebel² found that under similar conditions 'shade leaves' transpired more strongly than 'sun leaves'. Gêneau de Lamarlière,³ on the other hand, obtained exactly opposite results. The question is a complicated one, and the author hopes to deal with it more fully and critically in a future paper. For this reason no attempt will be made at the present time to do more than put forward certain *a priori* considerations, and to refer briefly to the work of other botanists.

¹ Haberlandt ('09), p. 116. This author himself performed some experiments on the effect of hairs on transpiration (l. c., p. 138).

² Von Hoebel ('79), quoted by Burgerstein ('04).

³ Gêneau de Lamarlière ('92), p. 542. Cf. also the literature cited in Burgerstein ('04), p. 55 et seq. Also Hesselman ('04), p. 402 et seq.

Wiegand¹ has recently experimented with various materials, so arranged as to simulate the hairy and cutinized coverings of plants, and determined the extent to which they hindered evaporation. From his experiments he concluded that hairy coverings (even when of a thin, strigose nature) markedly retard transpiration in wind, but have comparatively little effect in still air. They also have a marked retarding effect in sunshine. Further, that a waxy (i. e. cutinized) covering is more efficient in reducing transpiration than a hairy one.²

Wiegand's results confirm the previously expressed opinions of Goebel³ and Haberlandt,⁴ that a dense covering of hairs may be especially effective in reducing transpiration when the plant is exposed to strong winds. Haberlandt also refers to their similar action under strong insolation. On theoretical grounds it is to be expected that the hairs would have this effect. Thus, when the leaf is exposed to wind, the effect of the hairs would be to diminish the gradient of density of water vapour outside the leaf, by hindering the removal of the humid air from its surface. The distance between the absorbing surface (the free air outside) and the supply is thus increased, and the rate of flow of water vapour outwards correspondingly diminished.⁵ On the other hand, if the air outside the leaf be perfectly still, the gradient of density would be much the same whether the hairs were present or not. Further, wind passing rapidly over the unprotected surface of a leaf would reduce the pressure just at the entrances of the stomatal apertures, and so tend to suck air (and consequently water vapour) out of them.⁶ This effect also would be prevented by the hairs. Again, when exposed to direct insolation, white, air-containing hairs, such as those of *Spiraea*, must reflect an appreciable amount of light. In consequence, less heat is absorbed, and the transpiration again diminished.

In the case of *Spiraea Ulmaria*, it has been shown that its characteristic pubescence is localized precisely in those parts of the plant which in nature are most exposed to the drying effects of wind, sun, &c. Conversely, the glabrous leaves are those found under conditions where transpiration and the effect of wind are at a minimum. The same is also true of the majority of plants mentioned in § 6. Perhaps the most striking instance of all is

¹ Wiegand ('10), p. 430 et seq. He used blotting-paper as the evaporating surface, laying over this various cotton materials to represent hairy coverings, and bees-wax for cutin.

² Probably Wiegand has exaggerated the differences between the two kinds of covering, as in his experiments the layer of wax would have nothing to represent stomata, while all the cotton fabrics would be abundantly furnished with small apertures.

³ Goebel ('81), p. 18.

⁴ Haberlandt ('09), p. 116.

⁵ Brown and Escombe ('00), footnote to p. 276, suggest that epidermal hairs may lessen the amount of CO₂ absorbed by the leaf when the air is in motion, by preventing air currents from sweeping away the external density 'shells'. The same must apply equally to the transpiration of water vapour.

⁶ This action is similar, as Dr. Schott suggests, to that of a hair-dresser's sprayer, or of a Gifford injector in sucking water into a boiler.

afforded by the intermediate, partially hairy leaves of *Spiraea*. In these the leaflets, and even the portions of leaflets, which are most exposed to the danger of excessive loss of water, are provided with a dense covering of hairs (see Pl. LXXXII and LXXXIII).

Bearing in mind all the facts adduced in this paper, it is difficult to avoid the conclusion that the production of hairs in *Spiraea* and certain other plants, under the stimulus of drought, is of the nature of an advantageous adaptive response. The most important physiological effect, then, of this response would seem to be to prevent undue acceleration of transpiration by air movements and, though to a less extent, insolation.

Turning once again to the question of root-hairs and palisade cells, the chief rôle of the former (i. e. to increase the absorbing surface of the root) seems clear. The functions of palisade cells, on the other hand, have been much disputed. Probably they perform several important physiological functions. The only view which need be mentioned here is that of Areschoug,¹ who regards a well-developed palisade tissue as of importance in reducing transpiration. Areschoug's view has been accepted by many authors, though so far direct experimental evidence is lacking.²

Granted the foregoing, it appears that the stimulus of a decreased supply of water promotes the formation of three different kinds of elongated cells, each of which is physiologically important (at least in certain cases) in connexion with the plant's water supply. At one end of the plant the root-hairs increase the intake of water: at the other the hairs and palisade cells assist in reducing the output of water from the leaves. There would thus seem to be in these cases, as in many others, a more or less definite connexion between the nature of the stimulus and the physiological advantage of the response.

§ 13. THE XEROMORPHY OF *SPIRAEA ULMARIA*.

Spiraea Ulmaria is far from being a pronounced xerophyte. Its leaves are thin and frequently of considerable size. They have a fairly thin cuticle, and generally wilt readily when gathered. Nevertheless the plant exhibits certain xerophytic characters which are practically confined to the upper, more exposed parts of the shoots. These characters are as follows:

1. The lower stomatal surface is covered by a dense pubescence.
2. The upper epidermal cells have a better developed cuticle than those of the lower leaves.
3. The mesophyll is much more compact; the internal transpiring surface being thereby considerably lessened.

¹ Areschoug ('82), p. 520, and ('06), p. 329 et seq.

² Hesselman ('04), p. 428, however, as a result of certain field experiments, is of opinion that palisade tissue does not markedly depress transpiration. Some of his experiments were actually carried out on *Spiraea Ulmaria*. Areschoug has discussed Hesselman's objections in his 1906 paper.

4. The leaf surface is much reduced. It is of course a very common thing to find the upper leaves of the shoots of herbaceous plants considerably smaller than those lower on the stem. But undoubtedly the effect of this diminution in size of the upper, more exposed leaves will be to reduce considerably the output of water from the terminal portions of the shoot. It has indeed been suggested above that this reduction in size of the leaf (or at least of its component cells) is in part due to development under conditions which strictly limit the available supply of water. In *Spiraea*, the leaves which present the greatest transpiring surface are placed in relatively sheltered, humid strata of the vegetation.¹ Though all shoots exhibit periodicity in the size of leaves, the actual sizes of the latter vary greatly according to the conditions under which they are grown (see Text-fig. 5).

5. When *Spiraea* leaves are exposed to strong insolation, they tend to assume the profile position. This is taken up, not by the leaf or leaflet as a whole, but by the two halves of a leaflet separately. A marked ventral curvature of the leaflet is thus produced. This will probably tend to a further reduction of transpiration. The phenomenon is a frequent one in marsh plants as well as others, but need not be fully discussed here, as it will form the subject of a forthcoming paper.

At first sight the more numerous stomata of the upper leaves suggest that they may counterbalance the characters which would otherwise reduce transpiration. But it has been shown (p. 828) that in all probability the possible transpiration per unit area of leaf surface, if the stomata alone are considered, would be little if any more from the upper than from the lower leaves. The balance of characters, then, shows that the upper parts of the shoots of *S. Ulmaria* are distinctly more xerophytic than the lower. But in any case the degree of xeromorphy is slight. The question now arises, is this degree of xeromorphy necessary or even advantageous to the plant?²

It may be regarded as an axiom that where functions such as transpiration are concerned, the need for special regulatory devices in a given species will be determined, not by the average conditions, but by what may be termed the normal extremes which the species is called upon to face in nature. In other words, to be successful, a plant must always be prepared for such emergencies as it may occasionally have to meet during the vegetative season.³

¹ Yapp ('09), p. 281.

² And if a dense pubescence is necessary to the type-form, why is it not equally so to the less hairy variety *denudata*? On this point all that can be said (though it is not advanced as being a complete answer) is that var. *denudata* appears to be a less successful form. It is rare in nature, while the type is common. So far as my experience goes, it usually occurs only in sheltered spots. Culture experiments on the roof of the College at Aberystwyth show that, especially if the soil is wet, it is much less able to endure the effect of wind than the hairy form. Moreover, after all, the hairiness of the two forms is merely a matter of degree.

³ A. R. Wallace ('10), p. 258, goes even further than this. He says: 'A dominant species has

Considering hairiness alone, we have seen that its distribution on the plant is correlated in the most minute way with differences of external conditions; that those parts of the plant which would, if the conditions were severe, tend to lose water most readily, are those which are furnished with this hairy covering; and further, that the hairy type is more successful than the less hairy var. *denudata*. It may therefore be concluded that hairiness in this species is a positive advantage to the plant, and in all probability actually necessary whenever transpiration conditions are unusually severe, e. g. in the event of strong drying winds or prolonged insolation. The same may be said of the other xerophytic devices enumerated above. In other words, *Spiraea Ulmaria* is structurally in complete harmony with its environment.

But so far only the aerial organs have been considered, and it may well be asked, why does a plant rooted in damp soil require these regulatory devices at all? And further, even if the necessity be proved for *Spiraea*, how far does this particular instance afford a clue to the problem of xeromorphy in marsh and bog plants in general? An attempt will be made in the next section to give a provisional answer to these questions.

§ 14. THE PRESENT POSITION OF OUR KNOWLEDGE OF 'SWAMP' XEROPHYTES, AND A TENTATIVE HYPOTHESIS.

Xeromorphy in plants growing on wet, peaty soils occurs all the world over.¹ A full historical account of the various theories put forward to account for the existence of these 'swamp xerophytes' need not be given here; but the positions taken up by certain authors will be briefly discussed.

Some writers maintain that the xeromorphic structures in question are, and others that they are not, present-day necessities to the plants which possess them.

The latter point of view may be dealt with first. Schwendener,² Clements,³ and others believe that these structures are primitive characters which have persisted in certain stable species (especially Monocotyledones), in spite of a fundamental change of habitat conditions. Perhaps the most important evidence for this view is the fact that hydrophytic species frequently grow side by side in nature with those possessing xerophytic characters. Even Warming, who believes that the xeromorphy is adap-

become so because it is sufficiently adapted to its *whole* environment, not only at any one time or to any average of conditions, but to the most extreme adverse conditions which have occurred during the thousands or millions of years of its existence as a species.⁴

¹ Warming ('09), p. 194.

³ Clements ('06), p. 126.

² Schwendener ('89), p. 73.

tive, says in this connexion: 'Finally, it may be noted that there are not only moors inclining to xerophily, but also others leaning rather to hydrophily, and that, in addition to the structural types and forms of leaves mentioned, there are others which apparently show no signs of xerophily, and cannot be shown to be in harmony with this habitat.'¹

Several *a priori* arguments may be urged against the view advocated by Schwendener and Clements. The widespread occurrence of the phenomenon; the existence of varying degrees of xeromorphy in different types of marsh and bog vegetation, these being correlated with marked differences of soil, &c.; the fact that many of these species 'can grow both on extremely dry, warm soil, and on extremely cold, wet soil';² and finally, the probability that xeromorphy, unless advantageous, would actually handicap marsh plants in their competition with other species—all suggest that such xerophytic devices are in some way related to a need imposed on the plant by the nature of the habitat. Further, the argument from proximity of position, which has been so frequently employed, depends on the tacit assumption that plants growing together are necessarily under the same conditions. This is most certainly not the case. Indeed, the present author believes himself to have shown that, so far as the water supply of marsh plants is concerned, few of the species have to face precisely the same set of physiological problems.³

Various authors have discussed the question of whether a bog is to be regarded as a hygrophytic or xerophytic habitat. In this connexion it may be pointed out that only in the more extreme cases, and particularly (so far as xerophytes are concerned) those in which the plant associations are open, can habitats⁴ as such be said to be markedly hygrophytic or xerophytic. In the great majority of closed, mixed associations, the mutual relations of the various species are such as to profoundly modify the general character of the habitat for each other; some plants being exposed, others sheltered, and so on.⁵ In this way, according to the growth forms of the species, and in varying degrees according to the general characters of the habitat and of the vegetation, the same habitat may be xerophytic to one species and hygrophytic to another. This is probably to some extent what Warming had in mind when he wrote the passage quoted in the introduction to this paper. The emphasis here laid upon this point of view is not out of place, for there is some danger that it may occasionally be lost sight of in the comparative study of vegetation in its broader aspects. This is especially so in view of the stress laid on the generally accepted ecological classification of plants into xerophytes, mesophytes, hydrophytes,

¹ Warming, l. c., p. 196. The italics are mine.

² Warming, l. c., p. 194.

³ Yapp ('09), pp. 306-8.

⁴ Using the term in its broad sense, i. e. to indicate the general physical environment of plant associations, rather than merely of individual plants.

⁵ Cf. Yapp, l. c., p. 279.

&c. Such a classification is admittedly useful, but it should not be forgotten that it is all a matter of degree, and that communities composed entirely of marked xerophytes, &c., are probably comparatively rare. Thus, though climatic and edaphic factors are the most important, in that they determine the general character of the vegetation, the inter-relationships of the various species also play a definite, if less conspicuous part, even in the case of relatively dwarf vegetation. But all this does not explain the paradox that certain of the plants rooted in the wet soil of marshes and bogs apparently need to exercise economy in respect to their water supply. We must therefore consider the theories put forward by authors who regard the xeromorphy of these plants as induced by the nature of the habitat.

It is at once obvious that either atmospheric or edaphic factors, or both, may be concerned. The present writer's researches have dealt mainly with the former, while most other observers have confined their attention to the latter.

i. *Edaphic factors* may be taken first, the following comprising the more important suggestions put forward:

1. *Actual physical drought.* Volkens¹ thought the important factor was the drying of the superficial layers of peat during summer. He pointed out that in some moorland and marsh habitats the soil is wet all the year round, while in others the upper layers become dry in summer. Studying the Carices in particular, he concluded that the more xerophytic species are largely confined to the second class of habitats. Davis² and Burns³ have come to a similar conclusion from their observations on the lowering of the water table during droughts in North American peat-bogs.

2. *The low temperature of wet soils* may, it is suggested, check root activity, and so reduce the absorption of water. Kihlman⁴ regarded this factor as of great importance in northern regions, especially when coupled with drying winds. Goebel⁵ came to the same conclusion with regard to the mountainous parts of Venezuela. Transeau⁶ found, as the result of laboratory experiments, that a cold substratum caused a reduction in size of both roots and leaves, and induced the formation of xerophytic characters in the latter. The effect was more marked when, in addition, the soil was badly aerated. He is of opinion that substratum temperatures are of prime importance in northern latitudes, but that they are inadequate to account for xerophytic structures in bog plants in Southern Michigan.⁷

3. *Paucity of oxygen in the soil.* Transeau's experiments showing the effect of a deficiency of oxygen have already been quoted. Again,

¹ Volkens ('84), p. 24.

³ Burns ('11), p. 119.

⁵ Goebel ('91), Teil ii, p. 11.

⁷ Transeau, l. c., p. 36.

² Davis ('06), p. 160.

⁴ Kihlman ('90), p. 107 et seq.

⁶ Transeau ('06), p. 22 et seq.

Warming¹ remarks that an insufficient supply of oxygen may obstruct respiration, and so depress the functional activity of the roots. The researches of Kosaroff,² too, show that the absorption of water is retarded by suppressing the supply of oxygen to the roots. In this connexion it may be noted that the roots of many 'dry-marsh plants' tend to assume a markedly horizontal position, especially when growing in wet peat. This is very striking in the case of the tap-roots of certain Umbelliferae. The phenomenon may well be correlated with the paucity in oxygen of the water-logged soil.³

4. *The presence of free humus acids.* Schimper⁴ attributed the need for xeromorphy in the plants of peat-moors to the action of humus acids in impeding the absorption of water by the roots. This was accepted by Warming and others as 'the weightiest cause of the physiological dryness of the soil'.⁵ But the importance of free humus acids has been disputed by Livingston,⁶ Transeau,⁷ and Dachnowski.⁸ Indeed, according to the recent important researches of Baumann and Gully,⁹ it is extremely doubtful whether, in the so-called free humus acids of sour peat soils, we are dealing with organic acids at all. These authors attribute the acid character of such soils to adsorption by the colloidal cell-walls of plants, especially *Sphagnum*. They produce evidence to show that the cell-walls bring about decomposition of salts in solution, a greater proportion of the base than of the acid being adsorbed. The acid reaction, then, is due to the presence of free hydrogen ions yielded by the acid after the removal of the base.

5. *The presence of bog toxins*, which act on the roots of plants much as do drying media. The existence of such substances in bog water and bog soils has been rendered probable by the work of Livingston,¹⁰ and later of Dachnowski.¹¹ These authors published a series of suggestive papers from 1904 onwards. They conducted many careful culture experiments, using polymorphic lower plants as indicators. They both conclude that inhibition from bogs of plants other than those possessing xerophytic characters is largely due to the presence of these injurious substances, which are soluble in water. Dachnowski¹² states that the toxicity of bog water can be corrected by various means: e.g. by the addition of certain adsorbing agents, and also by aeration. The latter acts, according to him, by slowly oxidizing the toxic substances, and not directly on the living roots, as supposed by other authors.

6. *The great water-retaining power of peat.* Of all soils peat has

¹² Dachnowski ('08), p. 134, &c.

the greatest water capacity. It would therefore seem probable that an appreciable amount of the water actually present will not be available for absorption by the plant. With a view of determining what the actual percentage of non-available water may be in moorland soils, Crump¹ has conducted a number of interesting wilting experiments. He calculates that certain plants (e. g. *Eriophorum angustifolium*) are unable to absorb more than about 48 per cent. of the total water present.

The above are some of the more important suggestions that have been made with respect to edaphic factors. But, as both Livingston and Dachnowski point out, our knowledge of the chemistry of bog water and bog soils is still very incomplete.

ii. *Atmospheric factors.* Certain authors deny the importance of these. E. g. Dachnowski,² referring to the xerophytic characters of bog plants, says, 'None of these features are correlated with atmospheric influences.' Elsewhere, however, he seems to admit that they may play a part.

On the other hand, both Kihlman and Goebel (see 2 above) emphasize the importance of drying winds, especially when accompanied by coldness of soil.

The present author³ has shown that even in the comparatively dwarf vegetation of a marsh, great and constant differences of relative humidity exist in the different aerial strata. Thus the leaves of plants which occupy the lower strata are, on e. g. dry and windy days, exposed to transpiration conditions far less severe than leaves growing in the upper strata of the vegetation. More recently Dachnowski⁴ has obtained similar results in the bog vegetation of Cranberry Island. The position, then, of the transpiring organs of the various plants must be of considerable importance.⁵ Indeed, a slow absorption of water can only be prejudicial in so far as it is liable to be accompanied by excessive transpiration from the aerial parts.

Another factor that has to be taken into account in this connexion is the length of the vegetative period of the different species. So far, for instance, as the danger arising from limitation of absorption by reason of low soil temperatures is concerned, it is obvious that, in temperate latitudes, this will be experienced to the greatest extent by evergreen plants during the winter or spring time. Schimper⁶ was the first to emphasize the connexion between the coldness of the soil and the xerophytic structure of the leaves of evergreen trees and shrubs in temperate regions. Früh and Schröter⁷ similarly attribute the need for such structure in the plants

¹ Crump ('12).

⁴ Dachnowski ('11), p. 146.

⁵ Kearney ('01), p. 442, in his survey of the Dismal Swamp Region, points out that the tall, reed-like plants of freshwater marshes protect the smaller, more hygrophytic forms against excessive transpiration.

⁶ Schimper ('90), pp. 15-17.

⁷ Früh and Schröter ('04), p. 15.

of a *Hochmoor* partly to difficulties of absorption, and partly to the prevalence of the evergreen habit.

A TENTATIVE HYPOTHESIS.

Much remains to be done before the causes which have contributed to the production of xeromorphy in bog and marsh plants can be stated with exactitude. In particular, our knowledge of the physical chemistry of peat soils is still very incomplete. It is also uncertain as yet to what extent the stomata of marsh plants are capable of normal movement.¹ Again, the osmotic properties of the cell-sap of marsh and bog plants would be worth investigating. But the problem is gradually becoming less obscure. As seen above, many possible factors have been suggested by different authors, each factor in turn being assigned a position of paramount importance.

Probably the truth is that a number of factors, both edaphic and atmospheric, are operative. Further, it is probable that while some factors are of greater importance than others, the importance of any given factor will vary according to circumstances. As regards edaphic factors, the general trend of evidence, a good deal of it experimental, renders it increasingly probable that the soils of peat-marshes and bogs are to a certain extent, if not physically, at least physiologically dry to plants. But the factor, or combination of factors, which renders absorption difficult is not the same in all cases. For example, low soil-temperatures probably play a part in far northern latitudes, at high altitudes, and in the case of evergreen plants during the winter-time. But the same factor may be entirely inoperative in the case of plants which only produce leaves during the summer-time; and especially in the bogs and marshes of warmer latitudes. Again, the presence of toxic substances or the lack of oxygen (whether this acts directly, or merely by oxidizing injurious compounds) may possibly affect chiefly the more deeply rooted plants.² On the other hand, plants rooted on or near the surface may secure abundant oxygen, but are exposed to the danger of physical drought if the water table is lowered to any considerable extent. Further, it is probable that chemical, and perhaps also physical, differences between the soils of bogs and marshes (i. e. *Hochmoore* und *Flachmoore*) respectively, are largely responsible for the fact that xeromorphy is more prevalent in the plants of the former than in those of the latter (but see below). Doubtless in many cases two or more soil factors, often in different combinations, co-operate.³ At the same time, we know little of the ultimate causes which limit the absorption of water by the roots.

But edaphic factors alone cannot suffice to account for the fact that xerophytic and hygrophytic species so frequently occur side by side in

¹ Cf. Darwin ('88), p. 552, and the literature there cited. Also Fröh and Schröter ('04), p. 14.

² Cf. Yapp ('08), pp. 74-5.

³ Cf. Warming ('00), p. 195.

nature. It is here that atmospheric factors become important. Granted that the characters of the substratum are such that the rate of absorption of water is slow, then the atmosphere will play a differentiating rôle. A reduction in the amount of water absorbed does not injuriously affect the plant, provided that transpiration is reduced in the same ratio. The latter is effected in one of two ways, according to the position of the aerial parts of the plants. (1) For the taller plants, the shoots of which occupy the upper strata of the vegetation, and are therefore liable to exposure to strong winds, insolation, &c., xeromorphy may well be a necessity; and even more so if the plants are evergreen. (2) On the other hand, the leaves of the smaller plants occupy the lower strata, where they are protected from wind, and transpire into a constantly humid atmosphere. As is to be expected, these lower strata do actually contain the more hygrophytic species, e. g. *Hydrocotyle vulgaris*, &c., and also the hygrophytic seedlings and lower leaves of other species. Conversely, the more xerophytic species, e. g. *Cladium Mariscus*, or parts of shoots (cf. *Spiraea Ulmaria*), are those occupying the most exposed positions.

So far as atmospheric factors are concerned, the less dense the vegetation, and the larger the proportion of plants of an evergreen habit, the more xerophytic may the vegetation be expected to be. In this country these two conditions obtain to a greater extent in bog than in marsh vegetation. It is therefore not surprising, seeing that atmospheric and (probably) also edaphic factors are in general more favourable, that the vegetation of peat-marshes should contain a larger proportion of hygrophytic species than that of bogs; and, conversely, that the latter should support a greater number of xerophytic types.

The general nature of the habitat is of course important, but having made due allowance for that, the whole matter really resolves itself into a consideration of the different problems of individual species.¹ And if this be so in any given marsh or bog, much more is it true when we come to compare different types of swamp vegetation and different latitudes and climates.

As an example, two species of marsh plants may be briefly compared:

Spiraea Ulmaria is a plant of the drier parts of marshes. Its roots grow in moist but not water-logged soil. Probably they rarely experience lack of oxygen, and absorption in the well-aerated soil is unlikely to be much impeded by toxic substances. The vegetative period is comparatively short (about March to October), so that coldness of soil will scarcely play a very important part in these latitudes. On the other hand, it is liable to suffer from actual drought through lowering of the water table. The aerial parts have been discussed at length in this paper, and it has been shown that the exposed leaves exhibit a definite if slight degree of xeromorphy,

¹ Cf. Yapp ('09), pp. 306-8.

while the sheltered leaves are more hygrophytic in character. Probably the chief danger to this species is the drying effect of wind, especially when coupled with a temporary desiccation of the surface layers of soil.

Cladium Mariscus presents somewhat of a contrast. It is a wet-marsh plant, which is more pronouncedly xerophytic than *Spiraea*. Its roots grow in water-logged soil, and are indeed frequently entirely submerged. It is a relatively tall plant, and not only are the upper parts of its leaves exposed to wind and sun, but they are evergreen. Absorption, then, may possibly be impeded by such factors as lack of oxygen, toxic substances, &c., in the summer time, and by low soil temperatures in winter and spring. At the same time the leaves may be exposed to unduly severe transpiration conditions at any time of the year. Hence it is not surprising that, as is actually the case, *Cladium* should be more decidedly xerophytic than *Spiraea*. The comparison could readily be extended to include such diverse types as *Hydrocotyle vulgaris*, *Andromeda polifolia*, &c., &c.

To sum up, there is every reason to suppose that associations of bog and marsh plants are as much in harmony with their environment as are those occupying other distinctive habitats, such as the various woodland, desert, and other plant associations. But to arrive at this conclusion, it is necessary to take many factors into consideration. In all probability edaphic factors, climatic factors, the growth forms of the plants, with the resulting differences of exposure and shelter, the duration of the vegetative period, and possibly other factors as well, have all contributed to the production of a series of physiologically intricate, and at first sight paradoxical types of vegetation.

Finally, it may be once more emphasized that the xeromorphic structures in question are required to meet, not so much the everyday needs, as the extremes, possibly even only the occasional extremes, which the plants possessing them are called upon to face.

SUMMARY OF RESULTS.

1. The present paper is an experiment in what may be called species-ecology. It is an attempt to see how far the intensive study of a single species, supplemented by observations on others, may help towards an explanation of the problem of xeromorphy in marsh plants.

2. The species selected (*Spiraea Ulmaria*) is a 'dry-marsh' plant, the leaves of which are densely pubescent on the lower surface. This pubescence is subject to a kind of periodicity, and appears only under certain definite conditions. The chief rules governing the appearance of the hairs are as follows: (a) The seedlings, also all leaves formed during the first year, are glabrous. (b) On the erect flowering shoots of adult plants, there is a regular succession of glabrous, partially hairy, and completely hairy

leaves. The earliest radical spring leaves are glabrous, the cauline leaves hairy (see Pl. LXXXI). (c) The non-flowering shoots of adult plants produce only radical leaves. The earliest of these are glabrous as in (b). Subsequently, the successive leaves exhibit increasing hairiness up to June or July, after which they are decreasingly hairy, till finally glabrous leaves are once again produced in autumn. (d) The distribution of pubescence on the partially hairy leaves is interesting. The terminal leaflet is invariably the most hairy, and there is a regular decrease in hairiness from above downwards. Individual partly hairy leaflets generally possess a marginal band of hairs, with sometimes additional bands running inwards between the main veins (see Pl. LXXXII and LXXXIII).

3. In reality this seasonal periodicity in the production of hairs is a widespread phenomenon. *Spiraea Ulmaria* was the most striking case observed, but many other marsh, and also certain land, plants exhibit the same general succession of glabrous, partly hairy, and more or less completely hairy leaves.

4. Similarly, there are marked seasonal differences in leaf structure. The lower glabrous leaves have on the whole a more or less definite 'shade' structure, while the upper, more exposed, hairy leaves approximate to the 'sun' type. The former have large epidermal cells, with sinuous lateral walls, and few but relatively large stomata. The mesophyll is loose, with large intercellular spaces. On passing up the erect stem, the following progressive changes in leaf structure may be observed: the leaf becomes thinner, but the cuticle thicker; the epidermal cells smaller, and their walls less sinuous. The stomata are more numerous but smaller, and the hairs much more abundant. The mesophyll is more compact, and the intercellular spaces are gradually reduced to a minimum (see Text-fig. 4). Speaking generally, the upper leaves show a distinctly greater degree of xeromorphy than the lower. These changes are independent of the actual size of the respective leaves.

5. The variations in the number of stomata are remarkable. There is a gradual though fluctuating rise in the number of stomata through the successive leaves of the entire shoot. In one shoot, for instance, the numbers varied from about 300 to nearly 1,300 per sq. mm. of lower leaf surface. The latter number is the highest yet recorded for any species. At first sight it might appear that these numerous stomata of the upper leaves would neutralize the effect of the xeromorphy referred to above (4). But the stomata of the lower leaves have larger pores, and it is calculated that under similar conditions, and *considering stomata alone*, the possible transpiration from the upper leaves could be but little, if any more, per unit area of leaf surface, than that from the lower.

6. The effect of environment on the development of certain leaf tissues, especially hairs and palisade cells, is considered. The results of many

investigators show that in general these are most fully developed under conditions which impose on the plant some necessity for increased economy of water, i. e. under conditions which either promote transpiration or hinder absorption. *Spiraea Ulmaria* is found to be less plastic than many other species in respect to hairiness. Many experiments show that it is difficult to inhibit the formation of hairs on leaves which are normally hairy, though their number and length can be readily influenced. At the same time, the distribution of pubescence on the plant (described in 2 above) corresponds in the most striking manner with the average physical conditions of the natural environment. Thus the curves of hairiness in *Spiraea* follow very closely the mean curves of evaporation and light-intensity. This is true whether the vertical changes in these factors (due to the density of the vegetation) or the annual march of evaporation and light-intensity are considered (cf. Pl. LXXXI and Text-figs. 9 and 10).

7. The localization of hairs on the partially hairy leaves of *Spiraea* (in particular the marginal and interveinal bands of hairs) shows a marked correspondence with the localization of withering in leaves in general, when such withering is due to the effect of wind, &c. (cf. Pl. LXXXII and LXXXIII, and Text-fig. 11). Anthocyan in young leaves in spring-time, the local effect of freezing, &c., often show a similar distribution. As regards their water supply, these regions of the leaf-lamina (i. e. the margins and interveinal parts) are physiologically different to the remaining parts. They are more liable to lose water, and are also the most remote from the water supply coming up from below.

8. The development of the leaves is described, and it is shown that no hairs are developed in the bud until the first foliage leaves have expanded and become functional. Hairs then appear on the main veins of the developing leaves, and the hairiness of these veins (while still in the bud) increases *pari passu* with the general increase of transpiration from the shoot. But the hairs on the finer veins, and those which occur over the parenchyma 'islands', only appear when the leaf has emerged from the bud; i. e. when some parts of it are already in contact with the outer air (Text-figs. 7 and 8). It is these later formed hairs which are most conspicuous in the mature leaves (see 2 above).

9. The causes of the formation of the hairs, &c., are discussed, and it is shown that a parallel may be drawn between the epidermal hairs of leaves and stems, the palisade cells of leaves, and to some extent root-hairs as well. In so far as the development of these special elongated elements is determined or accelerated by external conditions, it would appear that similar factors are usually operative in all three cases.

Hair formation in *Spiraea Ulmaria* is considered in detail. In this case the factors which determine the presence or absence of hairs on the leaves are probably the following: (a) heredity, (b) individual variation,

and (c) external conditions. It is shown that evidence of many kinds points to hairiness being associated with a diminished, and glabrousness with an abundant supply of water (see 6 and 7 above). In so far then as *Spiraea* is plastic in respect to hairiness, the course of events would seem to be somewhat as follows. As transpiration increases with the unfolding of the leaves in spring-time, the amount of water available for the apical bud becomes diminished. Certain cells of the developing leaves are thereupon stimulated to form hairs. This is a case of what Wiesner has called 'correlative transpiration'. When the partially developed leaf emerges from the bud, its supply of water is still further lessened by cuticular transpiration from its surface (cf. 8 above). The initial stimulus which leads to hair formation is thus afforded by diminished turgor; the actual growth in length of the hair cells, however, cannot take place till turgor is once more restored. This takes place at more or less regularly recurring intervals, especially at night-time. Thus hair production is promoted by marked periodic fluctuations in the turgor of the hair-producing cells. *Spiraea Ulmaria* possesses only a limited degree of plasticity in regard to hairiness. It is suggested that the species is tending to become fixed, in the direction of response to the different conditions to which the upper and lower leaves respectively have been exposed in nature for many generations.

10. With regard to the physiological effect of the hairs, &c., it is concluded that the pubescence prevents undue acceleration of transpiration, and especially that due to air movements and, to a less extent, insolation. It is probable that the stimulus of a decreased supply of water during development promotes the formation of three special kinds of elongated cells, each of which is physiologically important in connexion with the problems of water supply. At one end of the plant the root-hairs increase the intake of water, and at the other the hairs and (probably) the palisade cells assist in reducing the output of water from the leaves.

But the experimental treatment of the subject of the effect of leaf structure on transpiration is reserved for a future paper.

11. Structurally, the leaves of *Spiraea Ulmaria* show considerable differences according to position and time of development. The lower sheltered leaves are hygrophytic, while those which are exposed to wind, strong insolation, &c., are distinctly more xerophytic in character. It is concluded that this degree of xeromorphy of the upper leaves (hairiness, &c.) is a positive advantage to the plant, and probably actually necessary, at least under unusually severe transpiration conditions.

12. The whole position of our knowledge of 'swamp xerophytes' is reviewed, and the conclusion arrived at that all the evidence points to the various bog and marsh associations being as much in harmony with their environment as are those (e.g. woodland, desert associations, &c.)

occupying other distinctive habitats. In other words, xeromorphy is of physiological utility to those bog and marsh plants which exhibit it. It may be regarded as directly related to the needs imposed on the plant by the special nature of the habitat. But in each case the special regulatory devices are required to meet, not so much the everyday needs, as the extremes, possibly even only the occasional extremes which the species has to face in nature.

The environmental factors of a bog or marsh habitat are complicated. No single factor can be regarded as of sole importance in determining the need for xeromorphy. The hypothesis is put forward that, as suggested by so many authors, the soil is to some extent physiologically dry. The degree of physiological drought varies in different cases (e.g. bog soil is doubtless drier to plants than marsh soil), as do the factors or combination of factors which occasion it. But edaphic factors alone cannot account for the fact that hygrophytic and xerophytic species often live side by side in nature. Here atmospheric factors become important. Granted that the characters of the substratum are such that absorption of water is slow, then the atmosphere will play a differentiating rôle. A retardation of absorption is only prejudicial when accompanied by an excess of transpiration. On the whole the more hygrophytic species, or the more hygrophytic stages or portions of other species (e.g. seedlings, or the lowest leaves of herbaceous plants), occupy the lower humid strata of the vegetation. On the other hand, the more xerophytic species, or the more xerophytic parts of others, are those which grow under more severe transpiration conditions; e.g. evergreen plants, and those occupying the drier, more exposed strata of the vegetation.

Thus, in all probability, edaphic and climatic factors, the growth forms of the various species, with the resulting differences of exposure and shelter, the duration of the vegetative period, and possibly other factors, all play their part in determining the need or otherwise of special devices for regulating transpiration in swamp plants. In short, after making due allowances for the general nature of the habitat, the whole matter really resolves itself into a consideration of the different problems of individual species.

The work embodied in this paper was carried out chiefly at Aberystwyth, but, in addition, work was done at certain times at the Cambridge Botanical Laboratory and the Jodrell Laboratory, Kew. In addition, therefore, to various acknowledgements made in the course of this paper, I wish to express my thanks to Professor A. C. Seward, and to Lieut.-Col. D. Prain, for permission to use these laboratories, respectively. Also to Mr. L. A. Boodle, for kindly providing facilities at the Jodrell Laboratory, and for several helpful suggestions and criticisms; to Mr. R. I. Lynch,

Curator of the Cambridge Botanic Garden, for the trouble he took in growing a large number of *Spiraeas* for me, for the purposes of this paper; and finally to my pupil, Mr. C. M. Green, who is investigating some other species of marsh plants, and who has furnished me with information concerning their degree of xeromorphy.

EXPLANATION OF PLATES LXXXI-LXXXIII.

Illustrating Professor Yapp's paper on *Spiraea Ulmaria*, L.

The plates consist of photographs taken from dried and pressed leaves of *Spiraea Ulmaria*, L., to illustrate the distribution of hairiness. In each case, only the lower surface of the leaf is shown. *Hairy parts are white, glabrous parts dark.*

PLATE LXXXI.

Shows all the leaves formed during one season on an erect flowering shoot. The leaves are arranged and numbered in order of development. Leaves 1-7 are radical, and 8-16 cauline. There is (as always) a gradual transition from glabrous to hairy leaves. The shoot was grown under fully insulated conditions. Note the narrowing of the leaflets in the upper leaves (cf. Text-fig. 5).

PLATE LXXXII.

A selected series of radical leaves. N.B. These were taken from a number of different non-flowering shoots. This series is arranged to illustrate the distribution of hairiness on partially hairy leaves. Note the increase in hairiness of successive leaflets as the individual leaf is ascended: the terminal leaflet is invariably the most hairy. Compare the increase in hairiness of successive leaves as the entire plant (flowering shoot) is ascended—see Pl. LXXXI. In individual partially hairy leaflets the hairs usually form a marginal band, with sometimes (e. g. Nos. 4, 6, and 9) extensions in the form of bands between the main veins (cf. the localization of exposure withering—Text-fig. 11).

PLATE LXXXIII.

Three partially hairy leaves. No. 1 shows the marginal bands of hair; No. 3 the additional interveinal bands. The terminal leaflet of No. 2 illustrates a not infrequent case in which only the innermost portions of the interveinal bands are developed. These now show, in addition to the marginal bands, patches of hairs occupying the forks of the veins.

Some Conditions influencing the Fixation of Nitrogen by *Azotobacter* and the Growth of the Organism.

BY

FLORENCE A. MOCKERIDGE, B.Sc., A.K.C.

Layton Research Scholar at King's College, London.

DURING the progress of some research upon the utilization of various organic substances as food material by *Azotobacter*, of which an account will appear in due course, considerable difficulty was experienced in obtaining and keeping pure liquid cultures of the organism. Other investigators appear to have encountered a similar difficulty, for many different nutrient media and methods of culture are recommended by various authors. Most of the solutions advocated by them were tested in turn, with such unsatisfactory results that it was at last deemed advisable to make a thorough examination of the behaviour of the organism in these different culture solutions, both in respect of the rapidity and purity of the growth, and the extent of fixation of nitrogen obtained per unit of the carbohydrate consumed. The work was undertaken in the first place solely for the author's convenience, in order to clear away these preliminary difficulties as a preparation for further research, but the results appear to be of sufficient importance to warrant publication, and are embodied in the following account, in the hope that they may be of use to other workers on the subject.

Undoubtedly the best method of obtaining a luxuriant growth in a short space of time is by the use of plate cultures in the manner advocated by Hoffmann and Hammer, in which the surface of a mannite-agar plate is covered with 5 or 10 c.c. of a suspension of *Azotobacter* in 0.9 per cent. sodium-chloride solution. By this means a prolific growth is obtained uniformly over the whole surface of the plate, and, if the medium is sterile in the first place, no difficulty is experienced in keeping pure vigorous cultures on these agar plates. The trouble arose when liquid cultures were required, and it was necessary, in the first place, to arrive at some conclusion as to what are the optimum conditions with regard to alkalinity; and, in the second place, to decide which are the inorganic constituents of the nutrient medium which are necessary and beneficial to the organism, the

best organic constituent having been accepted for the time being as mannite. Mme Krzemieniewski has shown that potassium, calcium, sulphur, magnesium, and phosphorus are all essential to the development of *Azotobacter*. Recent work by Omeliansky and Ssewerowa, and also by Remy and Rösing, has brought out the importance of iron, while Kaserer lays stress on the need for aluminium and silicon also; but further reference will be made to this work later.

The solutions, apart from those containing iron, aluminium, and silicon, which had been used with more or less success, practically resolve themselves into two classes: firstly, those in which neutralization of the acid potassium phosphate had been effected simply by the addition of excess of calcium carbonate; and, secondly, those in which the acidity had been neutralized by the addition of dilute sodium-hydrate solution, either to the whole culture solution, or to a solution of the phosphate made separately and afterwards added to the main bulk, the necessary calcium being supplied to the medium in the form of a small amount of a salt other than the carbonate. A combination of the two methods is found in the medium used by Ashby, who dissolves the phosphate separately, just neutralizes it with sodium hydrate, and, after the addition of this to the main portion of the solution, adds an excess of calcium carbonate. The solution used by Beijerinck consisted of:

Tap water	1,000 c.c.
Mannite	20 grm.
Di-potassium phosphate	0.2 grm.

and, having used this for purposes of experiment, he claims that *Azotobacter* will not, in pure culture, fix nitrogen. Chester points out that the medium is at fault, since no attempt is made to correct the acidity of the phosphate, and he reports that a good fixation of nitrogen has been obtained at the New Jersey Experiment Station on a medium consisting of the following:

Tap water	1,000 c.c.
Mannite	15 grm.
Di-potassium phosphate	0.5 grm.
Magnesium sulphate	0.2 grm.
Calcium chloride	0.02 grm.

the whole being rendered alkaline by means of sodium hydrate. Many attempts have been made by the writer to obtain growths of *Azotobacter chroococcum* on this medium, with very little success; and when a surface film has developed at all, it has been very scanty, the best having been obtained in solutions which had been rendered just neutral by sodium hydrate, the presence of any excess, even in very small amounts, of the latter proving fatal to development. No determinations of the nitrogen-

fixation upon this medium were made, for failure to obtain any growth at all occurred so frequently as to prove that this solution was far from favourable for the development of the particular strain of *Azotobacters* concerned in this investigation. No good results could be obtained in any medium which did not contain an excess of calcium or magnesium carbonate ; and, this having been decided, the chief remaining point to be considered in this connexion was the question as to whether the addition of sodium, either as the hydrate or in any other form, is *beneficial* to the organism ; the fact that *Azotobacter* will grow and fix nitrogen without it proving that it is not *necessary*. Since the isolation of the organism from the soil in 1901 by Beijerinck, many workers have devoted a considerable amount of time to a determination of the conditions under which the most luxuriant growth of vigorous *Azotobacters* can be obtained ; for the importance, from a practical, agricultural point of view, of a precise knowledge of these conditions cannot be over-estimated, and the more simple the culture solution which can be used, the better. As regards the elements supplied, apart from the sodium and the neutralizing agents, the solutions used, except for the recent work above mentioned, are all practically similar, so that the liquid medium hitherto used by Professor Bottomley in the Botanical Laboratory at King's College was tested as a type of those without sodium, against Ashby's solution representing those containing sodium salts. At the suggestion of Professor Bottomley, an investigation was also made to obtain some idea of the efficiency of basic slag as a substitute for calcium carbonate, of which further details will be given later.

When the questions of the relative merits of Bottomley's and Ashby's solutions, and of calcium carbonate and basic slag as neutralizing agents, were settled, there arose the problem as to what is the best quantity of nutrient solution to supply to ensure maximum fixation. The practical worker requires a maximum yield of combined nitrogen for the minimum expenditure of carbohydrate ; and it has been suggested that the activity of the organism varies inversely, to a certain extent, with the quantity of food material supplied, i. e. that when provided with a very small portion of food, the *Azotobacter* economizes, using the carbohydrate to the best advantage ; so that under these conditions fixation is relatively greater than in a liberal supply of food material. Closely connected with this is the question as to whether the organism is able to utilize the last traces of carbohydrate in the medium as a source of energy for the fixation of nitrogen, or whether, as has also been suggested by various workers, after a certain period of time, while some of the carbohydrate originally supplied is still present in the solution, a process of auto-digestion sets in, nitrogen-fixation coming to an end for the time being. In the experiments described by different authors, amounts of nutrient solution ranging from 10 to 1,000 c.c. have been employed, with concentrations of carbohydrate ranging from 0.1 to 2

and even 5 per cent., whilst the cultures have been allowed to grow for widely divergent periods of time before analysis has been made of their contents. The results reported by different workers as to the amounts of nitrogen fixed appear to be somewhat conflicting, but they are not strictly comparable one with another, since Gerlach and Vogel have shown that the activity of the organism varies with the concentration of the carbohydrate, and with the age of the culture, which latter statement is borne out by the results obtained in the course of the present work.

Some attempt having been made to solve the foregoing problems, some consideration was given to the question of aeration. Considerable attention has been directed by various investigators to the discovery of some means of improving the aeration of organisms grown in liquid cultures. Freudenreich more particularly advocates the method of using gypsum plates, placed in Petri dishes and soaked in nutrient solution, and Krainski reports that he obtained the characteristic browning in from two to four days by the adoption of this method; while strips of gypsum placed in test-tubes containing some of the solution are favoured by other workers. For solid media, Koch recommends the use of large Petri dishes containing a thin layer of mannite-agar, and this method has been universally adopted in cases where it is suited to the special requirements of the occasion. Whatever be the vessels used for the production of liquid cultures, the use of a layer of nutrient solution as thin as is consistent with convenience is always recommended; and some workers, notably Hoffmann and Hammer, advocate the use of white quartz sand, which is shaken to one side of the flask, and forms a slope which rises well above the surface of the liquid. The use of these sand slopes proved to be by far the most efficient and convenient method of improving the aeration of the organisms in the course of the present work, for a suspension of the Bacteria could readily be obtained by adding water, well shaking the vessel, and allowing the sand to subside; while when required for analysis, the whole of the contents of the flask could most easily be transferred to a Kjeldahl flask by means of a jet of distilled water from a wash-bottle. Accordingly some attempt was made to obtain an idea of the extent of the superiority of this method over that of the ordinary liquid culture, as far as the fixation of nitrogen per unit of carbohydrate consumed was concerned.

In order to ascertain the best medium, as regards the inorganic constituents, for the growth of *Azotobacter*, a pure culture of the organism was first obtained on a mannite-agar plate. A colony was transferred by means of a sterilized platinum wire to about 30 c.c. of sterile water contained in a large test-tube, which was then well shaken, to ensure a uniform distribution of the Bacteria. One cubic-centimetre of this suspension was transferred by means of a sterile pipette to each of the flasks to be used for the experiment, for the purposes of which three nutrient solutions were

Nitrogen by Azotobacter and the Growth of the Organism. 875

used. The first was that which had hitherto been used for the isolation and growth of the organism by Professor Bottomley in the Botanical Laboratory at King's College, and consisted of:

Mannite	10 gm.
Di-potassium phosphate	2 gm.
Magnesium sulphate	0.2 gm.
Calcium carbonate	2 gm.
Distilled water	1,000 c.c.

50 c.c. of this solution were put into each of seven 300 c.c. Jena glass Erlenmeyer flasks, which had previously been sterilized. The contents of the flasks were then boiled, 50 gm. of quartz sand, which had been previously washed, dried, screened, and recently ignited, were added, and each flask was plugged and allowed to cool, when the liquids were inoculated as described above. These flasks were numbered from 1 to 7.

The second solution employed was a modification of the first, suggested by Professor Bottomley, in which 0.2 per cent. of basic slag replaced the 0.2 per cent. of calcium carbonate. The acidity of the phosphate was neutralized by the lime in the slag, which, in addition, contained small amounts of the oxides of iron, manganese, magnesium, silicon, and aluminium, as shown in the analysis of the slag given later. The solution was thus made up as follows:

Mannite	10 gm.
Di-potassium phosphate	2 gm.
Magnesium sulphate	0.2 gm.
Basic slag	2 gm.
Distilled water	1,000 c.c.

50 c.c. of this solution were then put into each of seven flasks, which were provided with sand slopes and otherwise treated in a manner exactly similar to that adopted with the first seven. These were numbered from 8 to 14 inclusive.

The third solution tried was that used by Ashby, but only 10 gm. of mannite were used per litre, instead of 12 to 20 gm. as advised by Ashby, the alteration being made in order to render the solution comparable as regards the concentration of the carbohydrate with the preceding ones. The solution consisted of

Mannite	10 gm.
Mono-potassium phosphate	0.2 gm.
Magnesium sulphate	0.2 gm.
Sodium chloride	0.2 gm.
Calcium sulphate	0.1 gm.
Calcium carbonate	5.0 gm.
Distilled water	1,000 c.c.

The acid phosphate was dissolved separately and just neutralized by means of a decinormal sodium-hydrate solution before being added to the main bulk. The seven flasks used in this case were numbered from 15 to 21 inclusive. The whole series of 21 flasks was inoculated at the same time with the same suspension of *Azotobacter*, in order that the conditions should be as uniform as possible, and Nos. 1, 8, and 15 were sterilized, after inoculation, in the autoclave for ten minutes at a temperature of 13.5° C. These served as controls, one for each of the solutions used, and by inoculating the flasks before sterilizing a knowledge of the actual fixation of nitrogen was arrived at, and not the nitrogen fixed plus the small amount of nitrogen supplied in the bacterial cells. The twenty-one flasks were then incubated at a temperature of 28° C. for seven days, at the end of which period the contents of each were transferred by means of distilled water from a wash-bottle to round-bottomed flasks, to undergo analysis by the Kjeldahl process for their nitrogen content. The results of these analyses are given in the following table:

TABLE I.

Flask No.	Culture Solution.	Nitrogen Content.	Gain in Nitrogen on $\frac{1}{2}$ grm. Mannite.	Nitrogen-fixation on 1 grm. Mannite.	Average Nitrogen-fixation.
1.	Bottomley's Solution (I) ¹ —sterile	0.14 mg.			
2.	" " with <i>Azotobacter</i>	4.78 mg.	4.64 mg.	9.28 mg.	9.70 mg.

15.	Ashby's solution—sterile	0.11 mg.			
16.	" " with <i>Azotobacter</i>	3.10 mg.	2.99 mg.	5.98 mg.	6.08 mg.
17.	" " "	3.30 mg.	3.19 mg.	6.38 mg.	
18.	" " "	2.81 mg.	2.70 mg.	5.40 mg.	
19.	" " "	3.09 mg.	2.98 mg.	5.96 mg.	
20.	" " "	3.23 mg.	3.12 mg.	6.24 mg.	
21.	" " "	3.37 mg.	3.26 mg.	6.52 mg.	

While the results show a very decided fixation of nitrogen in all the media, yet both of Bottomley's solutions appear to be better than Ashby's medium, and the presence of basic slag seems to have a beneficial effect. The fixations in each series appear to be fairly uniform among themselves, and are consistent with other results which have been obtained, so that, as a result of these determinations, Bottomley's solution (II),

¹ 'Bottomley's Solution (I)' is the solution containing calcium carbonate, while 'Bottomley's Solution (II)' is that containing basic slag.

which contains basic slag as the neutralizing agent, has since been used in the Botanical Laboratory of King's College for isolation and growth of *Azotobacters*. This nutrient medium is one of the simplest which have been used, and by the addition of 2 per cent. of agar-agar, answers equally well for plate cultures.

One further point in connexion with the nutrient solution remained to be determined; i. e. whether, after complete neutralization of the acidity of the solution due to the phosphate, any further addition of basic slag produced a beneficial effect. Hoffmann and Hammer have shown that, so long as the liquid is neutral, increase in nitrogen-fixation does not follow upon increase of calcium carbonate in the medium; but it seemed probable, since the presence of the slag appeared to give a distinct impetus to the fixation of nitrogen, that one or more of the constituents of the slag other than lime might have a tonic effect on the organism, which effect might be increased by the addition of a greater proportion of slag to the medium. The presence of 0.2 per cent. of the slag was sufficient to render the liquid neutral to litmus-paper, so five solutions were made up, each containing 1 per cent. mannite, 0.2 per cent. di-potassium phosphate, 0.02 per cent. magnesium sulphate, with the addition of 0.2, 0.4, 0.6, 0.8, and 1.0 per cent. of basic slag respectively. 50 c.c. of the solution containing 0.2 per cent. of slag were put into each of three flasks, which were provided with sand slopes and otherwise treated exactly as in the foregoing experiment. These flasks were numbered from 1 to 3, and, similarly, three flasks were used for each of the other four liquids, the total number being thus fifteen. Each one was then inoculated with the suspension of *Azotobacter*, and Nos. 1, 4, 7, 10, and 13 were sterilized to serve as controls. The whole series was incubated for seven days at a temperature of 28° C., and at the expiration of this time the contents of each flask were transferred to a Kjeldahl flask and analysed for their nitrogen content, with the following results:

TABLE II.

Flask No.	Proportion of Slag.	Nitrogen Content.	Fixation on $\frac{1}{2}$ gm. Mannite.	Fixation on 1 gm. Mannite.	Average Fixation.
1.	0.2 %	0.55 mg.			
2.	0.2 %	6.54 mg.	5.99 mg.	11.98 mg.	12.30 mg.
3.	0.2 %	6.86 mg.	6.31 mg.	12.62 mg.	
4.	0.4 %	0.70 mg.			
5.	0.4 %	7.56 mg.	6.86 mg.	13.72 mg.	14.28 mg.
6.	0.4 %	8.12 mg.	7.42 mg.	14.84 mg.	
7.	0.6 %	0.77 mg.			
8.	0.6 %	6.58 mg.	5.81 mg.	11.62 mg.	11.34 mg.
9.	0.6 %	6.30 mg.	5.53 mg.	11.06 mg.	
10.	0.8 %	0.84 mg.			
11.	0.8 %	6.02 mg.	5.18 mg.	10.36 mg.	10.78 mg.
12.	0.8 %	6.44 mg.	5.60 mg.	11.20 mg.	
13.	1.0 %	0.98 mg.			
14.	1.0 %	7.56 mg.	6.58 mg.	13.16 mg.	13.02 mg.
15.	1.0 %	7.42 mg.	6.44 mg.	12.88 mg.	

It appears from these figures that while a good fixation is obtained with 0.2 per cent. of slag, an even better one results from the use of 0.4 per cent. The addition of more than this, however, produces a perceptible, though not very considerable deterioration in nitrogen-fixing power, which effect increases with increase in the proportion of slag until 1 per cent. is reached, when the presence of this quantity appears to stimulate the organisms to greater activity than does the use of 0.6 or 0.8 per cent. The proportion of 0.4 per cent., however, obviously produces the most beneficial effects, probably on account of the stimulative effect of certain constituents of the slag; the addition of these substances in larger quantities than are contained in 0.4 per cent. being not only unnecessary, but harmful to the organism. The results obtained by the use of 1 per cent. of slag occasioned considerable surprise, but it seems possible that in this quantity just sufficient of another constituent, present in the slag in lesser proportion, has been added, to exert a second tonic effect, and overcome, to a certain extent, the depressing influence of over-doses of those elements to which the first stimulation was due. In order to test the truth of this hypothesis and to ascertain the effect of still larger proportions of slag, further series of experiments are now in progress, the results of which will be given as soon as possible.¹ It is clear, however, that the effect of the slag is not limited, as is that of calcium carbonate, to a simple neutralization of acidity, but that certain constituents, though not essential to the growth of and fixation of nitrogen by *Azotobacter*, yet when added in the correct proportions, exert a beneficial influence on the activity of the organisms.

The question of the best liquid nutrient medium having been thus far settled, the next point to be ascertained was whether the Bacteria are able to utilize the last traces of carbohydrate food material present in the culture solution, or whether, when the solution of the nutrient has become sufficiently dilute, the process of auto-digestion before mentioned sets in, no further increase in the nitrogen content taking place. It is generally recognized that the carbohydrate in 50 c.c. of 1 per cent. solution is practically used in seven days, so two series, each consisting of six flasks, were taken. These were numbered from 1 to 6 and from 7 to 12 inclusive. Each of the first six contained 50 c.c. of 1 per cent. Bottomley's solution, and each of the second six was supplied with 50 c.c. of 1 per cent. Ashby's solution, every one being provided with 50 grm. of sand to form a slope, and all being inoculated with 1 c.c. of the suspension of *Azotobacter* in sterile water. Nos. 1 and 7 were autoclaved at a temperature of 135° C., and the whole series was incubated at 28° C. The object of the experiment was to determine the fixation in each solution at the end of seven days, and also the fixation consequent on the consumption of the whole of the carbo-

¹ Since the completion of this paper, these results have been obtained, and are given on p. 885.

hydrate. In order to prevent any vitiation of results by the abstraction of small quantities of the solution for examination for the presence of carbohydrate, the following method was adopted. One flask more than was required for analysis was included in each series, and since all the flasks had been supplied with exactly the same quantity of culture solution, and inoculated with the same amount of bacterial suspension, it was assumed that growth would take place at the same rate in each, and when the mannite in the extra flask had been consumed, it would also have disappeared from the others. Nos. 6 and 12 were used as these extra flasks, and at the end of the seventh day Nos. 1, 2, 3, 7, 8, and 9 were analysed for their nitrogen content, while a drop was extracted from each of Nos. 6 and 12, evaporated to dryness on a glass slide, and examined microscopically for the crystals of mannite. Since the latter appeared to be present in both cases, Nos. 4, 5, 6, 10, 11, and 12 were re-incubated for another day, when Nos. 6 and 12 were again examined. This time no crystals appeared in the drop extracted from No. 6, so Nos. 4 and 5 were analysed, but No. 12 still contained traces of the food-stuff. The remaining three of the series were accordingly re-incubated, and this process of testing No. 12 each day for the mannite repeated until all the latter was consumed, when Nos. 10 and 11 were subjected to analysis. In this way some idea was obtained of the relation between the fixation in seven days upon 50 c.c. of the solution containing $\frac{1}{2}$ grm. of carbohydrate, and that upon the total $\frac{1}{2}$ grm. The results are shown in the following table:

TABLE III.

Flask No.	Culture Solution.	Time taken.	Nitrogen Content.	Gain in Nitrogen.	Average gain in Nitrogen.
1.	50 c.c. Bottomley's solution—sterile . . .		0.41 mg.		
2.	" " with <i>Azotobacter</i>	7 days	5.67 mg.	5.26 mg.	5.40 mg.
3.	" " "	7 "	5.95 mg.	5.54 mg.	
4.	" " "	8 "	6.22 mg.	5.81 mg.	
5.	" " "	8 "	6.31 mg.	5.90 mg.	5.85 mg.
7.	50 c.c. Ashby's solution—sterile . . .		0.55 mg.		
8.	" " with <i>Azotobacter</i> . .	7 "	4.39 mg.	3.84 mg.	3.70 mg.
9.	" " "	7 "	4.12 mg.	3.57 mg.	
10.	" " "	18 "	4.27 mg.	3.72 mg.	
11.	" " "	18 "	4.42 mg.	3.87 mg.	3.79 mg.

It is obvious that nitrogen-fixation was almost complete at the end of seven days in both series. In Bottomley's solution, however, the presence of mannite was manifested for only one day after this period, and the increase in nitrogen content for this day was nearly a half-milligramme; whilst in Ashby's solution, although the mannite was not completely used for eighteen days, yet the increase in nitrogen for the last eleven days of that period was scarcely beyond the range of experimental error in analysis. It is clear, how-

ever, that even after the expiration of eighteen days there is no *loss* of nitrogen, and the evidence goes to show that the organisms are capable of utilizing the last traces of carbohydrate supplied to them, and, under the most favourable conditions, are able to continue the process of nitrogen-fixation until the food supply is exhausted. Exactly why the organisms should not have shown greater activity as regards the fixation of nitrogen in the cultures in Ashby's medium which had been left to grow for eighteen days is not clear, unless it be that the accumulation of certain products, either of partial decomposition of the mannite, or of excretion of the *Azotobacter*, or both, may have, in this rather less favourable medium, put an end to the nitrogen-fixing activity of the organism for the time being. Upon inoculation of a fresh portion of the culture solution with *Azotobacter* from flask No. 12 a good and strong growth was obtained, so that evidently the organisms were in a perfectly healthy condition. Since these results have been obtained, an account of an investigation conducted by Koch and Leydell has come to hand, in which they state that nitrogen-fixation comes to an end after five to eight days, the remainder of the carbohydrate being utilized for respiration and other purposes. This would account for the presence of carbohydrate for eighteen days, during the last eleven of which no fixation of nitrogen took place in Ashby's medium, but under the best conditions *Azotobacter* appears to fix nitrogen vigorously while the carbohydrate lasts.

Three series of cultures were taken in order to determine whether, in the same percentage solution, the fixation of nitrogen is strictly proportional to the amount of carbohydrate consumed; i. e. whether the increase in nitrogen consequent upon the consumption of 1 grm. of mannite is essentially twice that on $\frac{1}{2}$ grm., or four times that on $\frac{1}{4}$ grm. Each series consisted of four cultures; the flasks of the first series, numbering from 1 to 4, each containing 100 c.c. of 1 per cent. Bottomley's solution and 100 grm. of sand to form a slope; those of the second, numbering from 5 to 8, each containing 50 c.c. of the same solution and 50 grm. of sand; while those of the third, numbering from 9 to 12, each contained 25 c.c. of solution and 25 grm. of sand. When all had been inoculated, and Nos. 1, 5, and 9 afterwards sterilized in the autoclave in order to serve as controls, all were incubated at 28°C. Nos. 4, 8, and 12 were tested from time to time for the presence of mannite, by evaporating a drop to dryness and examining for the crystals, and when one of these cultures no longer showed evidence of the presence of carbohydrate, the contents of the three remaining flasks of the series were analysed for their combined nitrogen, with the following results:

TABLE IV.

Flask No.	Culture Solution.	Time taken.	Nitrogen Content.	Gain in Nitrogen.	Average Gain in Nitrogen.	Relative Gain on 1 grm.
1.	100 c.c. 1 % solution—sterile		0.69 mg.			
2.	" " with <i>Azotobacter</i>	10 days	9.21 mg.	8.52 mg.	8.38 mg.	8.38 mg.

The flasks used were all of the same size, namely Erlenmeyer flasks of 300 c.c. capacity; hence the depth of the liquid, and consequently the aeration, varied with the quantity of solution supplied. It follows that the organisms in the 50 c.c. cultures obtained a better aeration than those in the 100 c.c., and this fact probably accounts for the slightly greater nitrogen-fixation, relatively, in the former than in the latter. Directly opposed to this is the comparatively small increase in the 25 c.c. cultures, though the organisms in this case possessed the greatest advantage as regards aeration. It is a well-known fact, however, that when supplied with soluble nitrogen, *Azotobacter* does not fix until this available nitrogen has been consumed, so the very small fixation in the 25 c.c. cultures is probably explained by the assumption that the Bacteria first of all utilize the small amount of nitrogen present in the medium, as shown by the control, using at the same time a portion of the mannite as a source of energy. When the process of nitrogen-fixation began, a relatively much smaller amount of mannite would be available as a source of energy in these cultures than in the 50 and 100 c.c. ones, and hence a smaller gain in nitrogen would be expected. All the materials used were supposed to be chemically pure, but every control so far examined shows the presence of nitrogen. The growths were apparently perfectly healthy, but it is fairly evident that the organisms used throughout the series were more or less weakened by continued growth under artificial conditions, since the fixation per gramme of carbohydrate consumed amounted to only between 8 and 9 mg., while in the earlier part of the work the organisms originally obtained from the same source gave fixations amounting to 14 mg. However, Hoffmann and Hammer obtained good fixations in 25 c.c. of 1 per cent. solution, so that, when multiplied by four, their results gave fixations of 14.40 mg. on 1 grm. carbohydrate used—results which are not comparable with any of those obtained in 25 c.c. cultures in the course of the present work.

In connexion with the question of aeration, some experiments were started to obtain some idea of the extent of the superiority of the sand-slope method over that of ordinary liquid cultures as regards the yield of nitrogen per unit of carbohydrate used. Two series of six flasks each were employed, the first series, numbering from 1 to 6, containing Bottomley's solution, and the second, numbering from 7 to 12, being supplied with Ashby's solution. 50 c.c. of 1 per cent. solution were put into each flask, and 50 grm. of sand to form a slope were added to Nos. 4, 5, 6, 10, 11, and 12. The process of inoculation was carried out in exactly the same manner as before, with the suspension of *Azotobacter* in sterile water, and Nos. 1, 4, 7, and 10 were sterilized in the autoclave to act as controls, after which all were incubated at 28° C. for seven days. At the end of this period the contents of each vessel were transferred to a Kjeldahl flask and analysed for its nitrogen content, the results being as follows:—

TABLE V.

The effect of the increased aeration due to the sand slope is made very clear by these figures, and the difference between the simple liquid culture, and that on a sand slope, in rapidity of growth was equally apparent to the eye. On the sand slopes, the gelatinous growth appeared earlier, grew more rapidly, and darkened much more quickly than did that on the liquid. On the sand-slope cultures in Bottomley's solution, the film of *Azotobacter* appeared over the whole surface on the third day; its formation was deferred until the fifth day in the sand-slope cultures in Ashby's medium and in the ordinary cultures without sand in Bottomley's solution, while in Ashby's liquid cultures no perceptible growth occurred, and the fixation of nitrogen, as shown in the above table, was very slight. The effect on the rapidity of growth of the increased aeration due to the sand was very strikingly shown at the same time by some cultures grown on ethyl alcohol. When an ordinary liquid medium was inoculated, growth took place very slowly, the film appearing over the surface only after the

lapse of about ten days, while at the end of the same period a prolific growth was apparent in the vessels containing the sand slopes, the particles of the white quartz sand which had been used having become almost black, due to the darkening of the film of *Azotobacter* which thus evidently covered each grain. The better aerobic condition maintained by the presence of the sand was also effective in assisting to the purity of the cultures, any anaerobic *Clostridium* with which they had become contaminated developing here with much greater difficulty than under the less aerated conditions found in the ordinary liquid cultures. *Clostridium*, where present, was also seen to develop decidedly better in 100 c.c. cultures than in 50 c.c. ones, the deeper layers of the larger volume being obviously more suited to its requirements than those of the smaller culture. The presence of sodium also seemed to favour the growth of these butyric organisms, and more particularly was this evident in the New Jersey medium, where, if the feeble growth of *Azotobacter* became contaminated with *Clostridium*, the latter developed vigorously, while the further development of the former was inhibited. This is due to the fact that no excess of the neutralizing agent was present in the medium, to correct the acidity of the products of vital activity of *Clostridium*, the accumulation of acid products proving fatal to *Azotobacter*.

CONCLUSIONS.

The conclusions which have been arrived at as a result of this investigation appear to be of some importance in connexion with the production of large quantities of vigorous Azotobacters, especially when they are required for soil inoculation, in which case the strongest possible cultures are desirable. The main points are as follows :

In the first place, the presence in the medium of an excess of calcium, or magnesium carbonate, or basic slag, as a neutralizing agent, is more advantageous than that of sodium hydrate ; and the former substances not only assist the rapidity of the growth, but also help to maintain its purity.

The figures obtained show clearly that the presence of sodium salts is not only unnecessary, but exerts a depressing influence on the activity of *Azotobacter* as regards the fixation of nitrogen. The beneficial effect of the sodium-chloride solution in inoculating agar plates is due to the fact that this liquid is isotonic with the cell-contents, a solution of similar concentration of many other salts answering the purpose equally well.

Basic slag is an excellent substitute for precipitated chalk as a neutralizing agent in the nutrient medium, and it evidently also contains ingredients which exert a tonic effect upon the organism, increasing its activity in connexion with nitrogen-fixation by as much as 23 per cent. Exactly which of the constituents of the slag have this influence is not known, but probably the iron and manganese present are the most important

884 *Mockeridge. — Some Conditions influencing the Fixation of*

in this respect. Appended is an analysis of the slag which, together with samples of the material, was furnished by the courtesy of the Manager of the Chemical Works—late H. and E. Albert.

Silica	6.95 per cent.
Alumina	5.42 "
Ferrous oxide of iron	4.83 "
Ferric " "	8.49 "
Lime	47.02 "
Phosphoric acid	18.88 "
(Citric acid soluble phosphoric acid = 15.74 ")	
Manganese	2.30 "
Magnesium oxide	5.15 "
Sulphur	0.96 "
Total iron = 6.89 "	

The proportion of slag required to induce a maximum fixation of nitrogen is 0.4 per cent.

This solution, with basic slag as the neutralizing agent, contains all the ingredients which Mme Krzemieniewski states are essential to the development of *Asotobacter*, besides the iron which Omeliansky and Ssewerowa, and more particularly Remy and Rösing, find to be so important, and the aluminium and silicon which the experiments of Kaserer prove to be so beneficial. Mme Krzemieniewski states that the minimum amounts of the elements requisite for the consumption of 1 grm. of dextrose are potassium 0.38 mg., calcium 0.36 mg., magnesium 0.35 mg., phosphorus 2.46 mg., and sulphur more than 0.49 mg. These requirements are fulfilled by the medium the use of which is here advocated, and the results obtained appear to be in accordance with those of the investigators mentioned.

Although nitrogen-fixation can, and does, under favourable conditions, proceed until the food material is completely exhausted, yet the most active fixation of nitrogen in the small 50 c.c. cultures used in the laboratory is obtained during the course of the first week, possibly owing to some depressing influence which the accumulation of the products of their vital activity may exert upon the organisms.

The yield of combined nitrogen per unit of carbohydrate consumed is apparently not influenced by the depth of the layer of liquid to such an extent as to warrant the use in all cases of the minimum quantity, and, for the purposes of experiment in the laboratory, a volume of 50 c.c. of solution in a 300 c.c. Erlenmeyer flask gives a layer sufficiently well aerated to ensure a good fixation. The best results are evidently not obtained by the supply of only very small amounts of carbohydrate food material, but, once a good growth is obtained, the yield of nitrogen appears to be practically proportional to the amount of food supplied. The use of fairly thin layers of

liquid is, however, to be advocated as assisting in the aeration of the culture, and thus inhibiting, to some extent, the growth of any contaminating *Clostridium*.

The use of sand slopes, as a means of increasing the surface, and therefore the supply of oxygen and nitrogen to the organisms, is to be strongly recommended, the adoption of this method resulting in a more rapid, vigorous, and healthy growth, giving a much greater increase in nitrogen in a given space of time, and being much more free from contamination by anaerobic organisms than is the method of ordinary liquid cultures.

The use of the sand-slope method of culture, with Bottomley's medium in volumes of 50 c.c., results in the fixation of 14 mg. of nitrogen per gramme of mannite consumed, when the most vigorous organisms are used for purposes of inoculation.

Another important result of the present investigation is the confirmation which it gives to the statement of Gerlach and Vogel, that the nitrogen-fixing activity of *Azotobacters* decreases as their age increases, since in the latter part of the work, when the organisms had presumably become weakened by successive subculture under artificial conditions, they were able to fix only between 8 and 9 mg. of nitrogen, their yield in the earlier part of the work having been 14 mg. per gramme of carbohydrate consumed.

In conclusion, my grateful thanks are due to Professor W. B. Bottomley for the many helpful suggestions given and the kindly interest maintained during the progress of the work.

ADDENDUM.

As a result of the unexpected fixation of nitrogen obtained on 1 gram. of mannite in a medium containing 1 per cent. of slag, nine solutions were made up in order to test the effect of increasing proportions of this neutralizing agent. These solutions each contained 1 per cent. mannite, 0.2 per cent. di-potassium phosphate, 0.02 per cent. magnesium sulphate, with the addition of 1.2, 1.4, 2.0, 2.8, 4.0, 5.0, 6.0, 8.0, and 10.0 per cent. of basic slag respectively. 50 c.c. of the solution containing 1.2 per cent. were put into each of three flasks, and 50 gram. of sand were added to form a slope. These flasks were numbered from 16 to 18, and, similarly, three flasks were used for each of the other solutions, the total number being thus twenty-seven. Nos. 16, 19, 22, 25, 28, 31, 34, 37, and 40 were autoclaved to serve as controls, and the whole series was incubated for seven days at a temperature of 28° C. They were then analysed for their nitrogen content, and the total results obtained with the varying proportions of slag are as follows:

886 *Mockeridge.—Some Conditions influencing the Fixation of*

37.	8.0 %	0.43 mg.			
38.	8.0 %	1.86 mg.	1.43 mg.	2.86 mg.	2.57 mg.
39.	8.0 %	1.57 mg.	1.14 mg.	2.28 mg.	
40.	10.0 %	0.71 mg.			
41.	10.0 %	0.64 mg.	—	—	—
42.	10.0 %	0.71 mg.	—	—	

It appears from these results that a proportion of 0.4 per cent. of basic slag has the most beneficial effect upon the activity of the organisms. Their nitrogen-fixing power declines when more than 0.4 per cent. is used, but receives a further stimulation in a medium containing 1 per cent. A steady decrease in nitrogen-fixation follows upon increase in the proportion of slag above 1 per cent., until 5 per cent. is reached, when it begins to fall rapidly and is rendered impossible in a medium containing 10 per cent.

These observations appear to lend support to the hypothesis put forward in a previous paragraph, that the effect of basic slag is not limited to a simple neutralization of acidity, but that there are at least two constituents, probably iron and manganese, present in the slag in different proportions, which exert a tonic influence upon the organisms; the maximum effect of the one being obtained in a proportion of 0.4 per cent., the other being most efficacious in a medium containing 1.0 per cent.

A Physiological Study of the Germination of *Helianthus annuus*. II. The Oily Reserve.

BY

EDWIN C. MILLER.

IN a previous paper¹ I reported a study of the general chemical changes which occur in the reserves of the seed of the sunflower during different stages of its germination, and concluded that the carbohydrates which appear in the seedling during germination have their origin in the oily reserve. Only a slight study of the oil itself was made at that time, however, so that it was thought advisable to make a further study of it at different stages in the development of the seedling in order to determine what changes it might undergo during germination.

In the previous paper a review was given of the work carried on by different investigators on the changes which take place in oily seeds during their germination as far as references to these works could be found. One paper, however, which escaped my observation, might well be reviewed here. Deleano,² in a study of the seed and seedling of *Ricinus communis*, could not detect the smallest trace of free fatty acid or glycerine at any stage of the seedling. He observed that the quantity of reducing sugar at the time when the disappearance of the oil was most rapid, was small compared to the amount of oil which disappeared, but that the amount of substances soluble in water at that time was large. He found also that the quantity of catalase diminished as the oil disappeared. From these observations he reached the conclusion that the oil contained in the seed as a reserve is not saponified in the cells at all, but that it is transformed into soluble compounds which are easily translocated to the growing parts. These compounds, then, give rise to the carbohydrates which are found in the seedling. He also believes that the catalase plays some part in the transformation of the oil. In the present paper reference will be made only to

those investigations which are deemed necessary for a clear discussion of the results obtained.

STAGES OF THE SEEDLING EXAMINED.

The oil was examined in the resting seed and in five different stages of the seedling. The stages examined were the same as those studied in the previous investigation with the exception of Stage I. Previously the first examination of the seedling was made when the hypocotyls and roots had attained a length of 2.5 to 3.5 cm. Experience showed, however, that it was difficult to obtain a sufficient quantity of hypocotyls and roots to yield the amount of oil necessary for the determinations that were to be made. The seedlings, therefore, were first examined at a later stage of development, when the roots and hypocotyls had a length of 3.5 to 5 cm. The seedling reached this stage in about three and a half to four days.

A brief description of the last four stages of the seedling examined is given here for convenience. If a more detailed explanation is desired, the description and figures of the different stages may be consulted in the former paper.

Stage II. The hypocotyls and roots had a length of from 7.5 to 11 cm., and the arch of the hypocotyl was just breaking through the surface of the ground. The cotyledons had not yet emerged from the seed-coat. The seedlings reached this stage about five days after the planting of the seed.

Stage III. At this stage the hypocotyls had reached a length of from 5 to 6 cm. above the surface of the ground, and the main roots were about the same length with numerous side roots about 2.5 to 3.5 cm. in length. The cotyledons were a bright green, and were spread out perpendicular to the hypocotyl. The plumule had not yet developed. The time required for the seedling to reach this stage was about seven days.

Stage IV. The hypocotyls had now a length of from 8 to 10 cm. from the surface of the ground to the cotyledons. The main roots had reached a length of 6 to 7 cm., and had developed an abundant growth of lateral roots. The cotyledons had broadened and lengthened, and the plumule was slightly developed. The young plant reached this stage of development in about ten days after the planting of the seed.

Stage V. The seedling at this stage differed little from that of Stage IV in general appearance, except that the plumule was more fully developed and the cotyledons had become more leaf-like. The seedling reached this stage in about fourteen days after the seed was planted.

PREPARATION OF MATERIAL FOR ANALYSIS.

I. *Preparation of Dry Material.* The seedlings for this experiment were grown in ordinary quartz sand in the greenhouse. As soon as the

seedlings had reached the desired stage of development, they were taken up and washed free from the sand. The hypocotyls were then separated from the cotyledons, and the two parts then ground up separately in an ordinary meat chopper. The ground material was then covered with 95 per cent. alcohol and left until it could be treated further.

Previous experience had shown that the ether extract of the sunflower seed and seedling is very easily oxidized. In order to prevent oxidation, or to reduce it to a minimum in the preparation of the dry material of the seed and seedling, the following method was used :

The alcoholic material was placed in two litre glass jars, the lids of which were provided with 'Bunsen valves'. These jars were placed on the steam bath, and the alcohol and water driven off as nearly as possible. The material was then transferred from the jars to large desiccators and dried *in vacuo* over sulphuric acid. When the material was dry it was thoroughly pulverized and placed again *in vacuo* over sulphuric acid until ready for use.

II. *Preparation of the Ether Extract.* The dry powdered material was placed in a large Soxhlet extraction apparatus and extracted for sixteen hours with absolute anhydrous ether. The ethereal solution was then placed on the water bath, and a portion of the ethereal solution distilled off. The concentrated ethereal solution was then placed in a desiccator, and the ether evaporated *in vacuo* over sulphuric acid until no trace of it remained in the oil. The ether extract was then transferred to small tightly corked bottles until ready for use.

III. *Preparation of the Neutral Oil.* It was thought advisable to examine the neutral oil at the various stages of development of the seedling, in order to ascertain what changes, if any, it might undergo as compared to those taking place in the entire ether extract. The method used for obtaining the neutral oil was as follows :

95 per cent. alcohol was added to the ether extract in the proportion of 10 grammes of ether extract to 50 c.c. of alcohol. The mixture was placed on the steam bath and heated to boiling, and then titrated with $\frac{N}{10}$ sodium hydroxide, using phenolphthalein as an indicator. To the cooled mixture was then added an equal volume of petroleum ether, and the mixture shaken gently in a separatory funnel. In this manner is obtained a separation of a solution of soap in 50 per cent. alcohol, and a solution of neutral oil in petroleum ether. The solution of soap was separated from the petroleum ether solution, and the latter again washed with 50 per cent. alcohol to remove all the soap. The petroleum ether solution was then placed on the water bath and most of the petroleum ether driven off. The concentrated solution was then placed in a closed vessel which was connected with the filter pump, and the vessel heated on the water bath until all trace of the

petroleum ether was removed. The neutral oil thus obtained was placed in small tightly corked bottles until ready for analysis.

METHODS OF ANALYSIS.

Upon the ether extract of the seed and of the cotyledons and hypocotyls at the different stages, the following constants were determined in duplicate: free fatty acid, saponification value, total insoluble acids, total soluble acids, iodine number, and acetyl value. The saponification value, total insoluble acids, total soluble acids, and iodine number were determined for the neutral oil of the seed and cotyledons at the different stages of the seedling. The amount of ether extract in percentage of the dry material and in grams per 100 cotyledons and hypocotyls was determined for each stage of the seedling examined.

All of the determinations, with the exception of those noted below, were made according to the official methods of the American Association of Official Agricultural Chemists.

The iodine number was estimated by the method of von Hübl.

For the estimation of the acetyl value the following course was followed:

A quantity of oil was heated for two hours with twice its volume of acetic anhydride in a round-bottomed flask with a reflux condenser. The acetylated oil was then transferred to a large beaker and boiling water was added. After boiling for half an hour the water was siphoned off. The process was repeated a second and a third time, after which the acetylated oil was shaken up with petroleum ether in a separatory funnel in order to remove all the water from the oil. The petroleum ether solution of the acetylated oil was then placed on the water bath and part of the petroleum ether distilled off. The concentrated solution was then transferred to a closed vessel connected with the filter pump, and the vessel heated on the water bath until all the petroleum ether was driven off. A weighed portion of the oil thus acetylated was then saponified in the usual manner and the acetyl saponification value determined. The excess of sodium hydroxide was titrated with $\frac{N}{2}$ HCl, the alcohol driven off on the water bath and the acids precipitated by $\frac{N}{2}$ sulphuric acid. The flask containing the precipitate was then filled to the neck with boiling water and heated on the steam bath, until the insoluble acids collected in a layer at the top of the flask. The insoluble acids were then solidified by the immersion of the flask in ice water, after which the liquid content of the flask was filtered and the filtrate collected. Hot water was again added to the flasks, and the same process repeated a second and third time. The collective filtrates were then

by Peters¹ for the seedlings of *Cucurbita Pepo*, and by Schmidt² for the sunflower and other seedlings.

* Estimated as oleic acid.

† Estimated as butyric acid.

Acid Value. By the acid value of an oil is meant the number of milligrams of caustic potash necessary to neutralize one gramme of the oil. It is

¹ Peters, Ed.: Zur Keimungsgeschichte des Kürbissamens. Versuchs-Stationen, iii, 1861, pp. 1-9.

² Schmidt, R. II.: Ueber Aufnahme und Verarbeitung von fetten Oelen durch Pflanzen. Flora, lxxiv, 1891, p. 300.

thus a measure of the amount of free fatty acid present in the oil, and indicates the degree of hydrolysis which it has undergone. The acid value of the ether extract of the seed is only 1.6, and this value remains constant for the oily matter of the cotyledons for the first two stages of the seedlings, until one-half of the ether extract has disappeared. In Stage III the value has risen to only 4.6. This value increases to 12.8 in Stage IV and to 66.8 in Stage V, when only 5.3 per cent. of the original ether extract remains in the cotyledons. The acid value of the ether extract of the hypocotyls and roots is 18.2 in Stage I, and gradually increases until it has a value of 97.8 in the last stage examined.

The acid value, however, indicates nothing as to the nature of the free acids present in the ether extract. They may represent organic acids other than the fatty acids, since many of the former are soluble in ether and would thus be present in the ether extract. In this investigation no attempt was made to identify the free acids present in the ether extract, and they were arbitrarily calculated as oleic acid. If fatty acids of lower molecular weight, however, are present, the value obtained would indicate a greater percentage of free fatty acid than really occurs.

The amount of free fatty acid estimated as oleic is less than 1 per cent. of the ether extract of the seed, and that value remains constant for the oily extract of the cotyledons until Stage III of the seedling, when it amounts to 2.3 per cent. of the ether extract present in the cotyledons. The amount gradually increases until it constitutes one-third of the oily material present in the cotyledons at the last stage examined. Some of the free acids present in the ether extract of the cotyledons at the later stages of the seedling are those of low molecular weight and soluble in water, as the estimation of the total soluble acids shows. Not all the free acids, however, are those of the lower groups, for the determination of the soluble acids present in the oil shows a quantity too small to account for all the free acid present in the ether extract of the cotyledons. For example, take the ether extract of the cotyledons at Stage IV. The free fatty acid calculated as oleic that is present in the oily material amounts to 13.8 per cent. If the acid were calculated as butyric it would amount to 4.3 per cent. of the ether extract. But the total quantity of soluble free and combined fatty acids, estimated as butyric, at that stage amounts to less than 1 per cent. of the ether extract. It seems probable, then, that most of the free acids present in the ether extract of the cotyledons represent those of higher molecular weight than those that are soluble in water.

In the hypocotyls and roots the amount of free fatty acid, estimated as oleic, increases from 9.1 per cent. of the ether extract at Stage I to 49.1 per cent. at Stage V. During the first three stages examined there is evidence that a considerable part of the free fatty acid present in the ether extract of the hypocotyls and roots represents acids of higher molecular weight. Thus

the amount of free acid in the ether extract estimated as butyric gives a value two to three times greater than that found in the estimation of the total soluble acids. In the last two stages, however, the amount of free acid estimated as butyric would be less than that of the total soluble acids shown to be present. This fact is probably due to the presence of glycerides of lower molecular weight in the ether extract at those stages.

From the above it seems evident that in the ether extract of both the cotyledons and hypocotyls of the sunflower free fatty acids of high molecular weight are present. This can be determined definitely, however, only by a qualitative study of the acids present.

Saponification Value. The saponification equivalent or value of an oil is the amount of caustic potash in milligrams that is neutralized during the saponification of one gramm of the oil by the combined and free fatty acids which it contains. It is in reality an indication of the mean molecular weight of the fatty acids which enter into the composition of the oil. Thus oils which are glycerides of the higher fatty acids give a lower saponification value, while those that are glycerides of the lower fatty acids give a higher saponification value.

The saponification value of the ether extract and neutral oil in the cotyledons of the seed is the same. There is no change in the saponification number of either the ether extract or the neutral oil until the last stage of the seedling examined, when only 5.3 per cent. of the original ether extract remains in the cotyledons. The marked increase of the saponification value of both the neutral oil and ether extract at the last stage of the seedling is significant in the fact that it is the first indication given of the presence of glycerides or free fatty acids of lower molecular value than those originally contained in the cotyledons of the seed.

In the hypocotyls and roots the saponification value of the ether extract begins to increase only in the later stages of development of the seedling. It is a very striking fact that the saponification value of the ether extract in the hypocotyls and roots is identical with that of the oil contained in the cotyledons of the seed and seedling up to a period when the hypocotyls and roots have attained a length of 7.5 to 11 cm. and one-half of the oil originally present in the seed has disappeared. Even after the cotyledons are above ground and spread out perpendicular to the hypocotyl, and after over two-thirds of the original oil has disappeared from the seedling, the saponification value of the ether extract of the hypocotyls and roots has increased but slightly over that of the oil of the cotyledons. Up to the time when two-thirds of the original oil has disappeared from the cotyledons we can say, then, that the saponification values of the oil in the cotyledons and hypocotyls and roots are practically identical with the saponification value of the original oil of the seed.

Total Insoluble Acids. By the total insoluble acids of an oil is meant

the percentage of fatty acids insoluble in water that is yielded on the saponification of the oil. The determination, then, of the insoluble fatty acids of an oil gives some information as to its composition. Thus, if the oil contained in the seed shows during the course of germination a decrease in the percentage of insoluble fatty acids, it indicates that the higher fatty acids are being replaced by those of the lower groups which are soluble in water.

The percentages of total insoluble fatty acids present in the ether extract and in the neutral oil of the seed are, respectively, 95.4 and 94.6. The values thus are practically identical. These values remain constant for both the neutral oil and ether extract until Stage IV of the seedling, when seven-eighths of the original oil of the seed have disappeared. At this period there is a considerable decrease in the amount of insoluble fatty acids in both the neutral oil and the ether extract. The decrease, however, is almost identical in both, so that the amount of insoluble fatty acids remaining in each is practically the same. The amount in the ether extract is 87.6 per cent. and in the neutral oil 88.9 per cent. In the last stage of germination the amount of insoluble fatty acids in the ether extract falls to 84.8 per cent.

The percentage of insoluble fatty acids in the ether extract of the hypocotyls and roots in Stage I when they had reached a length of 3.5 to 5 cm. was 89.6, a value considerably lower than that of the original seed. This value remains the same during the two stages of the seedling, and then rapidly decreases until the value has fallen to 57.2 in the last stage of the seedling examined.

The determination of the insoluble fatty acids indicates that there is no change in the solubility of either the combined or free fatty acids of the oil of the cotyledons until a late stage of development, when nearly all the oil has disappeared. At least, up to that time there is, as will be explained later, no accumulation of soluble acids that can be detected. In the hypocotyls and roots, however, the decrease in the amount of insoluble fatty acids of the ether extract at the first stage of the seedling indicates that in these organs from the beginning of germination the insoluble fatty acids are being replaced to a small extent by the fatty acids which are soluble in water. This replacement becomes very marked in the last two stages of the seedling.

Total Soluble Acids. The total soluble acids of an oil represent both the free and combined acids of the oil which are soluble in water, and represent the fatty acids of lower molecular weight. The amount of acids soluble in water in the ether extract and the neutral oil of the seed is less than 1 per cent. This value remains almost constant for both until the last stage of the seedling examined, when it suddenly rises to 4.5 per cent. of the ether extract and 3 per cent. of the neutral oil. It seems evident from the results that no fatty acids of the lower series are produced from the oil in the cotyledons until only a small part of the original oil remains.

The large amount of soluble acids in the neutral oil of the cotyledons in Stage VI indicates that there are present considerable quantities of the glycerides of the lower fatty acids. The quantity of soluble acids in the ether extract of the roots and hypocotyls, however, amounts to 1 per cent. at the first stage of the seedling and to 1.6 per cent. and 1.8 per cent. respectively in the next two stages. The amount of soluble acid rises rapidly in the last two stages and composes 16.1 per cent. and 18.5 per cent. of the ether extract in Stages V and VI respectively.

The determination of the soluble acids supplements remarkably well the results obtained in the estimation of the total insoluble fatty acids. Wherever there is a decrease in the percentage of insoluble fatty acids there is an increase in the amount of the soluble acids.

The Iodine Number. By the iodine number of an oil is meant the amount of iodine that the combined and free unsaturated fatty acids of an oil will take up expressed in percentage of the weight of the oil. It is really a measure of the quantity of unsaturated fatty acids in the oil. Thus, if the iodine number of the oil decreases during germination, it is indicative of the fact that the unsaturated fatty acids of the oil are becoming saturated, probably by the addition of oxygen.

The iodine numbers of the ether extract and neutral oil of the seed are practically identical, being 125.5 and 124.9 respectively. This value holds constant for both the ether extract and neutral oil of the cotyledons until Stage IV, when there is a like decrease in the value of the iodine number of each. The iodine number for each at this stage is 120. At this period of development seven-eighths of the original oil have disappeared and 13.8 per cent. of the ether extract remaining is composed of free fatty acid. In the last stage of germination, when only 5.3 per cent. of the original oil remains in the cotyledons, and one-third of the oily material present is composed of free fatty acid, the value of the iodine number for both the ether extract and neutral oil is the same and amounts to 111.8.

These results are significant in that they indicate that neither the combined nor the free fatty acids of the ether extract of the cotyledons show any signs of becoming saturated until a late stage of the seedling, and even then the degree of saturation is comparatively slight. It further indicates that the combined and free fatty acids of the ether extract are equally saturated, and that this is the case even when one-third of the ether extract is composed of free acid.

In my previous work I found that the iodine number of the ether extract in Stages IV and V fell to 77.5 and 67.4 respectively. I attribute this low result, however, to the oxidation of the oil during the preparation of the material. In the preparation of the material for this investigation, however, methods were employed, as explained elsewhere, which reduced the oxidation of the oil to a minimum.

In the ether extract of the hypocotyls and roots, however, entirely different results are obtained from that of the cotyledons. At Stage I the iodine number has fallen to 117.7. It stays constant during the next stage and then falls rapidly, amounting to only 43.3 in the last stage of the seedling. This indicates that the free and combined fatty acids of the ether extract of the hypocotyls and roots become saturated to a considerable extent at the beginning of germination, and that this saturation becomes more and more complete as germination progresses.

The Acetyl Value. The acetyl value of an oil gives the number of milligrams of caustic potash required to neutralize the acetic acid that is set free when one gramme of the acetylated oil is saponified. The acetyl value is really a measure of the amount of the hydroxyl groups which an oil contains.

The acetyl value of the ether extract of the seed is 40.1. The value remains practically constant for the oily material of the cotyledons during all stages of the seedling. The slight decrease in the acetyl value at the last stages comes within the limit of error of the process. It seems, then, that there is no increase in the amount of the hydroxyl groups of the ether extract of the cotyledons during any stage of germination.

The acetyl value of the ether extract of the roots and hypocotyls was determined for the first three stages of the seedling. The value amounts to 71.2, 114.0, and 95.1 for each of the respective stages. The results are thus much higher than those obtained for the ether extract of the cotyledons. The amount of soluble glycerides present is far too small to account for this high value. It seems, then, that the ether extract of the roots and hypocotyls has a much larger amount of hydroxyl groups than that of the cotyledons.

GENERAL CONSIDERATIONS.

The Oily Material of the Cotyledons. The saponification value, total insoluble acids, total soluble acids, and iodine number of both the ether extract and neutral oil of the cotyledons of the seedling remain constant up to the time when seven-eighths of the original oily reserve present in the seed has disappeared. A marked change in these values takes place only in the last stage examined, when only 5.3 per cent. of the original oil remains in the cotyledons. The change in values for the above constants indicates that the oily material at that stage consists to a small extent of glycerides and free fatty acids of lower molecular weight than those composing the original oily reserve of the seed. The change in the iodine number indicates that both the free fatty acids and glycerides are becoming partially saturated, probably by the addition of oxygen.

The acetyl value of the ether extract remains constant for all stages of the seedling, and indications are thus given that the amount of hydroxyl

groups of the oily material remains the same until all the reserve has disappeared from the cotyledons.

The only marked change in the nature of the oily reserve in the cotyledons is the increase in the amount of free acid present. The acid value of the oily reserve remains constant until over two-thirds of the ether extract have disappeared from the cotyledons, when it rises to 4.6.

The most marked change in the ether extract at the last stage of seedling examined is the amount of free acid present. The acid value of the ether extract at that stage is 66.8. Calculated as oleic acid the amount of free acid present would amount to one-third of the oily material found in the cotyledons at that stage. Some of the free acids present, however, are of low molecular weight and soluble in water; but the greater part of the free acid is composed of fatty acids of high molecular weight which are insoluble in water.

The results obtained in this investigation indicate that, with the exception of an increase in the amount of free acid, no change takes place in the oily reserve of the cotyledons until nineteen-twentieths of the oil originally present has disappeared from them.

The Oily Material of the Hypocotyls and Roots. The saponification value of the ether extract of the hypocotyls is practically the same for the first three stages of the seedling examined as that of the ether extract of the cotyledons at those stages. After the third stage of the seedling the saponification value increases rapidly.

The amount of insoluble fatty acids remains constant during the first three stages, but is about 10 per cent. less than the amount of insoluble acid present in the ether extract of cotyledons at the same stages. After that the amount of insoluble fatty acids falls rapidly and amounts to only 57.2 per cent. of the oily material present at the last stage of the seedling. The amount of soluble fatty acids during the first three stages increases but little, but the amount present is greater than that found in the ether extract of the cotyledons during those respective stages. During the last two stages of the seedling the amount of soluble fatty acids increases rapidly, and amounts to 18.5 per cent. of the oily matter at the last stage of the seedling. The acid value increases gradually from 18.2 at the first stage of the seedling to 97.8 at the last stage examined. During the first three stages there is evidence that a considerable portion of the free acid is composed of acids of higher molecular weight which are insoluble in water. During the last two stages, however, the free acids present seem to be composed entirely of those of low molecular weight which are soluble in water.

The iodine number is constant for the first two stages, but is considerably less than that of the ether extract of the cotyledons at that time; after the second stage of the seedling the iodine value falls rapidly and amounts to only 48.3 at the last stage examined.

The acetyl value for the first three stages averages about twice as great as that of the ether extract of the cotyledons at the respective stages.

It will be noticed that the constants which were determined for the ether extract of the hypocotyls and roots for the first three stages have a striking resemblance to those of the ether extract of the cotyledons during those stages. The results indicate, however, that the changes in the oily material during the first two stages consist in a gradual but evident breaking down of the higher free fatty acids and glycerides into those of lower molecular weight, the saturation of the fatty acids, and an increase in the amount of the hydroxyl groups present. During the last two stages, however, these changes are rapid and very marked, as indicated by the value of the different constants determined.

SUMMARY.

1. The acid value of the ether extract of the seed is low, amounting to only 1.6, and this value remains the same for the oily material of the cotyledons until two-thirds of the oily reserve has disappeared from them. After that the acid value increases rapidly. There is evidence that the greater part of the free acid present in the ether extract at all the stages is composed of free fatty acids of high molecular weight which are insoluble in water.

2. The results obtained indicate that, with the exception of the increase in the amount of free acid, no change takes place in the oily reserve remaining in the cotyledons until the last stage, when the seedling has become an independent plant. At that stage only 5.3 per cent. of the original oily reserve remains in the cotyledons.

3. The results indicate that the change taking place in the oily material of the cotyledons when only 5.3 per cent. of the oily reserve remains, consist in a breaking down of the higher fatty acids and glycerides into those of lower molecular weight, a partial saturation of the free and combined fatty acids, and a marked increase in the amount of free acid.

4. The amount of oily material contained in the hypocotyls and roots remains practically constant for all stages of the seedling examined.

5. Some of the constants of the oily material of the hypocotyls and roots during the first three stages of the seedling have a striking resemblance to those of the oily reserve of the cotyledons at those stages. The results in general, however, show that during these stages there has occurred a gradual but well defined breaking down of the oily material into free fatty acids and glycerides of low molecular weight, a marked saturation of the fatty acids, and an increase in the amount of the hydroxyl group of the oily matter. During the last two stages of the seedling these changes are very rapid and very marked.

The Development of the Grain of Barley.

BY

WINIFRED E. BRENCHELEY, D.Sc., F.L.S.

With twenty-two Figures in the Text.

A. PROCESSES OF NUTRITION.

THREE plots, of as diverse treatment as possible, were selected to provide material for experiment. One plot, A, cropped under a four-course rotation, has received a dressing of cake-fed dung one year in every four, the last application falling in the year of the experiment, so that the plot, while plentifully supplied with all the essential plant foods, is specially rich in nitrogen. A second plot, B, comes under the same rotation but receives no manure, and is therefore deficient in plant nutrients, especially nitrogen. The third plot, C, is in the permanent barley field, which has carried barley since 1852, and it has received no phosphoric acid since that date, though an adequate supply of the other essential elements is provided in the form of alkali salts and ammonium salts. Thus the samples collected should show the results obtained from a nitrogenous general manuring, from a rotation without any addition of manure, and also the effect of phosphoric acid starvation in the presence of a sufficiency of nitrogen, potash, and other alkalis.

The same methods of sampling were adopted as in the case of the previous wheat experiments.¹ Ears were marked with ties of red wool on the day on which they first came into flower, thus ensuring uniformity in age. The plots A and B flowered within three days of one another, but the plants on the P_2O_5 -starved plot C were ten days later in protruding the first anthers. As might have been expected, the plants with nitrogenous manure were long and heavy in straw, and were badly laid in places within five days from flowering.

Cuttings from these marked shoots were made at three-day intervals between 5 and 7 a.m. After transference to the laboratory the grain was stripped from the ear and the awns cut off close to the grain as rapidly

¹ Brencley, W. E., and Hall, A. D.: The Development of the Grain of Wheat. Journ. Agr. Sc., vol. iii, part II, 1909, p. 197.

as possible. As with the wheat, and for the same reasons, the material contained in 1,000 grains was selected as the unit—a unit which will represent with the minimum of variation from period to period the material grown upon a unit area.¹ The several lots of 1,000 grains were counted out, weighed, dried in a steam oven for three days at 100° C., then weighed again. Various determinations—ash, nitrogen, phosphoric acid—were made, and after being expressed as percentages of the dry weight of the grain the results were recalculated to give the actual amounts associated with 1,000 grains in each case. The results obtained have been expressed graphically as curves, one for each property. In order to make a fair comparison between these curves the zero point was always reckoned as the day on which the first cutting was made, seven or eight days after flowering, so that

FIG. 1. Green and dry weights of 1,000 grains. Upper set of curves represent green weight, lower set dry weight.

the grains at each period were of the same age, and had approximately reached the same stage of development. As barley is always allowed to become dead ripe in the field the fruiting period of the plant is an extended one, about fifty-six days clapsing between flowering and harvesting the ripe corn.

Weight of Grain, Water Content, &c. Fig. 1 shows the actual green and dry weights of each sample of 1,000 grains. In the two earlier plots (A and B) the green weight rises for twenty-seven days and then falls steadily. The later P_2O_5 -starved plot (C) reaches its maximum green weight six days earlier, and then shows a similar but rather accentuated fall. The dry weight rises steadily for twenty-seven to thirty-six days, then

¹ Brenchley and Hall, loc. cit., pp. 197-8.

the P_2O_5 -starved (C) and the unmanured (B) plots show a practically flat curve, while the nitrogenous plot (A) indicates a slight but steady fall for the last twelve days before cutting. In each case the maximum green weight of the grain was attained from six to nine days before the maximum dry weight.

In comparing the dry weight with the green weight (Fig. 2), it is seen that the percentage of dry in green rises almost to the end. In all three plots the relationship runs a very equivalent course for about eighteen days,

but then, while A and B keep on rising steadily, C shows a more rapid rise until about six days before harvesting, when the ratio remains steady.

Fig. 3 shows the actual amount of water contained in 1,000 grains. There is a steady and very rapid rise for nine to fifteen days, then a fairly constant level is maintained for about four periods, followed by a gradual fall up to the time of harvesting. Two of the plots show a somewhat inexplicable rise in water content during the last period.

Nitrogen. The percentage of nitrogen in the dry matter of the grain (Fig. 4) falls steadily for four to six periods, after which a rise sets in, this increase being most marked in A, with nitrogenous manure. The rise is much more gradual in both B and C.

FIG. 4. Percentage of nitrogen in dry matter of grain. Mean curve is placed three squares too low for the sake of clearness.

The actual nitrogen in 1,000 grains (Fig. 5) rises steadily at first in A and B. A reaches its maximum content about twelve days before cutting, and then probably remains constant, while B rises steadily almost to the end. C, on the other hand, is very different in behaviour. After running parallel with the other plots until about the seventh period the curve flattens off considerably, and after rising very slowly for a few days more, the amount of nitrogen present remains practically constant until harvest.

The rise in the percentage of nitrogen in the dry matter is somewhat unexpected, though some indications of it had been noticed in the earlier experiments on wheat. The composite curve D, showing the mean proportion of nitrogen in the dry matter of the grain for the three plots, indicates that this rise is real. There is, of course, the possibility that such an increase is merely a seasonal effect, and further investigations will be necessary to settle the point definitely. Further corroboration of this result

is obtained by a recalculation of results so as to indicate the proportion of nitrogen in the dry matter that entered the grain between successive dates. Owing to the accumulation of small experimental errors, the results are somewhat erratic, but are sufficient to point out that dry matter stored in the later periods is richer in nitrogen than in the earlier periods, a fact that

FIG. 5. Actual nitrogen contained in 1,000 grains.

is much accentuated towards the end. The trend of this increase can best be shown by calculations made at nine-day intervals.

This rise is much more evident than with wheat, because of the longer maturation period, during which the migration into the grain has practically ceased while respiration is still continuing, though probably slowing off gradually. The loss due to respiration falls altogether on the non-nitrogenous (carbohydrate) constituents of the grain, hence the relative increase in the proportion of nitrogen present. While the figures at the earlier periods indicate a considerable rise in the proportion of nitrogen in the grain before any great decrease has occurred in the amount of material entered, still there is not sufficient evidence to prove any change in the proportion of nitrogen actually taken in by the plant, since as development continues the

FIG. 6. Percentage of protein nitrogen in total nitrogen.

quantity of respiring substance becomes much greater, causing a corresponding increase in the amount of non-nitrogenous material broken down, so entailing a consequent rise in the percentage of nitrogenous material present.

Fig. 6 shows the results of estimating the proportion of protein nitrogen in total nitrogen. The curves, when smoothed, seem to indicate a slow but steady rise up to about a fortnight before cutting, followed by a period in which the protein nitrogen is either constant or slightly falling off. The actual non-protein nitrogen in 1,000 grains (Fig. 7), though very erratic, tends to increase gradually all along the line.

Ash and phosphoric acid. The proportion of ash to dry matter (Fig. 8) is considerably higher in the two normal plots A and B than in the P_2O_5 -starved plot C. In the first two the proportion falls steadily for six periods

FIG. 7. Actual non-protein nitrogen in 1,000 grains.

FIG. 8. Percentage of ash in dry matter.

and then remains constant right up to harvest. In C, on the contrary, the fall continues for a much longer time, for thirty days, before a constant level is reached.

The actual amounts of ash and phosphoric acid in 1,000 grains (Figs. 9 and 10) correspond with those of the amount of nitrogen present in that the

representative curves, while differing in proportion, change their direction at corresponding periods in all three cases, indicating some correlation in the entry of these constituents into the grain.

A calculation of the ratio between the nitrogen and phosphoric acid (expressed in Table II and Fig. 11) yields very interesting results. The two normal plots show very similar ratios, while that of C is distinctly higher,

FIG. 11. Ratio between the nitrogen and phosphoric acid in the grain.

showing that in the presence of plenty of available nitrogen in the soil, but with an insufficiency of phosphoric acid, the plant is able to take in a larger proportion of nitrogen than when there is no lack of P_2O_5 . The $\frac{N}{P_2O_5}$ ratio falls during the first four or five periods, but eventually rises. In plot C a constant level is maintained after the eighth period.

The theory has been put forward that the P_2O_5 acts in some way as

a vehicle for the conveyance of nitrogen, but while the result from plot C would seem to corroborate this hypothesis, those from A and B do not bear it out, in that on a plot (A) with plenty of available nitrogen and of phosphoric acid the proportion of nitrogen to phosphoric acid is practically the same as on a plot (B) with a deficiency of both substances.

Other Determinations. Fig. 12 shows the percentage of sugar (dextrose) present in the dry matter of the grain. A slight fall occurs at the begin-

FIG. 12. Percentage of dextrose in dry matter of the grain.

ning, after which the percentage of dextrose is very constant, showing hardly the slightest decline to the very end. The actual dextrose present in 1,000 grains (Fig. 13), after an initial fall, rises slightly for three days in A and B, remains constant for about nine to twelve days, then falls somewhat.

FIG. 13. Actual dextrose contained in 1,000 grains.

In C, however, the rise is prolonged over four three-day periods, and the fall sets in immediately, without any intervening period of constant level.

The *diastatic power* of the grain was determined by macerating the grain and adding it to starch paste; the quantity of maltose thus produced by 100 parts of dry matter is shown in Fig. 14: the experimental error is very large, but it is evident that the diastatic power of the grain rises steadily for about twenty-seven to thirty-six days, and falls rapidly for a few days more, finally remaining approximately constant.

Relation of Migration Processes to the Nutrition of the Whole Plant.

The straw belonging to each of the marked ears collected was cut off close to the ground, and a series of analyses made parallel to those of the grain.

FIG. 14. Maltose produced per 100 parts of dry matter.

FIG. 15. Curve showing the progressive ratios between the dry weights of the straw and grain. (Weight of straw at each period is taken as a constant, 100.)

Calculations were made to determine the dry weight of the straw associated with 1,000 grains at each period. The progressive ratios between the straw and grain are shown in Fig. 15, in which a constant figure, 100, is adopted for

the dry weight of the straw. This shows that the dry weight of the grain in relation to the straw rises steadily for ten or eleven periods, then remains practically constant for about nine days longer, showing some inclination to fall for a few days before cutting, except in the plot C, which is later than the other two, and which may be somewhat slower in ripening.

Fig. 16 shows the *dry weight* of the whole plant and the grain. The dry weight of the grain increases right up to the time that desiccation begins. As the curve remains flat from that time until harvest, it is indicated that the loss of matter due to respiration in the grain is just

FIG. 16. Dry weights of whole plant and grain. (Whole plant = weight of 1,000 grains + weight of straw calculated as being associated with 1,000 grains.)

counterbalanced by immigration of material from the straw. In the whole plant, however, some fall in dry weight occurs after the beginning of desiccation, showing that from that time onward the intake of food material from the soil, if it still continues, is somewhat overshadowed by the destructive metabolic functions of the plant. In plot C the maximum dry weight of the whole plant is reached at an earlier date than in the other two plots, i. e. at the seventh or eighth period, which is such a critical point in the history of this plot.

The *nitrogen* in the whole plant (Fig. 17) in the two normal plots would seem to reach its maximum at about the time at which desiccation sets in, remaining fairly constant afterwards. In C, on the other hand, the whole of

the nitrogen is in the plant by a much earlier date, by the sixth period (rather before the critical date for the plot), after which a gradual decline in quantity is noticed. The depletion of the straw in favour of the grain is strongly marked during the long ripening period in barley, for the migration of nitrogen into the grain continues for at least a week after the plant has obtained its maximum supply. This is still more evident in plot C, in which the grain continues to gain in nitrogen even when the total nitrogen in the plant is on the downgrade.

Wilfarth, Römer, and Wimmer¹ have demonstrated a great loss in

FIG. 17. Actual nitrogen contained in whole plant and in 1,000 grains.

the amount of nitrogen present in barley during the period of ripening, and these authors assume that this loss is due to part of the plant food being returned to the soil by a downward flow of the sap. Le Clerc and Brezeale² confirm this loss of nitrogen to some extent, but interpret it as the result of leaching by rain and dew. In the Rothamsted experiments the barley from plot C is the only one in which this loss of nitrogen is evident, and even there it is very slight, being much less than in the investigations of Wilfarth, Römer, and Wimmer, but approximating more closely to the results of Le Clerc and Brezeale.

¹ Landw. Vers. Stat., lxiii, 1905, p. 1.

² Plant Food removed from Growing Plants by Rain and Dew. Year-book Depart. Agric. Washington, 1908.

The curves of the intake of ash into the whole plant and the grain (Fig. 18) show that the points of maximum ash content coincide with those of the maximum nitrogen content. When once the maximum is reached,

FIG. 18. Actual ash contained in whole plant and in 1,000 grains.

however, the ash in the whole plant begins to fall steadily, though the migration into the grain continues for some little time. In C the total ash in the plant shows a steady fall for four weeks before cutting, corroborating the American experiments.

FIG. 19. Actual phosphoric acid contained in whole plant and in 1,000 grains.

The *phosphoric acid* (Fig. 19) remains fairly constant in all the plots when once the maximum has been reached, which coincides with the maximum for the ash. The fall in the latter curve is therefore due to

other ash constituents than the phosphoric acid. This result does not agree with that obtained by Le Clerc and Brezeale, who indicate a possible loss of 36 per cent. of the phosphoric acid in the plant by leaching.

Figs. 20 and 21 illustrate how steadily the proportions of nitrogen and phosphoric acid in the straw decline during the formation of the grain,

FIG. 20. Percentage of nitrogen in dry matter of straw.

FIG. 21. Percentage of phosphoric acid in dry matter of straw.

owing to the rate of migration into the grain exceeding that of the intake into the straw.

In order to get a bird's-eye view of the relations existing between the various properties examined in barley, certain sets of figures have been averaged for the three plots and the results expressed, with appropriate

scales, in the composite curve (Fig. 22). This shows that the critical point at which maturation or ripening of the grain really begins occurs at the tenth or eleventh period, about fifteen or eighteen days before harvesting. Up to this time the diastatic power of the grain has been steadily increasing. Henceforward it as steadily and rapidly decreases. The dry weight of the grain, the phosphoric acid, nitrogen, and dry weight of the whole plant all

FIG. 22. Composite Curve. Plots A, B, C averaged for corresponding periods.

Dry weight ————— 1 division = 5 grammes

 Nitrogen 1 division = 0.1 gramme
 P_2O_5 — — — — — " "
 Dextrose —○—○—○—○—○—○—○—○—○— " "

reach their maximum at approximately the same period. The fact that the P_2O_5 and nitrogen in the grain continue to rise is an indication of the fact that migration of food material from the stem to the grain continues steadily throughout the ripening period. One thing is noticeable—that the amount of dextrose present in the grain apparently does not bear any relation to the diastatic capacity at any given time; the dextrose curve continues to fall for some time after the diastatic power has passed its

optimum, a slight rise occurring towards the end of the maturation period, which may or may not be real.

Comparison between the Composition of the Grain and the Whole Plant of Barley and Wheat at Progressive Stages of Growth. On account of the different morphological structure of the barley and wheat grains no comparison between the two can be strictly concordant. In wheat the grain is simply the true fruit of the plant, consisting of the pericarp and the seed, while in barley the grain has incorporated with itself in addition the palea and the flowering glume. Also, the growing period of barley is considerably the longer, wheat growing for about 39 days from the time of the first sampling, while barley runs on for about 48 days from the same starting-point.

Weight of grain, water content, &c. The green and dry weight of both barley and wheat reach their maximum in approximately the same time, the decided drop in the case of barley occurring during the long ripening period, which does not exist with wheat owing to the earlier harvesting. The range of weight is much the same in both the cereals. The *percentage of dry weight* is considerably higher in barley than in wheat in the early stages, probably owing to the presence of the dry chaffy glumes.

[At the first cutting the glumes and the grains were separated, and the green and dry weights of each determined. The percentage results show that the glumes contain considerably more dry matter than the succulent grains at such an early stage in development.

Percentage of Dry Weight to Green Weight in Shelled Grain and Glumes.

	<i>Shelled grain.</i>	<i>Glumes.</i>	
A. July 13	18.47	30.97]
B. July 16	19.15	40.96	
C. July 22	22.35	48.32	

This difference diminishes as time goes on, so that eventually the percentages correspond fairly closely. The final result in barley is 10 per cent. to 15 per cent. higher than in wheat as desiccation continues during the prolonged ripening period. The actual amounts of water present in 1,000 grains correspond very closely in both cases, though in barley the desiccation is continued until finally the dry grain contains only as much water as the newly formed grain at the first cutting.

Nitrogen. The actual nitrogen in 1,000 grains runs a very parallel course, though the percentage of nitrogen in the dry matter of the grain is at first somewhat higher in wheat than in barley, while later on in development the two grains are very similar in this respect. In barley the percentage of nitrogen steadily increases after it has dropped to its lowest value, whereas in wheat it remains practically constant from that time. Through-

out the *percentage of protein nitrogen* is rather lower in barley than in wheat.

Ash and phosphoric acid. In barley the percentage of ash in dry matter is distinctly higher than in wheat, except in the case of plot C, which is below the normal. The actual quantity of phosphoric acid per 1,000 grains, however, is approximately the same in both the grains.

The $\frac{N}{P_2O_5}$ ratio in wheat exceeds that of the normal barley plots, but falls considerably below that of C, the P_2O_5 -starved plot.

Dextrose and diastatic power. The percentage of dextrose in the dry matter of wheat falls far more slowly than in barley, reaching its lowest limit after about 24 days in the former, but in 6–15 days in the latter, after which a constant of about 2 per cent. is maintained in both cases. Consequent on this slower fall there is considerably more dextrose actually present in the wheat grain in the early stages than in barley.

The changes in the *diastatic power* of the grain, as shown by the amount of maltose produced, follow very different courses. Even at its maximum the diastatic power of barley is less than half that of wheat, and the greatest activity is reached at a considerably later date in barley, while the rise and fall are far more sudden.

The *maltose* formed by 1,000 grains, again, shows totally different curves in the two grains, curves between which no correspondence can be made out. In wheat the maltose rises steadily at first, finally remaining more or less constant, while in barley a considerable rise is followed by a corresponding fall.

From the above comparison it is clear that the progressive changes in wheat and barley run a very parallel course though varying in detail. The differences are seen to be chiefly due to the prolonged ripening period of barley, during which maturation changes occur which are not evident in the wheat, owing to the earlier stage at which the latter is harvested.

One difference between wheat and barley is very noticeable in these two sets of experiments. With wheat the manuring of the plots had very little effect upon the analyses of the grain and straw; the course of events ran very parallel, the P_2O_5 -starved plot giving results similar to those from more normal plots. With barley, on the contrary, the effect of P_2O_5 starvation is very marked indeed. For a certain time the analyses from plot C run fairly parallel to the others, A and B, but after the seventh or eighth three-day period a radical change sets in. Some limiting factor comes into play, presumably the limitation of available phosphoric acid, and the plant suffers accordingly. The dry weight, nitrogen, and ash contained in the plant show a steady falling off from this period, the phosphoric acid alone remaining constant. In the grain, however, these four properties remain constant or even increase slightly, showing that after immigration from the soil has

ceased, material is still transferred to the grain at the expense of the straw. It seems that in the case of barley the limiting of one factor of the food supply limits the availability of other food substances, i. e. that in the absence of a sufficiency of one essential food the plant is unable to utilize others even in the midst of plenty.

The effect of P_2O_5 -starvation is the more intensified with the barley from plot C, since the plant is supplied with an excess of potash and other alkalis in addition to nitrogen, the only shortage being in the phosphoric acid, whereas in the compared wheat plot a general deficiency existed in everything except nitrogen (of which an excess was present), so that the particular effect of lack of phosphoric acid was not so marked.

The difference in the effect of P_2O_5 starvation on barley and wheat is also partly due to the diversity in the root systems. Barley, being shallow rooted, rapidly exhausts the supply of a plant food of which a storage exists in the surface soil. Wheat, being deep rooted, is able to seek its food from a much greater area of soil in the underlying strata, and consequently in a soil continuously cropped and P_2O_5 -starved it is probable that such a sufficiency of phosphoric acid is available that the limiting factor does not come into play, and so far as the wheat is concerned phosphoric acid starvation does not exist in the plot considered.

B. POINTS OF BIOLOGICAL INTEREST.

Preparation of material. While the mature barley grain is of a composite nature, consisting of the fruit and the palea and glume welded inseparably together, the young developing grain can be easily separated into its constituent parts, as the union is a later feature in development. For about fifteen days from the time of flowering, fruit and glumes are distinct individuals, and they can be detached without injury to either member; the actual junction appears to occur fairly rapidly, within a very few days.

The existence of the semi-permeable membrane¹ is a source of difficulty with regard to the penetration of reagents. At least three days before the glumes begin to unite with the grain, this layer is evidently in full activity, as experiments indicated. Grains were taken fresh from the plant, placed for one day in 3 per cent. $AgNO_3$, then one day in 5 per cent. $NaCl$. Examination showed that the reagents penetrated the glumes freely, but failed to gain access to the endosperm, which remained quite colourless. The outer coats of the grain were a little darkened just under the glumes, showing that the $AgNO_3$ had probably succeeded in penetrating a short distance into the seed coats. In view of this difficulty in penetration, after the first ten days from flowering most of the grains selected for pickling were slightly pricked, so as to secure efficient killing and fixing of the material. The reagents used were acetic alcohol, with an immersion of

¹ Brown, A. J.: Ann. Bot., lxxxi, 1907, pp. 79-87.

a few hours to a day, according to the age of the grain, and Mann's fluid¹ applied for a few hours to two days.

Entry of Starch. The development of the barley grain has been well described by Johannsen,² while the mature structure is portrayed by Brown and Morris.³ These authors, however, do not give any detailed account of the entry of starch into the grain in its progressive stages.

The entry of starch into the grain was investigated by means of material preserved in acetic alcohol. Hand sections were cut, stained with iodine in potassium iodide, washed in water, and mounted in glycerine.

Four days after flowering very little endosperm could be made out, and there were no indications of starch. The pericarp, however, was very thick and fleshy, containing a good deal of starch in all its cells, especially in the layers near the seed. By the next day the endosperm appeared to be still deficient towards the embryo end, though it was fully formed at the other end; but no sign of starch had appeared. Plenty of starch existed in the pericarp, though it was only found thickly in the region of the vascular bundle. By the *sixth* day from flowering starch-formation had begun at the chalazal end of the grain, but the grains were so small that it required an 18 Zeiss ocular and either an AA or DD objective to trace them. Most of the grains had been laid down in cells in the middle of the flanks, none appearing as yet across the bridge. In some cells the association between the starch grain and the nucleus could be made out. A short distance from the chalazal end of the grain no trace of starch had yet appeared.

By the *seventh* day distinct progress had been made, as starch could be discerned for about two-thirds the length of the grain from the chalazal end, occurring as scattered grains in the flanks. The cells in which deposition first began contained considerably more starch than on the previous day, though as yet there was no considerable mass of it, as all the grains remained easily discernible and relatively few in each cell. By the day following that on which the sections were cut all the colour had disappeared from the endosperm starch, though it was retained by the pericarp starch. The pericarp at this time was still broad and uninjured throughout the length of the grain, with a good deal of starch scattered in the cells, though all the grains were easily seen individually. Just round the vascular bundle there was a dense mass of starch, especially on the side towards the endosperm.

By the *tenth* day from flowering starch infilling was in full swing. The embryo was in its early stages of development, and towards the lower

³ Brown, H. T., and Morris, G. H. : *Journ. Chem. Soc.*, vol. Ivii, Trans. 1890, pp. 460–6.

and a few starch grains occurred in a band of cells stretching across the flanks and the side of the bridge next the furrow. The outer mass of cells adjacent to the embryo remained quite free, while immediately below the level of the embryo the deposition of starch in the flanks was much more dense. The starch grains themselves stained an intense dark blue and retained the iodine coloration for two days after cutting, indicating a more mature stage in development. Proceeding down the grain the dorsal cells continued empty of starch for some little distance, the empty cells forming a kind of wedge in section, showing perfect nuclei. Gradually the wedge of infilled cells became smaller until towards the chalaza starch was evident in all cells right up to the aleurone layer on the dorsal side. One feature was noticeable in those parts of the grain in which a fair quantity of starch was deposited. While the starch grains themselves stained such a deep blue colour, it appeared that the matrix in which they were embedded also tended to stain, but with a violet colour, at least in the cells in the flanks. The violet tint was not noticed in the bridge at this time. Care has to be taken to ascertain that this violet colour is not an optical illusion due to the thickness of the section—i. e. that the colour is not due to superposed starch grains out of focus. Careful examination indicates that this coloured matrix is an actual fact. As a possible explanation the idea presents itself that the soluble sugars come in from the vascular bundle, passing first through the bridge in which the coloured matrix does not seem to occur. Passing outwards into the flanks, chemical changes begin to occur, and the sugars assimilate more to the nature of starch.¹ While still in this transition state it is possible that stages are reached, before the starch grain is actually laid down, which are stainable with iodine in KI to some extent, giving the violet or purplish matrix. As the perfect starch grains come into being they exhibit the characteristic deep blue or black colour with the stain. At this stage in the development of the grain the pericarp was beginning to suffer from the growth of the enclosed seed. At the top of the grain it was still very thick, containing a fair proportion of starch in the deeper seated layers and round the vascular bundle. Towards the middle of the grain the pericarp was becoming badly crushed on the dorsal side by the pressure of the enlarging seed.

By the *eleventh* day from flowering the starch was very thickly deposited in the flanks right through the grain, though it was still noticeable that the grains tended to segregate round the nuclei in the cells. Some little way below the level of the embryo the starch did not extend thickly right across to the dorsal surface, though all cells showed grains in association with the nuclei. A little nearer the embryo the outer cells were quite free from starch grains. High magnification seemed to indicate that each starch grain consists of a central core showing evident striation, surrounded

¹ Cf. Maquenne, M. L. : *Comptes rendus Acad. des Sciences.* Tome cxlvi, 1908, pp. 542-5.

by a clear hyaline space. Outside all is a kind of bounding layer or 'skin', which also stains with iodine.

Two days later, thirteen days after flowering, little advance had apparently been made in the infilling of starch, as the sector without starch at the embryo level was still very large and extended some distance down the grain. The starch itself, however, was far more retentive of stain, as the iodine coloration was still evident on the fourth day after staining, though the remnants of the pericarp starch had entirely lost their colour during the interval. In the thick body of the grain the matrix in the cells appeared granular and stained yellow with iodine, indicating the protein nature of part of these cell contents.

By the *nineteenth* day from flowering the main body of the starch was apparently laid down. The starch was thick in the flanks and across the bridge, right up towards the tip of the embryo. There was much protein in the flanks, staining with iodine, but there seemed to be less in the bridge. Along the outer edge of the endosperm, adjacent to the embryo, was a band of crushed cells, containing no starch, which persisted throughout the development of the grain. These were probably endosperm cells which had been depleted of their contents and crushed back by the embryo in the course of its growth.

Though the main skeleton of the starch is laid down in the first three weeks from flowering, the entry of starch into the grain is by no means completed in this time. The analytical figures show that the calculated amount of carbohydrate in the grain continues to increase for another fortnight or three weeks, practically doubling in quantity, after which time it remains fairly constant until the barley is cut. The variation in the time of infilling is probably due to weather effects, as bright sunny weather tends to hasten the process, bringing the grain to its full and mature development more rapidly. The change in colour from green to brown is also apparently more closely connected with the weather conditions than with the stage of infilling of the starch, as all the plots examined began to turn at about the same date, on the accession of sunny weather, though the dates of flowering, and in consequence the age of the grains, varied as much as ten days.

Disorganization of Nuclei. While the starch skeleton is being laid down, the nuclei are in full activity and are perfect in constitution, showing their nucleoli clearly. Just about the time that all the endosperm cells have received some quota of their starch, changes begin to occur in the nuclei, at first in those of the cells in the middle of the flanks at the end of the grain away from the embryo. The first indication of change is the disappearance of the nucleoli, the nuclei becoming much more solid and dense in appearance, staining very darkly with haematoxylin. Very soon they become irregular in shape and eventually develop

a coarse network structure. As the days go on these phenomena show a progression upwards, so that by the time the nuclei at the base of the grain have reached the coarse network stage, those a little higher up are getting deformed while those higher still no longer have nucleoli in evidence. The nuclei in the cells of the sub-aleuronic layer, and also those in the immediate neighbourhood of the furrow, do not begin to undergo any change for some time, but remain perfect. In ten or twelve days from the setting in of this 'nuclear senescence'¹ the flank nuclei are involved practically all through the grain, those at the base exhibiting networks of a much finer structure. The nuclei under the aleurone layer have lost their nucleoli, but are still in a solid condition, except in rare cases in which slight deformation into coarse networks has begun. The nuclei round the top of the furrow are still all solid or even perfect, showing no deformation. Three days later great strides have been made, as at the base of the grain many cells of the sub-aleuronic layer show nuclei in the fine network stage, and all the way up the grain to the embryo such cells have either network or badly deformed nuclei. At the base, too, some of the cells round the ventral furrow have now been involved, showing senescence of nuclei to some degree, while the flank nuclei have continued to become finer in a regular progression upwards. In about three weeks from the time that the starch skeleton was first laid down practically all the nuclei of the endosperm cells up as far as the base of the embryo are involved in the senescence, though a few solid or deformed nuclei seem to hang on indefinitely, not developing into networks, especially round the furrow.

While this progression upwards has been occurring in the lower part of the grain, similar changes have been taking place in the endosperm cells in the immediate neighbourhood of the embryo. The first nuclei involved are those in cells adjacent to the embryo, those further away from the embryo and those in the sub-aleuronic layer remaining perfect at first, except just at the point where the embryo abuts on the aleurone layer. The deformation appears to begin earliest at the tip of the embryo, proceeding downwards. The senescence spreads rapidly outwards through the flanks and bridge, until all cells are involved save those of the sub-aleuronic layer and those round the furrow. By the tenth or twelfth day from the beginning of the senescence most of the nuclei at the level of the embryo are deformed or are dense networks (except just under the outer aleurone layer), especially in the deeper seated flank cells and across the bridge. Towards the base of the embryo at this date a few cells in the sub-aleuronic layer show dense networks, though the nuclei round the top of the furrow are still perfect. Three days later, when most of the flank nuclei in the lower part of the

¹ See Brown, H. T., and Escombe, F.: *Proc. Roy. Soc.*, vol. lxiii, No. 389, 1898, p. 18; also *Trans. Guinness Research Lab.*, pp. 123-7.

grain show finer networks, similar nuclei are apparent in cells adjacent to the embryo while those in the middle of the flanks are coarser, some still being only deformed. At the base of the embryo at this date some of the cells of the sub-aleuronic layer are beginning to show deformed nuclei, and at this level too the flank nuclei are finer. The nuclei under the aleurone layer rapidly become more and more involved, and some of those round the furrow also show deformation.

In three or four weeks after the beginning of the nuclear changes most of the inner endosperm cells near the embryo are in the network stage, though some solid ones remain in evidence just under the aleurone layer and in some of the cells round the furrow.

By the time of harvesting, the majority of the nuclei in the grain are in the state of very fine networks, though those in the sub-aleuronic layer and round the furrow have not in all cases made so much progress in disorganization. But up to the last, the relics of the nuclei are still in evidence, and are stainable with Delafield's haematoxylin, indicating that they do not absolutely pass out of existence during the maturation changes. Brown and Escombe state that the cells are quite 'disintegrated' by the time the cells are completely matured. If by the term 'disintegrated' the total disappearance of the nuclei is meant, this statement is hardly borne out by the later observations, 'disorganization' expressing the state of affairs more accurately.

A comparison of the senescence of the nuclei in wheat and barley shows that in most respects the course of events is very parallel. The phenomena of senescence are exactly similar, and in both cases it is the nuclei of the cells in the middle of the flanks which first show signs of disorganization, while those round the furrow are not affected until comparatively late in maturation. One difference is to be noticed—in barley the processes of disorganization appear to advance from both ends of the grain simultaneously, the latest region of the grain to be involved being just below the level of the embryo; while in wheat the disorganization seems to proceed gradually from the tip of the embryo downwards, in exactly the opposite direction to that in which the starch is deposited. In barley, as in wheat, the changes are evidently caused by pressure, due to the deposition of starch, which crushes into the relatively soft nuclei, forcing them out of shape. It is quite possible that the difference in the order of progression in the two grains may be due to differences in the distribution and amount of pressure exerted, not only by the starch grains, but also by the developing embryo.

SUMMARY.

1. The weight of the whole plant increases steadily, until desiccation sets in about three weeks before harvest, after which a fall is evident.
2. The nitrogen, ash, and phosphoric acid increase until a maximum is

reached at about the time at which desiccation sets in. Then, while the nitrogen and phosphoric acid remain fairly constant, the ash decreases somewhat in quantity. The phosphoric-acid-starved plot gives somewhat abnormal results, differing in some respects from those of the other plots.

3. The long growing period of barley gives a prolonged period of desiccation, during which certain maturation changes are evident. These are hardly seen in wheat, as the latter crop is cut just when they are beginning.

4. With wheat the manuring had very little effect on the analyses of the grain or straw, whereas with barley the effect of phosphoric acid starvation is reflected in the results obtained.

5. The infiltration of starch follows a progressive course from the chalazal end of the grain up towards the embryo, the cells in the flanks of the grain being the first to show signs of the carbohydrate.

6. As the barley grain develops nuclear changes set in, due probably to the pressure of the increasing bulk of starch grains. The nuclei first lose their nucleoli and then gradually get deformed and squeezed out into networks of varying degrees of coarseness. The deformation seems to progress from both ends of the grain simultaneously towards the middle, the last cells to be involved being those of the sub-aleuronic layer of the endosperm.

APPENDIX.

<i>Date.</i>	<i>Green weight of 1,000 grains.</i>	<i>Dry weight of 1,000 grains.</i>	<i>Per cent. nitrogen in dry matter.</i>	<i>Per cent. ash in dry matter.</i>	<i>Per cent. P₂O₅ in ash.</i>	<i>Per cent. dextrose in dry matter.</i>	<i>Maltose produced per 100 parts of dry matter.</i>

Notes on the Anatomy and Morphology of *Pachypodium namaquanum*, Welw.¹

BY

D. G. LEE, B.A.

With Plate LXXXIV and eight Figures in the Text.

PACHYPODIUM NAMAQUANUM is a member of the family Apocynaceae; the genus is placed in the tribe Echitoideae by both Bentham and Hooker and Engler and Prantl. Its nearest relative is *Adenium*, from which it differs by being covered with spines. There are about twelve species, four of which occur in South Africa, the others in tropical Africa and Madagascar. One of the South African species is found in Zululand, two in the Coast and Central Regions. The fourth, *P. namaquanum*, which has the smallest range, has been found in two places: in Great Namaqualand by the Lions River,² and in Little Namaqualand at Dabainorup.³ In addition it was found in Namaqualand by Wyley,⁴ who gives no definite locality.

It was first recorded in Lieutenant Paterson's Travels in Africa, Journey 4, Oct. 1779, where it is figured over the class-name *Pentandria monogynia*, and is represented as having only two spines on each protuberance. He writes as follows²: 'At noon we passed the Lions River, the banks of which are in general inhabited by those animals. The country is extremely barren, and covered with small sharp stones, which proved very injurious to our horses' hoofs. In the evening we arrived at a small brackish fountain where we staid all night, and next day our way lay through a narrow path between two mountains. I found here the most beautiful plant I ever saw of the *Pentandria monogynia* class. It grows to six feet high, and is full of long spines from the ground to the top, and forms a large crown of crisped leaves and reddish tubular (*sic*) flowers, tinged with yellow and green.' Paterson's description is quoted in Harvey's 'Thesaurus Capensis', where, in addition, the leaf and flower are figured and described under the

⁴ Harvey (1).

name *Adenium namaquanum*¹ from material supplied by Wyley. It is here stated that the plant was popularly known as Elephant's Trunk; the aptness of this name can be seen from Text-fig. 1, which is a photograph of the whole plant in its natural habitat. Welwitsch transferred this species from the genus *Adenium* to *Pachypodium*.² The account in the 'Flora Capensis' is taken from that in Harvey, and hence, as in Paterson's figure, the spines are again erroneously said to occur in pairs.³

The material for this investigation, consisting of the upper parts of two stems preserved in spirit, was obtained by Dr. Pearson on the Percy Sladen Memorial Expedition, 1908-9. In the 'Gardeners' Chronicle' of Dec. 4, 1909, there appeared a photograph of the growing plant, together with an

TEXT-FIG. 1. Photograph of *Pachypodium namaquanum*.

article by Dr. Pearson,⁴ from which the following is quoted: 'It [*Pachypodium*] occurs on the very barren schistose ridges at Dabainorup, a few miles south of the Orange River, where it is associated with *Aloe dichotoma*, a species of *Commiphora*, and a few Acanthaceous bushes. The stout fleshy stem emerges from rocks which daily become so heated in the sun that a thick-soled boot is quite inadequate as a protection, and the nails therein become so enlarged that as soon as they cool they fall out. The inner tissues store an enormous quantity of water,⁵ and the development of hard-walled cells is so slight that the whole mass can be cut through with the

⁵ This water is stored in both the cortex and the pith, and drips from the stem when the latter is broken.

greatest ease by a pocket-knife. The large yellow flowers occur in June among the lower of the leaves which crown the stem; in January the seeds are already scattered and only vestiges of the dried-up corollas remain' (Text-fig. 1).

1. THE STEM.

(a) *External Appearance.* A number of protuberances are arranged in a close spiral all over the stem (Pl. LXXXIV, Fig. 1, A). At the apex of the stem each protuberance is seen to be situated in the axil of a leaf; the leaf soon falls off, and its scar is carried up the protuberance by subsequent growth at the base of the latter. The protuberances, when young, project from the stem at approximately right angles to it; later they are recurved. On the lower surface of each is the leaf-scar (*l. s.*, Fig. 1, B), and on the upper

TEXT-FIG. 2. Diagrammatic transverse section across the stem, showing the proportions of pith and cortex.

surface a scar which is no doubt left by the inflorescence (*i. s.*, Fig. 1, C). Each protuberance is fleshy and ends in three hard sharp thorns which bend downwards. The two lateral spines are longer than the median spine; they arise nearer the back of the protuberance, and bend down more sharply, than the median spine. Occasionally four spines are found in a group, in which case the two inner are shorter than the outer.

(b) *Anatomy.* The thickness of the stem is mainly due to the bulky pith (Text-fig. 2), the growth of which is almost entirely responsible for the increase in diameter of the stem. This growth is not caused by a cambium, but by the irregular division of the cells of the pith; this is clearly seen in section near the stem apex. The pith is very complex, consisting of large-celled water-storing parenchyma, in which medullary vascular bundles and laticiferous elements run in all directions (Fig. 2). With the limited amount

of material available it has been impossible to ascertain whether the laticiferous elements are vessels or cells; from their appearance in section near the apex of the stem they appear to be the former. Some of the large parenchymatous cells of the pith contain much starch in the form of grains split in the centre (Fig. 3). These are aggregated in very large numbers in the cells around the medullary bundles and laticiferous elements, being comparatively scarce in the other cells of the pith. Sclerosis and the formation of islands of soft bast, both of which are characteristic of Apocynaceae,¹ are absent from the pith in *Pachypodium*. The medullary bundles (Fig. 2) are composed of scalariform xylem elements and phloem, with a little parenchyma lying between the two. They are always accompanied by laticiferous elements (D, Fig. 2), which usually lie next to the xylem. Unlike those of some Apocynaceous plants, they have no definite orientation. They are given off by the vascular ring into the pith; owing to the

TEXT-FIG. 3. Diagrammatic transverse section of petiole, showing the arrangement of vascular tissue *a.* xylem; *b.* phloem; *S.* starch sheath.

lack of young material it has been impossible to ascertain whether they owe their origin entirely to the ring bundles or not. They pursue a most irregular course in the pith, both branching and anastomosing so as to penetrate every part of it. When a portion of the pith is macerated the medullary bundles alone are left, forming a complex network. The laticiferous cells branch and run in all directions through the pith,

either with or separate from the bundles. In a transverse section of the stem they are seen to enter the pith from the cortex through the medullary rays (Fig. 4), as in many other members of the order.²

The vascular bundles of the ring are collateral; very little wood is present, and the medullary rays are broad (Fig. 4). The xylem is composed of scalariform elements and parenchyma; cambium is present (C, Fig. 4), but the small amount of secondary tissue formed by it remains parenchymatous. The phloem (B, Fig. 4) consists of narrow sieve-tubes with sieve-plates on their terminal walls. The apparent absence of intraxylary phloem is very striking, for in all other investigated genera of Apocynaceae it has been found.³ Mr. Worsdell suggests that the intraxylary phloem bundles are present, but that they possess xylem, hence the medullary bundles. Evidence in support of this view will be given in the description of the structure of the protuberance and the petiole. No

¹ Solereder (5), p. 531.

² L. c., p. 530.

³ L. c., p. 531.

laticiferous cells occur in or accompanying the bundles. Outside each bundle is a number of pericycle fibres (F, Fig. 4), whose walls, which are very thick, give the cellulose reaction with iodine and sulphuric acid. The cortex is massive and fairly compact, composed of rounded parenchymatous cells, many of which contain calcium oxalate, a substance characteristic of the order.¹ It is found in highly refractive clustered crystals. Laticiferous cells are very numerous, traversing the cortex in all directions. Both here and in the pith they have thin walls and granular contents in which nuclei can sometimes be seen. These contents include proteid matter, which stains deep yellow with iodine and light yellow with nickel sulphate. The whole surface of the mature stem, protuberances, and spines is covered by a thick layer of tissue derived from a phellogen which arises in the second layer of the cortex. This tissue is suberized on the stem, but stains with haematoxylin on the young protuberances and spines.

2. THE PROTUBERANCES AND SPINES.

(a) *Structure of Protuberance.* Each protuberance projects from the stem at approximately right angles to it (Fig. 1, A). A number of ring bundles pass out into the protuberance in the form of a narrowing hollow

TEXT-FIG. 4. Diagram showing the course of the vascular bundles through the protuberance.
l.t. = leaf-trace; *i.c.* = inflorescence supply.

cylinder (Text-fig. 4). Some medullary bundles also pass out into the protuberance, running up within the cylinder. On their way up, the ring bundles are joined by a few of the medullary bundles, which may branch off again. Beneath the level of the scar left by the inflorescence the cylinder of ring bundles can be seen dividing into two unequal portions:

1. A trough of vascular tissue, with its open end upwards, bending

¹ Solereder (5), p. 530.

towards the lower side of the protuberance to supply the leaf (*l. t.*, Text-fig. 4). As the trough continues up the protuberance it becomes more and more compact in structure, as the separate bundles gradually join up. Inside the trough run a few medullary bundles, whose xylem gradually decreases in amount as they continue upwards, until they enter the petiole. Their subsequent appearance and behaviour in the petiole will be described later.

2. A cylinder of vascular tissue bending towards the upper side of the protuberance to supply the inflorescence (*i.e.*, Text-fig. 4). In section this cylinder is seen as a ring bounded by an irregular line staining deeply with haematoxylin, representing crushed laticiferous cells, phloem, or both (Fig. 6). The parenchyma inside the ring is traversed by laticiferous vessels running in all directions, the majority appearing in transverse section.

TEXT-FIG. 5. Diagram of transverse section across young spine. E = epidermis; P = parenchyma; W = water-storing region; C = central tissue; L = lignified tissue.

The vascular tissue consists of a ring of several groups of exceedingly small tracheides just inside the deeply staining line (Fig. 7), surrounding and distributed among which are small thin-walled cells resembling phloem. The inflorescence scar has round its margin a few minute spines; in a longitudinal section of one of these, one tracheide was seen running up the middle, but this appears to be exceptional. From their position around the base of the inflorescence these spines

are taken to be morphologically bracts.

The remaining medullary bundles run up between and beyond the ring bundles, and eventually separate into three portions which enter the three spines.

(b) *Structure of Spines.* A transverse section of a *young* spine (Text-fig. 5 and Fig. 8) shows a small central cylinder of thin-walled tissue (Fig. 9), in which are five small groups of xylem (A, Fig. 9) arranged roughly in a ring, and similar groups of smaller cells resembling phloem in appearance (B, Fig. 9). There is very little pith. The greater part of the spine is composed of parenchymatous ground tissue, consisting of rounded cells, irregular in shape, with intercellular spaces between them. Towards the periphery the parenchyma of the ground tissue becomes thickened and lignified (L, Fig. 8). Outside this layer the cells are again thin-walled, smaller, and more compactly arranged, passing off into several layers of square water-

storing cells surrounded by a definite thick-walled epidermis. In transverse sections of spines slightly older cork cambium is seen forming in one of the layers of water-storing cells (Fig. 10). It has been seen arising near the periphery in the second layer of the water-storing belt, and has also been seen arising as deep as the seventh layer of this belt. When the cork cambium has arisen the lateral walls of the cells immediately outside it disintegrate, causing the tissue external to it to fall off.

A transverse section of an old spine shows the small central group of cells now embedded in a mass of sclerenchyma. The parenchyma present in this central group of tissue in the young spine has been lignified, so that in transverse section the original xylem tracheides are no longer distinguishable. The phloem becomes crushed and eventually disappears, leaving small spaces in the sclerenchyma (Fig. 11). The belt of thick-walled tissue, which gives to the spine its tough character, is formed by the lignification of the cell-walls of the parenchymatous ground tissue of the young spine; the cells of which it is composed do not elongate. The surface of the spine is covered by a thick layer of tissue formed by the cork cambium, whose origin has been described above. This tissue resembles cork in origin and appearance, but stains with haematoxylin, and can therefore only be tissue destined to form cork, whose walls have not yet been suberized in the oldest spines examined. The lignification of the parenchyma progresses centripetally, finally obliterating the vascular tissue to the extent described above. Owing to this the mature spine loses the function of water-storing and all the phloem elements possessed by the young spine.

3. THE LEAF.

The leaves which crown the stem, borne singly on each protuberance, are $1\frac{1}{2}$ –2 in. long and about 1 in. broad, with an obovate-oblong lamina narrowing at the base into a very short hairy petiole. They are densely velvety on both sides, with a wavy margin and obtuse or retuse apex. The blade is bent up on either side of the midrib (involute), forming two grooves in which stomata are situated in small groups (Text-fig. 6). The stomata are also evenly distributed on both surfaces. They are very small, have no subsidiary cells, and are slightly above the level of the epidermis (Text-fig. 7 and Fig. 12); material has not been available for the study of their development. The epidermis is composed of oblong cells (E_1 and E_2 , Fig. 13), which have on their outer walls a thin cuticle which becomes very apparent when stained with a saturated solution of chlorophyll. It bears numerous trichomes and emergences whose complex structure is noteworthy when compared with the simple uniseriate or unicellular hairs found in all other members of the order¹ (except in the genus *Oncinotis*, where antler-

¹ Solereder (5), p. 529.

like trichomes are found¹). The trichome of *Pachypodium* usually consists of a multicellular base from which radiate a number of straight hairs, which have walls cuticularized like those of the epidermis, and well-marked nuclei. Near the apex unicellular hairs are common. The trichomes tend to pass into emergences which consist of several cells, varying in number from 6 to 10, arranged in a manner similar to that found in the trichomes, but possessing a massive stalk, in the formation of which the subepidermal cells take part (Text-fig. 8). Examples of these structures can be seen forming a regular series ranging from unicellular hairs to stellate trichomes and emergences.

The structure of the leaf is very compact, the mesophyll showing practically no differentiation into palisade and spongy tissue (Fig. 13). It is made up of oblong cells with well-marked nuclei, compactly arranged

TEXT-FIG. 6. Outline of leaf in transverse section, showing the lamina bent up on either side of the midrib.

TEXT-FIG. 7. Longitudinal section of a stoma.

except underneath the stomata, where there are large stomatal chambers. The cells underneath the upper epidermis are usually somewhat longer and more compactly arranged, forming a tissue slightly resembling palisade, in which there are no sclerosed cells such as are sometimes present in members of the Apocynaceae.² Calcium oxalate is present in the inner cells in crystals similar to those in the stem cortex. The vascular bundles are collateral, have no cambium, and are smaller than those in the stem (Fig. 13). They are accompanied by one or more laticiferous cells (D, Fig. 13) which are similar to those found in the stem, but here are never found apart from the bundles.

The bundle of the petiole is arc-shaped in transverse section (Text-fig. 3). The xylem (A, Fig. 5) forms a band interrupted by parenchyma; the phloem (B, Fig. 5) forms a band of very small sieve-tubes with sieve-

¹ Solereder (5), p. 530, Fig. 121.

² l. c., p. 549.

plates on their terminal walls; between the two is a distinct layer of cambium (C, Fig. 5). On the adaxial side of the protoxylem, embedded in the parenchymatous ground tissue, are several small islands of tissue (B¹, Fig. 5, and Text-Fig. 3) resembling phloem in appearance, but in which the presence of sieve-tubes has not been ascertained. In addition to these phloem groups there are also, on the adaxial side of the protoxylem, a few scattered xylem-elements, some of which are in contact with some of the phloem groups. Some of the latter, however, are entirely without xylem-

TEXT-FIG. 8. Longitudinal section through emergence.

elements. As the petiole bundle characteristic of the order is bicollateral,¹ it was at first thought that the bundle in *Pachypodium* was derived from a bicollateral bundle by the degeneration of the adaxial band of phloem to these small isolated groups. This, however, gives us no explanation of the scattered xylem-elements on the adaxial side of the protoxylem. After carefully following the course of the leaf-trace through the protuberance it was found that these isolated bundles in the petiole were the continuations of the medullary bundles which accompany the leaf-trace, and in which, as has been stated before, the xylem had gradually decreased.

¹ Solereder (5), p. 529.

We have here then a connexion established between the medullary bundles of the stem and the internal phloem groups of the petiole; a connexion which very strongly upholds Mr. Worsdell's opinion that internal phloem groups represent medullary bundles which have lost their xylem.¹

On the lower side of the arc-shaped bundle is an irregular layer of cells similar in appearance to the cells of the ground tissue, but containing starch in large grains (C, Text-fig. 3). This layer forms a definite sheath on the lower side of the vascular bundle. Much smaller starch grains may be present in the other cells of the ground tissue, but in no definite layer or group of cells. The ground tissue consists of loose spongy parenchyma. There are a few scattered laticiferous cells running up the petiole.

As the arc-shaped bundle of the petiole passes up the midrib it gives off successive branches from its free edges; these branches pass off into the lamina. In transverse section the structure of the midrib is seen to be the same as that of the petiole, except that the vascular bundle is smaller owing to its branching.

4. THE MORPHOLOGY OF THE PROTUBERANCES AND SPINES.

The morphology of the spines and protuberances is not clear. Little morphological importance can be attached to the arrangement of the vascular tissue of the spine, which might occur in either a stipule or a stem. Thus the stipules of *Acacia* have a structure similar to that seen in these spines. The course of the vascular bundles in the protuberance has been already described, but it is advisable to restate the facts briefly before discussing the morphology. Several vascular bundles leave the ring and run out through the protuberance in the form of a hollow cylinder, which later divides into two portions, the inflorescence supply and the leaf-trace (Text-fig. 4). Running up through the tissue enclosed by the hollow cylinder of ring bundles are a number of medullary bundles. A few of these join on to the cylinder of ring bundles, rarely branching off again, but the majority run straight up and separate into three portions, which supply the three spines. We see, therefore, that while the vascular supply of the inflorescence and leaf is derived from the bundles of the ring, together with some medullary bundles, that of the spines is derived entirely from the medullary bundles. It is known that medullary bundles generally originate from leaf-trace bundles which, after running down one or more internodes as part of the normal ring, turn into the pith.² The material available has not been sufficient to determine whether or not the medullary bundles of *Pachypodium* originate in this way.

¹ I wish here to express my thanks to Mr. Worsdell for his valuable suggestions and assistance in this question.

² Scott and Brebner (4).

Perhaps the most probable view of the morphology is that we have here two serial buds placed one above the other in the axil of an adnate leaf. The upper of these is an inflorescence whose vascular supply is derived from the vascular ring of the stem. The lower is the apex of the protuberance which receives its bundles from the medullary region only. This view leaves the morphology of the spines themselves an open question. They arise from the lower of the two buds, i. e. the apex of the protuberance, and not being merely emergences they are either stem-spines or modified leaves. That the middle one is a leaf and the two lateral stipules is improbable in view of the facts that stipules are uncommon in the order and when present are intrapetiolar. The three spines are therefore all stem structures, or all modified leaves, or the two lateral are leaves, the terminal and shorter being a stem. Against the first of these is the absence of any sign of reduced leaves subtending the stems; against the second is the apparently terminal position of the median spine; the third then seems the most probable, and is supported by the fact that the median spine has sometimes been seen branching into two.

If the above interpretation of the morphology of the spines and protuberances is correct, we have here two serial axillary buds differing entirely in the origin of their vascular supply. It will be seen that the knowledge of the origin of the medullary bundles, which has been impossible to determine, is necessary before the discussion can be carried any further. The facts that the mature spine loses its water-storing capacity, and that by the time it has matured the inflorescence has fallen off, suggest that the spines store water which is used up in the formation of the inflorescence belonging to the same protuberance. When the flower has fallen off the spines may perhaps be of biological importance in protecting the superficial tissues of the stem from the intense sunlight.

5. ANATOMICAL RELATIONSHIPS.

The most striking anatomical feature which distinguishes *Pachypodium* from all other members of the order is the presence of an anastomosing network of medullary bundles and the absence of intraxylary phloem bundles. With regard to this one of two opinions may be held.

- I. That intraxylary phloem bundles, wherever found, are due to the degeneration of medullary bundles. In all other members of the order this degeneration has taken place. This is the opinion of Mr. Worsdell, and is supported by the appearance in the petiole of medullary bundles degenerated into internal phloem groups.
- II. That in *Pachypodium* the intraxylary phloem bundles are present and have acquired xylem as an adaptation due to the immense water-storing pith.

Stated briefly, the question resolves itself into whether the medullary bundles are a primary character, or whether they have been acquired later owing to the necessity of some means of conduction in the water-storing pith.

In this connexion it is interesting to note that Scott and Brebner, in a paper on internal phloem, say: 'It is probable also, that the pith-cells themselves may be able to discharge both storing and conducting functions more efficiently when brought into direct relation with the phloem and its proteid contents.'¹ In *Pachypodium* the efficiency of the pith as a water-storing tissue is much increased by the presence of medullary bundles. Correlated with the presence of storage parenchyma and of medullary bundles is the small quantity of wood, in which *Pachypodium* differs from most Apocynaceous plants. Another adaptation to the habitat is seen in the possible water-storing and protective functions of the spines. In other characters, e.g. the occurrence of calcium oxalate and laticiferous elements, and the superficial origin of the cork, *Pachypodium* agrees with the other members of the order.

Regarding the origin of the medullary bundles all that can be said is that they have been seen to branch off from the ring bundles, and have no definite orientation. A study of the seedling structure would be necessary to follow up their development. In other genera of Apocynaceae² which possess medullary bundles there is present a cambium outside the inner phloem which gives rise to xylem, so that inversely orientated medullary bundles are formed. No sign of such a cambium has been seen in *Pachypodium*, where the medullary bundles are simply branches of the ring bundles.

In conclusion, I wish to express my thanks to Dr. Pearson for advice and many helpful suggestions in this investigation; and also to Miss E. L. Stephens for her kind assistance in preparing it for the press.

6. SUMMARY.

1. The stem is fleshy and consists to a great extent of the pith.
2. Branching and anastomosing medullary bundles varying in size and orientation traverse the pith in all directions.
3. The bundles of the ring are collateral, separated by wide medullary rays, and have very little secondary tissue.
4. Apparently no intraxylary phloem bundles are present. It is suggested that they are present, but possess xylem, and so form the network of medullary bundles.
5. Laticiferous cells are present in the cortex and pith of the stem, the

¹ Scott and Brebner (4), p. 261.

² Solereder (5), p. 531.

petiole, midrib, and lamina of the leaf, and the cortex of the spines. They have thin walls and contain nuclei and granular matter of a proteid nature.

6. It is probable that there are two serial axillary buds placed one above the other in the axil of an adnate leaf. The upper of these is an inflorescence, and the lower is the apex of the protuberance.

7. Of the three spines the median is probably a stem spine, the two lateral being modified leaves.

8. The functions of the spines may be to store water for the formation of the flower, and then to reflect the intense sunlight away from the stem. Near the base of the stem the spines fall off, their function here being probably performed by a thick covering of cork.

NOTES.

NOTE ON AN ABNORMAL PROTHALLUS OF *PINUS MARITIMA*, L.

—A large number of Pine prothalli were collected during October and November, 1911, with the object of making a comparative study of certain fixing agents, and of various methods of treating fixed material prior to embedding. Only a small part of this material has at present been sectioned, but in clearing it was noticed that one prothallus was quite different in structure to all the rest. This was embedded separately.

Externally, this prothallus was of about the normal size, but instead of showing the usual terminal group of two or three archegonia, there were two lateral groups of two archegonia each. The two groups were only slightly separated, and were almost, but not quite, in the same longitudinal plane.

In sectioning, great care was taken in orienting the material so as to get a median longitudinal section of the prothallus which should pass as nearly as possible through the median plane of each archegonium. For it to do so exactly was impossible, owing to the arrangement of the archegonia as described above, but the accompanying drawing was made almost entirely from one section, the details of the lower archegonia, however, being filled in from adjacent sections.

The prothallus was fixed on Nov. 5, 1911, in the following solution:

Picric acid, saturated solution in 50 per cent. alcohol, 100 c.c.

Glacial acetic acid 5 c.c.

Mercuric chloride 5 grammes.

washed in 50 per cent. alcohol, and embedded through cedar-wood oil.

The structure of the prothallus, as seen in section, is sufficiently explained by the drawing.

As far as the writer is aware, no case is recorded of a prothallus of any of the Abietineae which bears only lateral archegonia. The nearest is that figured and described by Miss Ferguson in *Pinus montana uncinata*, which formed archegonia *not only at the top*, but also along the sides of the prothallus, so arranged as to suggest a cock's comb.

The case here described, however, differs fundamentally from Miss Ferguson's in the *entire absence of apical archegonia*. Its chief interest lies in the resemblance to certain other groups—Araucarineae, Sequoiineae, and Callitrineae—in which lateral archegonia are the rule, and terminal archegonia entirely absent, except in Araucarineae, where they may apparently occur as well, especially in *Araucaria*. The resemblance is not a very close one, since in these tribes the archegonia may be, and often are, deep-seated; but this condition is paralleled in other recorded cases in the Abietineae. Here, however, there is no tendency for the archegonia to become embedded, each of

Section of Abnormal Prothallus of *Pinus maritima*, l..

the four being, in fact, less deeply sunk below the surface than in an average terminal archegonium of the same age, the neck being only a few microns from the megaspore membrane. The megaspore membrane seems to be fairly uniform over the whole of the prothallus, instead of being thinner over the apex as is normally the case, and is seen to be stretched over the depressions leading to the necks, instead of following the cell outlines.

The question naturally arises whether this lateral position of archegonia in *Pinus*, perhaps the most stereotyped of all Conifers in the details of its development, is to be regarded as a reversion to an ancient type, a new departure of the nature of a 'freak' or 'mutation', or a pathological condition induced by injury. As regards the last suggestion, it may be dismissed at once. Collections were only made from properly grown and uninjured ovules in healthy-looking cones, and neither before nor after sectioning was any trace seen of injury at or near the apex of the prothallus. The slight crushing seen in and near the two lower archegonia was almost certainly caused in dissecting out the prothallus for fixing. Between the two remaining alternatives it is not easy to decide. Most of the workers on the genera of Conifers with normally lateral archegonia (including the present writer) have regarded this feature as an ancient or 'reversionary' character, but the evidence is perhaps not very conclusive. In the only Cycad with lateral archegonia, the genus in which they occur appears in some other respects the most specialized member of the group.

Of all groups of plants the Conifers are probably the most puzzling in the apparent association of both 'ancient' and relatively 'modern' characters in the same plant, and it must not be hastily assumed, because lateral archegonia are associated in Araucarians with some undoubtedly ancient characters, anatomical and otherwise, that they therefore constitute a primitive feature. The discovery of wholly lateral archegonia in another tribe of Pinaceae may probably be best regarded in the present instance as rather of the nature of a 'mutation' than a 'reversion'; if so, it lends support to the view that the condition is a modern specialized one. This view certainly does not simplify the already rather complicated problem presented by the Araucarians, but if applied to the Callitrineae, it brings this character into better agreement with the reduced cones and male gametophyte, and other 'modern' characters which need not be further specified. In *Sequoia* the other evidence is also conflicting and therefore does not largely affect the problem one way or the other.

The view suggested is put forward tentatively, but in any case it seems clear that the abnormal prothallus, here described, must be taken into consideration as one link in a chain of evidence, not yet completed, which will eventually settle the question of the 'primitive' or 'specialized' nature of lateral archegonia in Conifers. Further investigation of the Araucarineae on the one hand, and of the Callitrineae on the other, is likely to shed considerable light on the problem.

W. T. SAXTON, M.A., F.L.S.

BOTANICAL LABORATORY,
SOUTH AFRICAN COLLEGE,
CAPE TOWN.

PELORIA IN SAINTPAULIA IONANTHA, WENDLAND.—The detection of the peloric form of *Linaria vulgaris* in 1742, near Upsal, was considered by Linnaeus so remarkable a circumstance, that he not inaptly applied the term *peloria* (signifying prodigy) to describe this phenomenon.

Since his time, however, such cases have not been infrequent, and their occurrence in widely separated groups of plants, especially under cultivation, point to a universality only really thoroughly appreciated by teratologists.

Masters, in his work on Vegetable Teratology, p. 219 (1869), distinguishes two forms of peloria, viz. regular and irregular, the former implying a non-development

FIGS. A and B. *Saintpaulia ionantha*, Wend. A. I. Normal flower, showing projecting style. II. Half profile. III. Inverted and laid open to show insertion of the stamens. B. I. Peloric form. II. Same, laid open. III. Calyx and gynaecium.

of the irregular portions, and the latter suggesting a formation of irregular parts in increased numbers so as to render the symmetry of the flower perfect. Both forms are sometimes observed on the same plant, as is exemplified in *Linaria vulgaris*, and the same remarks apply to the peloria under consideration. Since its introduction from the Usambara Mountains, Tropical Africa, *Saintpaulia ionantha*, a Gesnerad, which, owing to a superficial resemblance to the Violet, has earned for itself the popular name of African Violet, has responded to cultural treatment by producing a galaxy of colours varying from reds to blues and white, the tints not always being confined to individual plants, but often exhibiting solitary blue and red flowers on the same inflorescence. Indeed, Pynaert¹ describes and figures a plant bearing red, blue, and half red and half blue flowers, a circumstance which is paralleled by certain Azaleas, but which latter anomaly may doubtless be explained by the influence of stock upon scion. The existence of peloric flowers appears, however, not to have been observed, though the allied genera *Gesnera*, *Gloxinia*, *Streptocarpus*, and *Columnnea* are recorded as exhibiting this peculiarity. The two forms alluded to

¹ Rev. Hort. Belge, xxii, 1894, p. 109.

occurred in the preceding year on the same inflorescence of a plant flowering in the Begonia House at Kew, but the disposition of the individual flowers, whether terminal or lateral, was at that time not noted, nor has the writer observed a recurrence of the phenomenon. A reference to the accompanying sketches will illustrate the chief points of distinction; it will be noticed that the addition of three stamens in the peloric form has resulted in a consequent diminution of the coralline segments, the corolla having become rotate, and its segments more or less rotundate and slightly incurved, the stamens alternating with these, and except for an increase in number, and a slight dilation at the base of the staminal filaments, identical with those of the normal form. The calyx and gynaecium are apparently the same (the style, however, not exerted), the ovoid ellipsoid pollen-grains showing no points of distinction microscopically.

Intermediate 3-4 stamened forms connecting these two extreme types were also noticed, but in the majority of cases they were extremely depauperate and could only be designated as malformations.

There appears little doubt that these peloric types represent a retrogression of zygomorphism to a primordially actinomorphic form, or what Morren was pleased to term 'epanody'. As to the cause, much conflicting evidence exists, but a fertile explanation suggested by various authors lies in the excess of food many plants are liable to receive under cultivation. The plants at Kew are generously treated from a cultural standpoint, and the prevalence of peloriae, especially in gardens, suggests that this explanation is not without truth.

CHORISIS (?) IN *ARISTEA DICHOTOMA*, Ker-Gawl.

A point of teratological interest worthy of record was noticed by the writer during the preceding year at Kew. A profuse blue-flowering specimen of *Aristea dichotoma*, a dwarf Iridaceous type, exemplified a solitary instance of a four-staminate flower instead of the characteristic three-stamined type (see Fig. C). In its other characters the particular individual conformed to the species, being, with the exception of the androecium, trimerous in its remaining whorls. A close inspection of the flower infers that the supernumerary stamen may be explained by *chorisis* or the division of a normal stamen, as is evinced by the union of the two staminal filaments towards their base. The anthers are in all cases normally ditheous, with the exception of one which exhibits an atrophied anther-cell, the pollen-grains being globular, smooth, and surrounded by a comparatively thick translucent cell-wall. In this particular Order these cases are remarkably rare, but Messrs. C. H. Wright and W. R. Dykes inform me that they have observed it in several Irises.

FIG. C. *Aristea dichotoma*, Ker-Gawl. Four-staminate flower: (a) point of union of two staminal filaments, suggesting *chorisis*; (b) atrophied anther-cell.

R. A. DÜMMER.

Kew.

ABNORMAL FLOWERS OF AMELANCHIER SPICATA.—Double flowers resulting from petalody of the stamens occur so often in the Rosaceae, that it is interesting to meet with a reversal of this state of things where the flowers have staminoid petals. Such an instance is afforded by the flowers of two small plants of *Amelanchier spicata*, Koeh., growing in the Royal Botanic Gardens, Kew. *Amelanchier spicata* is common in the Northern States of America, and is regarded by Sargent as a variety of *Amelanchier canadensis*. Like those of the latter, its petals are white, strap-shaped,

FIGS. 1-8.

or slightly obovate, varying in length from 8 to 12 mm. In the flowers of the plants growing at Kew the petals show a more or less complete infolding of their lateral margins. The more complete this infolding, the less the development of the petal-tip and the more nearly do the resulting structures resemble stamens. (Figs. 1-7 show a series of the abnormal petals.)

The most petal-like of the structures are of a white colour slightly tinged with pink; they are considerably smaller than normal petals. The most staminoid have white filaments bearing at their tips what appear to be anthers of a light brown colour, whilst the normal stamen has white filaments with cream-coloured versatile anthers (Fig. 8).

That the resemblance is not merely superficial is shown by transverse sections of these structures, as well as by the fact that the more completely developed of them undergo dehiscence disclosing yellow pollen-grains. Some sections were kindly prepared by Mr. Boodle, Keeper of the Jodrell Laboratory. Figs. 1 a, 3 a, 7 a, and 8 a show sections corresponding respectively to Figs. 1, 3, 7, and 8. In the first of these there is a development of the fibrous layer at one end only; in Figs. 3 a and 7 a this development

occurs at both ends. In Fig. 7 *a* pollen-sacs have completely developed and dehiscence has taken place, leaving disorganized cells and a few pollen-grains within the fibrous

FIGS. 1 *a*, 3 *a*, 7 *a*, and 8 *a*.

layer. It may be added that the flowers showed a further deviation from the normal in having the top of the ovary and the styles glabrous.

J. J. CLARK.

ROYAL BOTANIC GARDENS,
KEW.

ON WELL-MARKED AEROTROPIC GROWTHS OF *BACILLUS MEGATHERIUM*.—For nearly three years I have had under my observation aerotropic growths of *Bacillus megatherium* which present a remarkable annual periodicity. These growths were first noticed on the removal of some boards forming the front of a large box in which the palm *Demonorops* was growing. On the projecting dead extremities of the roots and the surrounding earth thus exposed, white fungal masses

were found. The growths on the earth were better marked than those on the roots, and varied from small flat, whitish films to patches 8 mm. square and up to 4 mm. in height. The latter were amorphous masses of Bacteria which cultural and microscopical methods showed to be *B. megatherium* in a practically pure condition. The vitality of the growths was well marked during the late winter months, during which I easily obtained typical and rapidly growing cultures on agar-agar and gelatine. The greatest efflorescence was attained towards the end of spring. Later on the growths looked drier and more scanty, their creamy colour becoming dead white, and they did not flourish so readily on culture media. At this stage more spores than bacilli were observed in both growths than in the period of greatest development. The chalky, desiccated appearance, poor reaction to cultural methods, and preponderance of spores were intensified during the summer.

As a site for Bacteria the roots of the palm would not be unusual, but well-marked and diffuse bacterial growths on the surface of the earth are unique and less easy to account for. Although Bacteria are found plentifully in the upper six feet or so of undisturbed soil (not deeper, unless corpses or other sources of pollution exist below),¹ a well-defined positively aerotropic growth, even of aerobes, is not seen. The only exceptions seem to be the Myxobacteriaceae described by Thaxter,² which are found on various animal excrements, and exhibit Myxomycetes-like fructifications. Their nutritive conditions are, therefore, eminently favourable. Whether this may help to account for their specialized fructification is problematical, but there is no doubt that the question of nutrition exerts an important effect on the exuberance to which a bacterial development will extend, and I was inclined to attribute the peculiar efflorescence of *Bacillus megatherium* on the earth to some unusual source of nourishment, which with the favourable temperature of the plant house (average 80° F.) would conduce to free development. The interest of the conclusion that the earth-growth existed saprophytically on the persisting remains of products of the decayed wood in the earth was minimized by later observations. On the open, horizontal surfaces of the boxes and tubs in which other tropical plants were placed, I afterwards noticed several growths of the bacillus. Here the areas were mostly circular in outline. The smaller ones were flat, the larger somewhat raised, particularly towards the centre, and measured up to an inch in diameter. In these situations the existence of a marked supply of food material is not so obvious. I hope to note any gradual change from a flat film to raised growths like those on the earth around *Demonorops* which appear to connect the ordinary free living Bacteria with the more highly specialized fructifications of the Myxobacteriaceae.

J. CHARLES JOHNSON, M.A., M.Sc.

UNIVERSITY COLLEGE,
CORK.

¹ Young : Proc. Roy. Soc. of Edin., xxxvii, Part IV, p. 759.

THE EXTENT OF THE ROOT-SYSTEM OF CUCUMIS SATIVUS.—In Sachs's 'Lectures on the Physiology of Plants' (Eng. ed., p. 13) the following sentence occurs: 'S. Clark has taken the trouble to measure the length of all the roots of a large gourd plant and found that it amounted to 25 kilom.' This statement is repeatedly quoted in other treatises on Physiology, e.g. 'Pfeffer's Physiology,' Eng. ed., vol. i, p. 153, Jost's 'Lectures on Plant Physiology,' Eng. ed., p. 28, &c. The reference is not given in any of the more recent works nor by Sachs himself. It may be of interest to quote the original statement, which occurs in a paper by W. S. Clark, President of the State Agricultural College, Amherst, Mass., and published in the 22nd Annual Report to the Massachusetts State Board of Agriculture. The paper in question deals with a wide range of subjects, and is more in the nature of a popular discourse than a scientific research. Some of the statements made by the writer are sufficiently startling. For instance, he states that roots of Clover one year old penetrated the soil perpendicularly to a depth of 8 feet, Lucerne roots to a depth of over 20 feet, and that, on the authority of an unnamed Indian officer, those of *Prosopis spicigera* reached a depth of over 69 feet! The last statement, at least, must be accepted with reservations, more especially when resting on an anonymous statement by one presumably without special botanical knowledge. Pfeffer (Phys., vol. i, p. 258) quotes Clark as his authority for the record that the Birch gives off 6.8 kilos. of sap per day in cases of active bleeding. Clark's statement is, however, that a Paper Birch 15 inches in diameter gave off, in less than two months, over 1,486 lb. of sap, a maximum of 63 lb. 4 oz. being reached on May 5th. This would give on an average 24.4 lb., or approximately 11.1 kilos. per day over 60 days (nearly twice the amount quoted by Pfeffer), while the maximum would represent about 28.5 kilos.

In 'Nature' of June 3, 1875, Clark's paper is reviewed at some length, and the reviewer, although he says he has 'no reason to doubt the accuracy of the statements contained in Mr. Clark's paper', expresses a desire 'to see the observations repeated'—a scepticism justifiable in view of the remarkable observations recorded by Clark. One of these deals with the length of the entire root-system of a 'squash-vine' (*Cucurbita maxima*), and since Clark's measurements have been quoted again and again without comment, and as the original paper is not very accessible, it may be worth while to give the quotation in full:

'But our squash-vine affords the most astonishing demonstration of all that has been said about root-development. Growing under the most favourable circumstances, the roots attained a number and an aggregate length almost incredible. The primary root from the seed, after penetrating the earth about four inches, terminated abruptly and threw out adventitious branches in all directions. In order to obtain an accurate knowledge of their development, the entire bed occupied by them was saturated with water, and, after fifteen hours, numerous holes were bored through the plank-bottom, and the earth thus washed away. After many hours of most patient labour, the entire system of roots was cleaned and spread out upon the floor of a large room, where they were carefully measured. The main branches extended from twelve to fifteen feet, and their total length, including branches, was more than two thousand feet. At every node, or joint, of the vine was also produced a root. One of these nodal roots was washed out and found to be four feet long, and to have four hundred and eighty branches, averaging, with their branchlets, a length of thirty inches, making

a total of more than twelve hundred feet. As there were seventy nodal roots, there must have been more than fifteen miles in length on the entire vine. There were certainly more than eighty thousand feet; and of these, fifty thousand feet must have been produced at the rate of one thousand feet or more per day.

I cannot find any record that Clark's observations have been repeated or confirmed. Further, Clark does not state how the measurements were made, nor is there any evidence in his paper that he took these measurements himself, or checked them if carried out by others. Thinking that it might be worth while to estimate as carefully as possible the length of the root-system of another member of the same family, I asked the British Botanical Association, Holgate, York, to cultivate for me, under the *most favourable conditions*, a plant of *Cucumis sativus*, and requested the Scientific Director, Dr. Burt, to take special precautions as to the separation of the plant from the soil and preservation of all roots of whatever calibre. This, Dr. Burt assures me, was done with extreme care, under his own supervision.

The plant was grown in a frame 10 feet by 6 feet, and was a full-sized plant bearing fourteen fruits, none of which were removed until quite mature, and until the plant was ready for lifting. The soil was washed away very carefully, beginning at one end of the frame and working through to the other. No roots were lost, even a few fibres, disconnected unavoidably in the process of removal, being preserved for subsequent measurement. The shoot region, including all the smaller branches, measured approximately 32 feet with about 140 leaves, counting in those that had been functional but had withered away at some date previous to lifting the plant. All the roots were then cut off close to the stem, both the primary one as well as the adventitious roots springing from the nodes. After the statements made by Nobbe, that the root-system of cereals may reach a length of 500 to 600 metres, and by Clark, as quoted above, I was much surprised to note the comparatively limited root extent of *Cucumis sativus*. After trying various methods I came to the conclusion that the only satisfactory way of obtaining reliable data was to stretch the root taut, and by aid of compass and centimetre scale to measure the length of the roots individually. The total length obtained was only 85.75 m., or, taking a metre as = 3.28 feet, in English measurements and in round numbers, 281½ feet. The actual scale measurements were checked by a calculation of (a) volume, (b) dry weight.

In the former case, the entire root-system was vacuum dried and pressed down in a graduated measure; in the latter the vacuum-dried material was carefully weighed, the volume and weight of a definite length of roots of various thicknesses having been previously estimated. On the basis of the data so obtained, the volumetric estimate gave a length of 285½ feet, and the estimate by weight 279½ feet. It may be taken, therefore, that the total length of the root-system of this particular plant of *Cucumis* was about 280 feet.

Wheat cultures were also made, but, owing to the excessive dryness of the summer of 1911, the cultures were to a large extent spoilt, and it was thought better to discard them, and trust to obtaining more normal material in the present year. These measurements, for obvious reasons, have not as yet been made.

R. J. HARVEY GIBSON.

The Anatomy and Morphology of the Inflorescences and Flowers of *Ephedra*.

BY

MARY G. THODAY (SYKES),

Girton College, Fellow of Newnham College, Cambridge, and Honorary Research Fellow in the University of Manchester,

AND

EMILY M. BERRIDGE, B.Sc., F.L.S.

With Plate LXXXV and twenty-one Figures in the Text.

WE undertook this investigation because it seemed to us that the genus *Ephedra* required re-examination for the sake of comparison with recent work on the other genera of the Gnetales,

The material on which our work is based is largely supplied from collections, embedded material, and slides previously made by one of us for other work on the embryology of the genus,¹ and includes four species, *Ephedra altissima*, *E. distachya*, *E. fragilis*, and *E. nebrodensis*. Additional inflorescences of *E. altissima* in various stages were obtained from the Manchester University Botanical Laboratory, and herbarium material of various other species, *E. alata*, *E. Torreyana*, *E. trifurca*, and others, was supplied from the Manchester University Herbarium.

I. GENERAL MORPHOLOGY OF THE INFLORESCENCES.²

The male inflorescence in *Ephedra* consists of an axis arising in the axil of one of the ordinary leaves, and often dichasially branched, bearing generally one terminal and two lateral strobili (Fig. 1, Pl. LXXXV). The bracts at the point of branching have acute apices, like those in a similar position in *Welwitschia*.

In *E. distachya*, *fragilis*, *nebrodensis*, and *antisiphilitica*,³ &c., the female inflorescence axis also springs directly from the axil of a leaf on the

¹ Berridge and Sanday: Oogenesis and Embryogeny in *Ephedra distachya*. New Phyt., vi. 1907.

² Strasburger, 1872, pp. 76 ff. and 132 ff.; Land, 1904.

³ Coulter and Chamberlain, 1901, p. 372. In this and several other species the peduncle is so short that the strobilus appears to be sessile in the axil of the bract.

vegetative stem; it generally bears one strobilus only; in *E. distachya*, however, it is sometimes branched. In some cases, which are specially common in *E. fragilis*, two or three such peduncles appear in one axil; here the lateral ones are in reality branches of the median peduncle, the first internode of the latter having failed to elongate. This suppression of the first internode seems to be characteristic of the shrubby Ephedras; in *E. fragilis* as many as fourteen branches are sometimes found crowded together at a single node. In *E. altissima* the arrangement, though different in appearance, is the same in essentials; the tendency to suppression of internodes at the base of the branches is not so marked in the vegetative shoots and the peduncles branch freely, the strobili, some of which are abortive, drooping in loose clusters from the climbing stems (Fig. 2, Pl. LXXXV).

The frequent dichasial branching of the female inflorescences of this species is a feature of marked resemblance to the inflorescences of *Welwitschia*. It is interesting to find dichasial branching a recurrent feature in the Gnetales, as a comparison has already been made between the inflorescences of *Welwitschia*¹ and the dichasially branched inflorescences of *Wielandiella*,² the flower of which also approaches that of the Gnetales.³

In all the above species each female strobilus is made up of three pairs of decussate fused bracts which form three cupules, the lowest very small, the next larger, and the uppermost forming a large protective cup within which the ovules (or ovule) are enclosed (Figs. 2 and 3, Pl. I. XXXV).

In the tribe Alatae, which includes some of the other species examined, the bracts of the female strobilus are more numerous and are not fused, but become during the ripening of the fruit chaffy and membranous instead of succulent⁴ (Fig. 3c, Pl. LXXXV, *E. Torreyana*; there were here ten pairs of bracts). In *E. Torreyana* there was one case with as many as five ovules in the strobilus, and examples with three were fairly frequent. In the strobili bearing three ovules the alternating whorls of bracts are sometimes trimerous throughout. Usually, however, even in these species, where the cones have numerous membranous bracts, there are only two ovules in each cone.

In the cones of *E. distachya* and *E. fragilis*⁵ there are also two ovules, occurring one in the axil of each of the topmost pair of bracts, the main axis terminating in between them. In microtome series of *E. distachya* the true apex of the stem is visible between the ovules as a small projection of a few cells.

In *E. altissima*⁶ there is commonly only a single terminal ovule.

⁵ Var. *campylopoda*, Strasburger, 1871; also *E. antiyphillitica*, Coulter and Chamberlain, 1901, *E. helvetica*, Jaccard, 1894, and many other species, Stapf, 1889.

⁶ As in *E. trifurca*, Land, 1904; *E. Alata*, *E. campylopoda*, &c., Stapf.

Occasionally, however, a form with two ovules is met with in which the arrangement of the ovules is the same as that found in the other species; but in this case no sign of the stem apex could be detected, the two outer integuments being fused together at the base.

The ovule has two coverings similar in position and character to those immediately surrounding the ovules in the other Gnetales, and here regarded as the outer and inner integuments.

The male strobilus is similar to the young female, but above the single basal pair of sterile bracts there are several pairs of fertile bracts, in the axil of each of which is a male 'flower'. The male flower consists of two perianth segments and a stalk, frequently more or less bifid, bearing two groups of bilocular synangia (Figs. 4-6, Pl. LXXXV). The number of the synangia varies from eight in *E. distachya* and *nebrodensis* to two in *E. altissima*.

In *E. fragilis*, var. *campylopoda*, the strobilus is bisexual, with male flowers in the axils of the lower pairs of fertile bracts and ovules in the axils of the uppermost pair. The latter, however, never reach full development.

The strobili of *Ephedra* are obviously far more closely comparable with those of *Welwitschia*¹ than with those of *Gnetum*.² The branched male inflorescence with its compact strobili, and both male and female strobili with their basal sterile bracts and their upper fertile bracts with axillary sporangiophores, are strikingly similar in both genera, but in *Ephedra* the strobilus has a much more limited growth than in *Welwitschia*.

II. THE ANATOMY OF THE INFLORESCENCES AND FLOWERS.

(a) The Bracts.

The bracts of both male and female strobili are similar in character,³ though those of the female are tougher in the early stages than those of the male, and also undergo later various changes connected with the ripening of the fruit, becoming, in the different species, succulent or chaffy, &c. The members of each pair are fused together in the female strobilus, but only slightly connate at the base in the male.

Each bract receives two vascular bundles, which run unbranched nearly to its apex. As in the vegetative leaves, the bundle is accompanied by a small number of reticulate transfusion tracheides, occurring laterally in two groups (Fig. 7, Pl. LXXXV). These increase in number and size towards the apex of the bract, where the bundles approach one another. Finally, the endings of the bundles are lost in one common group of transfusion tissue

¹ Pearson, 1906, 1909; Sykes, 1910.

² Thoday (Sykes), 1911; Pearson, 1912.

³ Stapf, 1889, pp. 25 ff.; Bertrand, Fig. 12, Pl. III, figure showing similar structure of vegetative leaf.

which extends for a short distance further into the apex (Text-fig. II. 5, 6, 7, 8).

Fibrous cells with lignified walls are scattered through the tissues of all the bracts and are especially numerous just under the inner epidermis, where in the cupules of the female strobilus they form a definite layer, one or two cells deep in the outer cupules, two, three or more cells deep in the inner cupules (Fig. 7, Pl. LXXXV).

The outer epidermis is very thick and strongly cuticularized. The outer wall consists of three layers, an inner cellulose, a middle containing crystals, and an outer cuticularized layer. The stomata are mainly in the outer epidermis, they are very small and deeply sunk, and the inner surface of the guard cells is strongly cuticularized (Fig. 8, Pl. LXXXV). The epidermis and stomata of the vegetative leaves are very similar in structure.

The structure of the bracts in *Ephedra* is closely comparable with that in *Welwitschia*,¹ the main differences being due to the unbranched nature of the vascular bundles in the former genus. The distribution of the fibrous cells, the curious character of the outer epidermis,² the structure of the stomata, and the transfusion tissue are all points of similarity.

(b) The Peduncle.

(i) *General.* The peduncle or naked axis of the inflorescence closely resembles the young vegetative stem. It has a strongly thickened and cuticularized epidermis with stomata similar to those of the bracts; the cortex is mainly composed of thin-walled assimilating cells, but contains also strands of hypodermal sclerenchyma which, however, do not project and form marked ridges as in the stem. The phloem of each bundle is accompanied by a strand of fibrous cells. In *E. altissima* the hypodermal strands of thickened cells are absent, but the pith is strongly lignified, the cells showing simple pits, and well-marked lignified strands accompany the vascular bundles; in *E. distachya*, on the other hand, the pith is thin-walled and the strands bordering on the phloem are reduced to a few fibrous cells, but the hypodermal groups are constant and regular, although smaller than in the vegetative stem. *E. fragilis* shows an intermediate condition; the hypodermal strands are irregular and scattered, while the pith and bundle strands are thick-walled but unligified.

In the vegetative stem of *E. altissima* the lignification of the pith is confined to the region near the node, while in *E. distachya*, *E. fragilis*, and *E. nebrodensis* signs of lignification appear only at the margin of the pith in the neighbourhood of the bundles.

¹ Sykes, 1910, pp. 184-6, Figs. 5, 9 a and b, Pl. XVII.

² It compares still more closely with the epidermis of the vegetative leaves in *Welwitschia*. Ibid., Fig. 2, Pl. XVII.

The varied distribution of the lignified tissue in the different species of this genus is paralleled in *Welwitschia*, where in the male inflorescence the entire pith is lignified, while in the female inflorescence this happens only in the extreme base; elsewhere lignification is confined to strands of tissue on the periphery of the pith accompanying the vascular bundles.¹

(ii) *Vascular Anatomy of Naked Axis.* In *E. distachya* the peduncle is traversed by eight collateral bundles, occurring in a regular ring and remaining unbranched except where, in the male inflorescence, branching of the axis occurs. At this level and at the branchings of the axis of the female inflorescence in *E. altissima*, the behaviour of the bundle system is similar to that described later in connexion with the vegetative buds in the axils of the ordinary vegetative leaves. In the upper branches of the female peduncle of *E. altissima* the structure is somewhat different; there are here four small bundles and two large ones, which latter are seen by their behaviour in the strobilus each to represent two of the bundles in the lower parts of the peduncle.

TEXT-FIG. 1. Transverse section of peduncle of *E. altissima* near the base of a strobilus, showing six bundles, lignified pith (P), and fibres scattered in the cortex (F).

(c) Anatomy of the Female Strobilus.

The axis of the strobilus itself is similar in general structure, distribution of fibres, &c., to the naked axis bearing the strobilus. In describing the course of the vascular bundles in the axis of the female strobilus it will be necessary to treat the two species specially examined separately.

(i) *E. distachya.* The eight bundles which enter the base of the strobilus become arranged in two groups separated from one another by gaps in the ring (Text-fig. II. 1). Then the bundles on either side of each gap (Text-fig. II. 2 and 3, B) pass out to the first pair of bracts.

Four bundles are left in the axis; these now divide to form again the original number (Text-fig. II. 4). Next the eight bundles are rearranged into two groups at right angles to the previous arrangement, and two pairs of bundles pass out to the second pair of bracts (Text-fig. II. 5 and 6, B₂).

Four bundles are again left in the axis and once more divide to form eight, arranged in two groups corresponding in position to those below the first pair of bracts. Before, however, the lateral members of each group pass out to supply the third pair of bracts, a small bundle originates from each of them and fuses with the opposite one in the gap between the

¹ Sykes, 1910, pp. 191 and 201-2.

groups (Text-fig. II. 8 and 9). The two pairs of foliar bundles now pass out in the ordinary way towards the bract, and the little median bundles pass out a short distance with them (Text-fig. II. 9). After the bundles have entered the base of the bract the median bundle curves backwards a little towards the centre of the axis and with two of the axial bundles

TEXT-FIG. II. 1-11. Series of transverse sections through the female strobilus of *E. distachya*, described in text. B_1 , B_2 , and B_3 = bundles supplying lowest, middle, and upper pairs of bracts respectively; O_1 = bundles supplying outer integument. The middle cupule has been omitted in 9, and the upper cupule in 11.

TEXT-FIG. III. Plan of course of vascular bundles in the female strobilus of *E. distachya*; letters as in Text-fig. II.

enters the ovule. With the formation of the two ovules the growth of the axis ceases, and all the vascular elements are therefore used up in the ovular supply (Text-fig. II. 10).

The behaviour of the bundle system at the level of origin of the ovule is similar in essentials to its behaviour at the origin of an ordinary *vegetative*

axillary bud. The vegetative axillary bud receives a median trace,¹ derived from the two foliar bundles, which passes out first to the abaxial side of the bud and there divides into two again; also two lateral bundles which supply the adaxial side of the bud (Text-fig. IV. 1-5). The lateral traces are derived in some small part from the foliar bundles as they pass out to the subtending leaf, but chiefly from branches of the adjoining main bundles. In the case of the ovule none of the elements composing the two lateral traces are derived from the foliar bundles, and the adaxial side of each ovule is entirely supplied by two of the four main bundles left in the axis, which do not branch but themselves form the lateral traces; consequently no vascular elements remain to supply the minute stem apex.

TEXT-FIG. IV. 1-5. Diagrams of series of transverse sections through the node of the vegetative stem (*E. nebrodensis*). M = median axillary bundle; L = lateral axillary bundle; B = bundle supply of subtending bract; a, b, c, d = four main bundles, which fork to form eight, $a_1a_2b_1b_2, c_1c_2d_1d_2$, in between each node; M_2 = median axillary bundle for axillary bud at next node; T = bridge of transfusion tracheides connecting the bract bundles with the median axillary bundle.

The course of the *bundle system in the ovule*² itself is very simple. The three bundles, one median axillary and two lateral, which enter the base of the ovule usually each branch into three; sometimes the median or abaxial one remains unbranched. In either case the median bundle does not contribute anything towards the supply of the outer integument, but the latter receives the middle branch from the other two groups only.³ The outer integument thus receives two bundles which traverse the angles

¹ The earlier account by Strasburger states that this is not the case: the vascular supply of the ovule differing in this respect from that of an ordinary axillary bud; 1872, pp. 78 ff.

² See also Strasburger, 1879, p. 99.

³ The two bundles supplying the outer integument in *Welwitschia* originate in a very similar manner, each being derived from the middle bundle of a group of three; Sykes, 1910, p. 197, Diagram IX, especially Case 2.

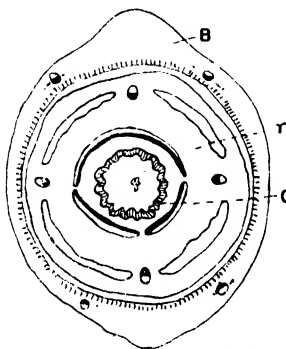

adjoining its flattened side (Text-fig. II. 11) and run unbranched into the apex. In *E. fragilis* the median bundle does commonly contribute a small bundle to the outer integument.

In *E. alata* and *E. Torrejana* there are three large bundles in the outer integument, derived exactly alike from the three bundles entering the base of the ovule. The integument in these species has three large projecting wings, one in the median and two in the lateral planes.

The five or seven bundles left in the flower axis form a ring which dies out low down in the base of the ovule and does not as in *Welwitschia* and *Gnetum* run up into the base of the inner integument. From the position of the ring the constituent bundles here also are clearly integumental.¹

The simple nature of the vascular system of the ovule in *Ephedra* as compared with that of the other Gnetales is very striking, and, like the unbranched pair of bundles supplying the leaves and bracts, would appear to point to reduction in this genus.

(ii) *E. altissima*. The main differences between this species and *E. distachya* in the course of the bundles in the axis of the strobilus and flowers depend on the fact that in *E. altissima* there is usually only one ovule. There is, however, a considerable range of variation in this species, and it becomes clear from an examination of the different cases that the uniovulate is a modification from the biovulate condition.

TEXT-FIG. V. Transverse section through base of ovule described as Case 2. The section is taken just at the level at which the outer integument with its four bundles is in the act of becoming free. B = upper cupule; r = ring of vascular tissue entering base of inner integument; c = suberized layer at the base of nucellus.

Case 1. Biovulate cones with both ovules fertile are occasionally found. In these cases the course of the vascular bundles is practically identical with that described in the cone of *E. distachya*, except that in the cases examined the integument always received three vascular bundles, and not two as is the rule in *E. distachya*, the median axillary bundle branching into three and contributing as well as the other two² to the integument.

Case 2. Among the material in the laboratory in Manchester, cases frequently occurred in which the single nut of the uniovulate cone had four angles instead of the normal three, and four bundles supplied the outer integument³ (Text-fig. V), running up these four angles. The course of the

¹ See pp. 966, 967. The tissues of nucellus and integument in *Ephedra* are differentiated from one another down to the base of the ovule.

² In *E. trifurca*, in which species also there is commonly only one ovule in the strobilus, biovulate cones also occasionally occur, in which the course of the bundles is the same as in Case 1 of *E. altissima*.

³ This is the normal case in *E. trifurca* (see also Land, 1904).

vascular bundles in this case is seen in Text-fig. VI. 1-10. Text-fig. VI. 8 represents the level above the origin of the uppermost bracts (B_3), and it is seen that four bundles run into the base of the single ovule. Of these the two smaller represent the median traces derived from the bract bundles and the two larger each represent two of the main axial bundles fused together. In all the uniovulate cones of *E. altissima* examined, the course of the bundles in the cone axis below this level only differed from that in *E. distachya* in that six bundles instead of eight occurred in the internodes (six

TEXT-FIG. VI. Illustrates three transverse series through the female strobilus of *E. altissima*, described in text. Case 2 = 1-10, Case 3 = 6'-10', Case 4 = 6''-10''; letters as before.

is also the number in the peduncle, p. 957). This appears to be the result of the tendency of the four main axial bundles, which ultimately supply the two ovules in the biovulate cone, but which in the uniovulate cone fuse into two in the base of the ovule, to fuse into pairs lower down also.

Cases 3 and 4. In other uniovulate cones the integument is three-angled and receives three vascular bundles. The two median traces may still both be formed from the bract bundles as in Cases 1 and 2, but in Case 3 one of them divides into two in the base of the ovule, and the halves fuse with the two main bundles, so that three bundles run up into the ovule

instead of four (Text-fig. VI. 6'-10'). This case is intermediate between the first two cases and Case 4, in which one of the median axillary bundles is not formed at all, and only three bundles enter the base of the ovule (Text-fig. VI. 6''-10''). This is the case described by Strasburger¹ as normal, but it here seemed to be exceptional, for it only occurred in one ovule out of seven or eight. Case 3 was the most common.

(d) Relation of *E. altissima* to *E. distachya*.

The series of cases just described seems to indicate that in fairly recent times changes must have taken place in *E. altissima* which have resulted in the modification of the biovulate to produce the uniovulate condition. There is other evidence which indicates that this change has been brought about by the fusion of the two axillary ovules to form one apparently terminal one. In some of the biovulate cones each ovule has

TEXT-FIG. VII. 1-3. Diagrams of three of the numerous uniovulate cones of *E. altissima* which show evidence of derivation from a biovulate condition. In Diagram 1 the abortive ovule is merely a mass of undifferentiated tissue with a cavity; in Diagram 2 the abortive nucellus is fused at the apex with the fertile nucellus; in Diagram 3 the abortive nucellus is much better developed and the wall of common integumental tissue which separates it from the fertile nucellus is continued upwards above the region of fusion of nucellus and integument, a small free portion being present. *p.*, prothallus; *n₁*, fertile nucellus; *n₂*, abortive nucellus; *i.i.*, common portion of inner integument free from the nucellus higher up (*x*); *o.i.*, outer integument; *c.*, cavity representing abortive nucellus.

both outer and inner integuments, but in many cases a common outer integument is present. In one example in which there was a common outer integument both ovules were fertile, but usually one is more or less abortive. This abortive ovule is often fused to the lower part of the inner integument of its fully developed companion, distorting and pressing aside its base; frequently it is merely a mass of undifferentiated tissue with a cavity in the middle (Text-fig. VII. 1), having an independent cup of suberized tissue at its base like that always found at the base of the fertile ovule. Sometimes, however, nucellar tissue² occurs within the cavity of the abortive ovule. This is the case in the example represented in Fig. 10,

¹ Strasburger, 1872, Fig. 55 *a* and *b*, Taf. XVI.

² It is remarkably easy in *Ephedra* to distinguish the nucellar tissue from the surrounding layers of the inner integument, even in the common basal region; pp. 966, 967, Text-fig. XI. 2.

Pl. LXXXV, and in Text-fig. VII. 2. Here the common wall of integumental tissue between the two nucelli is incomplete, and the small nucellar mass of the abortive ovule is fused at its apex with the fertile nucellus, so that in this section it appears as a long lobe of the latter extending downwards into the integumental tissue.

In a somewhat similar case (Text-fig. VII. 3) fusion of the two nucelli has only taken place at their extreme apices, and the common integumental wall runs up between them and ends in a small free lamina in the chink below the point of fusion. Here again only one nucellus contains a prothallium with archegonia.

Fully one-third of thirty-four strobili of *E. altissima* examined showed traces of the presence of a second abortive ovule within the outer integument.

(c) The Anatomy of the Ovule.¹

E. distachya. The ovules in *E. distachya* and other biovulate species are roughly triangular, compressed and flattened on their adjacent sides, but rounded abaxially.

Two vascular bundles traverse the *outer integument*, running in the two sharp angles of the flattened side. The outer epidermis of the integument is composed of large columnar cells and the inner epidermis of similar smaller cells except where it clasps the micropylar tube; there each cell is drawn out into a papilla. In the old ovule these become lignified and are firmly fused on to the micropylar tube (Text-figs. VIII and IX and especially XI. 3, and Fig. 11, Pl. LXXXV).

At the base of the integument it consists mainly of a layer of brown cells underneath the outer epidermis, which is continuous right round the bundles (Text-fig. VIII. 5), and internal to this is a band of tissue which even in the oldest ovule examined was still parenchymatous.

A little higher up (Text-fig. VIII. 4), fibrous cells with thick walls become differentiated in this parenchymatous band, and very soon there is a thick layer of fibrous cells on the inner side of the brown layer (Text-fig. VIII. 3). In the upper part of the outer integument there is, as well as the fibrous layer, a more conspicuous strand² of larger fibrous cells accompanying each vascular bundle on its inner side (Text-fig. VIII. 2); but at the tip, where the integument surrounds the micropylar tube, both the fibrous layer and the separate strands die out (Text-fig. VIII. 1). The brown layer gradually diminishes in prominence till in this region it is represented only by two small bands of tissue alternating with the two vascular bundles.

¹ Strasburger, 1872, pp. 86 ff., Pl. XVI, &c.

² In *E. nebrodensis*, the outer integument of which is very like that of *E. distachya*, these fibrous strands accompany the vascular bundles right to the base of the integument. The fibrous layer is also well marked and strongly lignified.

The vascular bundles throughout the upper third of the ovule are accompanied by large wings of transfusion tissue, which extends some distance round the fibrous strands (Text-fig. VIII. 2), and at their termination the bundles are lost in two large groups of transfusion tracheides (Text-fig. VIII. 1, T).

The *inner integument*, which becomes free about two-thirds of the way up the nucellus, projects in the early stages considerably beyond the outer covering, but in the mature seed this projecting portion is generally broken

TEXT-FIG. VIII. 1-6. Diagram of series of transverse sections through the ovule of *E. distachya*. P = papillae; T = transfusion tissue; I = inner integument; N = nucellus; C = layer of suberized cells at base of nucellus; cross hatching = xylem; dots = fibres; jagged lines = brown tissue.

off. The whole integument is very thin and its base is made up of thin-walled parenchymatous cells only; in the mycophylar tube there are three layers of cells, the inner epidermis, composed of large cells which are cuticularized to a most remarkable extent (Fig. 11, Pl. LXXXV), and two outer layers of much smaller cells whose walls are thickened in a minor degree but not cuticularized. A little mucilage appears in the tube shortly before fertilization; later this becomes hardened into a solid mass¹ which closes

¹ A similar secretion of mucilage is recorded by Pearson ('06) at the fertilization stage in *Welwitschia*; but it does not appear to be known whether this persists and becomes hardened afterwards.

the tip of the tube and which is continuous downwards as a thick mucilaginous lining to the tube. The chink between the micropylar tube and the integument is also closed by the papillae of the outer integument, and

TEXT-FIG. IX. Longitudinal section of ovule of *E. distachya*, older than the one drawn in Text-fig. VIII. The fibres internal to the vascular bundles are seen to be strongly lignified.

in this manner the developing embryo would appear to be as effectively protected as in *Gnetum*¹ with its special apparatus.

The ring of vascular bundles which enters the base of the ovule does not run up as far as the free region of the inner integument, but terminates quite low down in a mass of transfusion tracheides. One of the most characteristic features of the *Ephedra* ovule is the sharp demarcation of the large empty cells of the nucellar tissue from the smaller celled tissue which forms the free part of the inner integument and is also prolonged downwards right round the base of the nucellus (Text-fig. XI. 2). The ring of vascular tissue is situated in the integumental region. This differentiation is not of course present in the earliest stages, its cause being the proximity and growth of the prothallus, in consequence of which the cells of the nucellus become flattened and empty. Still the differentiation is of some interest, nothing of the kind having been seen in *Gnetum* or *Welwitschia*.

TEXT-FIG. X. Transverse section of nucellus and inner integument just above the level at which the integument becomes free. I = inner integument; N = nucellus; Pr = prothallus; L = layer of papillate cells on periphery of nucellus.

¹ Berridge, 1911; Thoday (Sykes), 1911.

The *nucellus* becomes very thin and papery in the seed, except at the apex, where it is still possible to distinguish the remains of the remarkably deep pollen-chamber, which has already been described in detail by other

TEXT-FIG. XI. 1-4. *E. altissima* ovule. 1. Longitudinal section showing general structure. N = nucellus; Pr = prothallus; PC = pollen-chamber; ii = inner and oi = outer integument; Muc. = mucilage; FS = fibrous strand accompanying vascular bundle; FL = fibrous layer on inner edge of outer integument; P = papillae; Mt = micropylar tube; B = hypodermal tissue; C = cup; VB = vascular bundle; TT = transfusion tissue. 2. Base of fused nucellus and inner integument, showing sharp line of demarcation. 3. authors¹ (Figs. 9 and 12, Pl. LXXXV). In the seed of some species the walls of the cells surrounding the pollen-chamber become thickened and lignified,

¹ Strasburger, 1872, Fig. 54, Taf. XVI; Jaccard, 1894; Land, 1904; Berridge and Sanday, 1907.

forming a little cap as in *Gnetum*.¹ For some little distance above the level at which the nucellus becomes free from the inner integument, the cells composing its epidermal layer are drawn out into papilla-like outgrowths (Text-fig. x).² At its base the nucellus is separated from the small-celled tissue belonging to the region of the inner integument by a thin layer of crushed cells, empty of contents, with suberized walls, which forms a cup, internal to the larger cup formed by the vascular bundles and their transfusion tracheides, extending upwards to about the same level, and separated from it by two or three layers of parenchyma (Text-figs. v, c, and xi. 2, c). It is very difficult to imagine what may be the function of such a cup of suberized cells.

TEXT-FIG. XII. 1-3. *E. altissima*. Diagrams of transverse sections through ovules; 1 = through apex of micropylar tube; 2 = through the outer integument at the level of the lower part of micropylar tube; and 3 = at a level about half-way up the ovule. Letters as before.

E. altissima. The single ovule of *E. altissima* differs to some extent from the ovule of the bisporangiate *E. distachya*. The great difference in size may be seen by a comparison of Figs. 2 and 3 a, Pl. LXXXV, which are magnified to the same scale. It is of course no longer laterally compressed by the presence of another ovule, though it is still angled, its angles being

¹ Thoday (Sykes), 1911, pp. 1113-14.

² Pearson has suggested that during the disorganization of the nucellar apex in *Welwitschia* a good deal of the mucilage afterwards found in the micropylar tube is formed, and he also produces evidence to show that some of this mucilage is secreted by the outer layers of the nucellar cone (1909, p. 343). It appears probable that in *Ephedra* also, while some of the mucilage originates by disorganization to form the pollen-chamber, some of it is similarly secreted by the papillate cells of the nucellar epidermis.

three or four in number, with a corresponding number of vascular bundles in the outer integument. The angles are not very prominent, but it is quite easy to tell their number by examination with the naked eye.

In the *outer integument* there is an outer soft and an inner fibrous layer as in *E. distachya*. In the outer layer the hypodermal brown tissue is only differentiated in the extreme base of the outer integument, where it forms a ring, and in the tip, where it is distributed in bands alternating with the vascular bundles. Text-fig. XI. 1 shows one of these bands cut longitudinally on the right side of the ovule, while on the left the section has passed through the region in between the bands and has cut one of the alternating vascular bundles. The inner fibrous layer is relatively less thick than in *E. distachya*; probably this is correlated with the abundant development of sclerenchyma throughout the outer parenchymatous layer (Text-figs. XI. 1, and x). The strands of fibres described in *E. distachya* accompanying the vascular bundles in the apical region of the ovule are differentiated here also, but are strongly lignified at a much earlier stage (FS, Text-figs. XI. 1, and XII). The vascular bundles have less transfusion tissue than in *E. distachya*.

The *inner integument* differs only in the fact that in the fertilized seed the tip of the micropylar tube is sometimes coiled over, and that reticularly thickened strengthening cells¹ are scattered through the base of the thin free portion below the micropylar tube (Text-fig. XI. 4).

The mass of hardened mucilage closing the apex of the micropylar tube was particularly well seen in this species (Text-fig. XI. 3).

(f) The Development of the Ovule.

The development of the ovule has been already described by other authors, and it is not proposed to give any details here, but merely to draw attention to the relations of the growth of the various parts of the ovule at each stage of development.

In the very young ovule the two integuments arise close together at the base of the ovule;² at the stage shown in Text-fig. XIII. 1 the bases of the two integuments are still almost on a level. From this stage onwards for some time the growth is mainly confined to the free apex of the nucellus, while very little development takes place in the region between the levels of origin of the two integuments. It will be seen that in Text-fig. XIII. 2, which is clearly a much older ovule than Text-fig. XIII. 1, this region has not begun to develop. Growth here begins about the time of cell-wall formation within the megaspore and continues with the enlargement of the prothallus; in the ovule figured in Text-fig. XIII. 3, which is not yet fertilized, considerable growth of this region has taken place. From this stage onwards the nucellar apex enlarges less in proportion to the rest

¹ It is probable that these were the cells once mistaken for tracheides. See reference in Thoday, 1911, p. 1117, note 3.

² See Fig. 2, Pl. XXII, in Berridge and Sanday, 1907.

of the ovule, and consequently the free part of the inner integument gets carried further up; in Text-fig. XIII. 3 its level of freedom is about half-way up the ovule, but in the ripe seed it is about two-thirds of the way up (Text-fig. XI. 1).¹ Even in the mature seed, however, the free apex of the nucellus is conspicuous and fairly massive.

It is interesting to compare the relative development of the different regions of the ovule in the three genera of the Gnetales. In *Gnetum* the method of development is similar to that in *Ephedra* in that the apical region of the ovule develops first, but in the later stages this region appears practically to cease to grow, and it is almost entirely to the great growth of

TEXT-FIG. XIII. 1-3. Three stages in the growth of the ovule in *Ephedra*. 1. Early stage with two integuments arising together at the base of the ovule. 2. Young ovule in which the apex has grown considerably, but the two integuments still originate close together. 3. Fertilization stage in which the region between the integuments has begun to enlarge.

the intermediate region, as in the Cycads, that the enlargement of the ovule is due. The apex of the nucellus after fertilization becomes hardened and withered, as it does also later and to a much smaller extent in *Ephedra*.

In *Welwitschia* we unfortunately know little of the earlier stages. In Text-fig. VIII, p. 196 of an earlier paper,² a stage is drawn in which the integuments are fairly close together. Here also the early growth in the apical region is followed by the enlargement of the intermediate region, but it also appears that here further great expansion of the apical region takes place, producing a massive nucellar apex far larger in size than that in *Ephedra*, though more like *Ephedra* than *Gnetum*. It has already been suggested³ that the Angiosperms illustrate the further development of this tendency.

³ Sykes, 1910, pp. 218-19.

(g) Anatomy of Male Strobilus.

The anatomy of the male strobilus is similar in all essentials to that of the female. The pair of lower sterile bracts have usually no buds in their axils, and each is supplied with two bundles in the same way as the pairs of sterile bracts of the female strobilus. At the other nodes, at each of which arise two bracts and two male flowers, the course of the vascular bundles is closely comparable with that at the origin of a vegetative bud.¹ The male flower receives, similarly, three bundles: the median trace, derived itself from the fusion of two bundles and originating early from the two bundles which supply the subtending bract, and two lateral traces which originate from the bract bundles as they pass out. Unlike the lateral traces of the vegetative bud, these lateral traces receive only a very small contribution from the bundles of the main stem, and are derived mainly from the foliar bundles (Text-fig. XVIII. 1-4).

(h) Anatomy of Male Flower.²

I. *General.* The male flower consists of a short axis which generally arises free in the axil of the bract, but in *E. fragilis* is fused for a short distance with the bract. On this short axis are inserted the two membranous appendages. Above their insertion the antherophore bearing the synangia extends upwards, its long axis being a continuation of the long axis of the flower. In *E. fragilis* it is folded back on itself in the bud (Text-fig. XIV) showing circinate vernation, but this curious configuration has not been found in any of the other species, in the buds of which the axis is very short and straight (Fig. 5 c, Pl. LXXXV).

TEXT-FIG. XIV.
Sporangiophore of
E. fragilis in bud,
showing the manner
in which it is folded
over. P = base of
perianth. x 23.

The antherophore varies considerably in the different species. It is generally cylindrical in the earliest stages, and it may remain so when mature, or may broaden out into a fairly wide lamina. In *E. Torrejana* (Text-fig. XVII) and *E. aspera*³ this lamina is well developed, and the synangia are borne on long stalks. In *E. nebrodensis* also the sporangiophore is flattened, as it is in several of the species figured by Stapf. In *E. distachya* and *E. fragilis* it is much more cylindrical, and in *E. altissima*, where it is probably most reduced, it shows little if any sign of broadening out into a lamina.

In some species, e.g. *E. distachya*, *E. nebrodensis*, the antherophore is clearly bifid. Each half bears four synangia, situated on the side of the

¹ p. 959 and Text-fig. IV.

² See also Strasburger, 1872, p. 132.

³ Both of these species have female strobili with numerous membranous bracts, and are presumably (pp. 954 and 976) among the more primitive of the species of *Ephedra*.

antherophore away from the main axis of the strobilus, but borne somewhat laterally and thus facing away from the axis of the antherophore. Apparently this arrangement represents the original form of the antherophore from which the other more reduced forms are derived by fusion of the synangia. The fused synangia are often bilocular, quadrilocular, or irregular in form. In *E. distachya* the division of the antherophore into two extends occasionally almost to its base,¹ but in other cases it may be quite absent, the two uppermost synangia being thus brought almost into contact with one another.

From this arrangement it is but a short step to the first stages of fusion and reduction in number of the synangia; this has taken place in *E. Torreyana* (Text-fig. XVII) and *E. aspera*, in which the two uppermost synangia, one belonging to each half of the antherophore, are fused, giving rise to a single apical, commonly trilocular synangium (Text-fig. XV, C). There is often considerable variation within the limits of a single species, various stages of fusion occurring in the different antherophores even of the same

TEXT-FIG. XV. Diagram of antherophores of the various species, illustrating the reduction in number of the synangia by fusion. A = *E. distachya*; B = *E. distachya*, *nebrodensis*, or *fragilis*; C = *E. aspera* or *E. Torreyana*; D = *E. aspera* or *E. Torreyana*; E = *E. Alte*; F = *E. aspera* or *E. altissima*; G = *E. altissima*.

strobilus. In *E. Torreyana*, for instance, cases occur in which the two inner synangia, like the uppermost pair, also fuse with one another (Text-fig. XV, D), so that there are two single median and two pairs of lateral synangia.

In *E. campylopoda*², a further fusion has occurred, the outer synangia of each half of the antherophore having fused with one another (Text-fig. XV, E), so that there are only four synangia, two median and two lateral. Next there are species in which the original eight synangia are represented only by three, one terminal and two lateral (*E. aspera*, *E. altissima*, *E. Alte* (Stapf), Text-fig. XV, F), and finally in *E. altissima* the terminal synangium, which when present is generally trilocular, is commonly abortive, and the antherophore bears only two lateral synangia (Text-fig. XV, G; Figs. 6 a and 6 b, Pl. LXXXV).

It is not intended to assert that these fusions here described are the only possible fusions among the synangia, all kinds of irregular fusions occur, distributed among the various species; even in *E. distachya* and

¹ Also recorded by Stapf, 1889, p. 21.

² Also in *E. Alte*, Stapf.

E. nebrodensis, cases were met with in which two otherwise independent synangia were fused by their adjacent ends. One of the most irregular species is *E. aspera*, in which occurred all the forms indicated in Text-

TEXT-FIG. XVI. Diagram of antherophores of *E. aspera*, showing the great variation in this species.

fig. XV. It is only meant to suggest that the forms shown in the diagram in Text-fig. XV indicate the main lines along which reduction has taken place.

II. *Vascular*. The three bundles which enter¹ the axis of the male flower fuse more or less completely into a single crescentic bundle (Text-fig.

TEXT-FIG. XVIII. 1-8. Series of transverse sections through axis of male strobilus and antherophore of *E. nebrodensis*. 1-4 = axis of male strobilus, showing contribution of one median and two lateral traces to the antherophore, all being derived from the foliar traces. 5-8 = antherophore in axil of bract; 5 shows crescentic bundle, in 6 it has broken into two with a minute bundle between which dies out, in 7 the two have divided to form four, and in 8 to form eight. P = 'perianth'; other letters as before.

XVIII. 4, 5). The fusion lasts only for a very short time, and takes place just below the level of insertion of the two leaf-like appendages. The crescentic mass thus formed almost immediately separates again into two large bundles, and between these a minute third one is commonly found on the abaxial

side. In *E. fragilis* this minute bundle passes out into the adaxial 'perianth' member (Text-fig. XX. 3, 4), and rarely this may even receive two bundles, but the other member appears to be always without a vascular

TEXT-FIG. XIX. Longitudinal section through two synangia of *E. nebrodensis*, showing trans-fusion tissue in septa.

TEXT-FIG. XX.¹ Diagram of male flower of *E. fragilis*. 1 = Longitudinal section; 2, 3, 4 = transverse sections from levels 2, 3, 4 in Diagram 1. The two bundles are seen to pass up unbranched to the level of origin of the synangia. The third bundle supplying the perianth is seen in 3, and the fusion of the base of the flower-stalk with the bract in 4. Higher up than 2 the perianth segments become separate from one another. 2, 3, 4 \times 23.

supply.² In all the other species the leaf-like appendages receive no bundles, and the minute third bundle dies out, while the two larger portions

¹ This figure is adapted from drawings kindly lent by Dr. Benson of Royal Holloway College.

² As in *Welwitschia*, but in *Gutium* these structures have a vascular supply.

of the crescentic mass supply the two halves of the bifid antherophore. In each half in *E. distachya* and *E. nebrodensis*, the bundle branches into two and then again into four, the eight bundles thus formed supplying the two groups of four synangia; each bundle ends in a mass of transfusion tracheides¹ in the base of the septum separating the two loculi of each synangium (Text-fig. XIX).

In most of the other species also the two main bundles branch quite early into a number of bundles corresponding with the number of synangia borne on the antherophore, but in *E. fragilis* they remain unbranched almost up to the level of insertion of the synangia, before they each divide up to form four traces supplying the four synangia.

III. MORPHOLOGICAL CONSIDERATIONS.

A. The Male Flower. In *Ephedra* the male flower axis is axillary, and it receives its vascular supply like an axillary bud; it bears two leafy appendages and a bifid antherophore. It therefore has the characteristics of an axillary shoot. The appendages are not however in the same plane as the first pair of leaves of a normal axillary shoot, but at right angles to it, that is in the position of the second pair of leaves; and where a vascular supply is present it corroborates this view: while the two halves of the antherophore are in the plane of the first or third pairs of leaves. Arber and Parkin² have adopted the view that the parts corresponding to the first pair of leaves are missing, and the second and third only are represented. The antherophore, they think, consists of two members originally standing laterally, but now by reduction of the flower and by fusion brought into a median position.

The male flower then becomes a very reduced strobilus, consisting of an axis bearing two pairs of appendages, the antherophore itself being a disc consisting of two fused sporophylls. Whether or no this view be the correct one, it does at any rate appear fairly clear, that whatever be the nature of the axis on which it stands, the antherophore is of foliar nature³: its broadened lamina in the species in which it is best developed, and especially its circinnate vernation in *E. fragilis* (Text-fig. 12), both combine to emphasize its leaf-like character: further, it is found that the two halves of the antherophore receive their bundles in the same manner as do the first and third pair of leaves of an axillary shoot, each half receiving at its base a contribution both from one of the lateral traces and from the median trace.

In view of the rapidly accumulating evidence⁴ suggesting that the

¹ Cf. *Welwitschia* antherophore; Sykes, 1910.

² Arber and Parkin, 1908, p. 499.

³ Coulter and Chamberlain assume it to be axial; 1910, p. 471.

⁴ Arber and Parkin, 1908; Sykes, 1910; Berridge, 1911; Thoday (Sykes), 1911.

Gnetales and Bennettitales are derived from the same stock, the leaf-like character of the disc of male organs in *Ephedra* and *Welwitschia* is of interest as tending to support this relationship. We now know, among the Bennettitales themselves, many examples of discs of male sporophylls much reduced from their original leafy and pinnate form. In *W. rajmahlensis*,¹ for example, the segments of the disc are few in number and no longer flattened, but consist of a branched axis-like structure, bearing each a row of bilocular synangia, seemingly very suggestive of the male organ in *Ephedra*. Wieland² also has lately drawn attention to the resemblance between the small male discs of *Wielandiella*, the reduced structure of which has recently been redescribed by Nathorst,³ and the disc of six fused male sporophylls in *Welwitschia*. Such simple discs as those of *Williamsonia whitbiensis*⁴ are perhaps even more suggestive of the staminate disc of *Welwitschia*. In this species there is a disc of fifteen simple leaf-like segments, fused at the base, projecting freely above; the free portion of each segment bears a row of paired bilocular synangia, while below the free portion this row is continued downwards by synangia which have become abortive. So that here reduction in the size of the segments and abortion of the lower synangia has already begun. Granted only the further continuation of reduction and abortion, the separate flattened segments of such a disc may easily be compared with one of the two flattened segments, fused below, free above, of the sporangiophore of such a species as *Ephedra distachya*, in which a row of only two pairs of bilocular synangia is borne by each half of the bipartite disc. *Welwitschia* differs in that the six members of its disc, similarly fused below, are continued upwards, not as flattened segments bearing paired bilocular synangia, but as cylindrical axes each terminating in a single trilocular synangium. In Wieland's staminate disc of *El Consuelo*,⁵ in some respects less reduced than *W. whitbiensis*, the free portions of the disc are not flattened but cylindrical, and bear paired lateral synangia on stalks, and we have already seen in *Ephedra* itself⁶ how easily a stage with paired lateral synangia can undergo reduction by fusion and abortion of the synangia, in the process of fusion trilocular synangia being produced. All that is required to derive the male disc of *Welwitschia* from Williamsonian discs such as these is the abortion of the lower pairs of synangia, already begun in *W. whitbiensis*, and the fusion of the topmost pair to form a trilocular synangium, such as is produced by fusion in *Ephedra*.

B. *The Female Strobilus* (cone). The restricted number of ovules in the female strobilus (cone) of *Ephedra* stands in marked contrast to the numerous ovules found in the strobili of the other Gnetales. In the groups of species in which the bracts are succulent the whole strobilus is very

¹ Wieland, 1911, p. 461.

² l. c., p. 438.

³ Nathorst, 1910.

⁵ Wieland, 1909, p. 433.

⁶ p. 971.

reduced in size, only three or four pairs of bracts being generally developed. The Alatae, however, the group in which numerous membranous bracts occur below the single fertile pair, is suggestive of an originally greater development than is found at present, which would be more comparable with the strobilus of *Welwitschia* with its numerous membranous bracts and axillary ovules. *E. alata*, *Torreyana*, &c., which have numerous bracts more or less loosely arranged and ovules which stand fairly free in the centre of the strobilus, are, we think, nearer the primitive form than the more reduced species. It is probable that more than a single whorl of bracts was originally fertile; indeed in one cone of *E. altissima* small masses of abortive tissue suggestive of undeveloped sporangiophores were found in the axils of the bracts next below the fertile ones; perhaps at the base of the strobilus there were male flowers as now in *E. fragilis*, var. *campylopoda*.

The increase in thickness and succulence of the bracts of groups other than the Alatae is accompanied by their decrease in number and by greater pressure on the ovules. These no longer stand free in the centre of the strobilus, but are tightly enclosed by the subtending bracts, and the three well-marked wings, each with its vascular bundle characteristic of the ovules of the Alatae, become modified by pressure. The ovules become laterally flattened, the two lateral wings being retained while the median one is lost; in *E. fragilis* and *E. nebrodensis* a small median wing with its vascular bundle is still present, but in *E. distachya* there is little trace of a median angle to the seed, and the median vascular bundle is hardly ever formed.

In *E. altissima* the very thick and succulent fertile bracts are fused together and tightly enclose in a cup the single ovule which has finally resulted from fusion of the two ovules originally present. The seed is no longer winged, but is round and almost smooth except at the apex where three or four slightly projecting ribs or angles can be distinguished.

C. The Female Flower. The ovule in *Ephedra*, like the male flower, is axillary in position, and perhaps as a consequence of this position it receives its bundles in the same manner as a vegetative axillary bud. Whether these facts can be regarded as proof that it is therefore the equivalent of a vegetative axillary bud is not easy to decide.

From a study of *Welwitschia* one of us¹ was inclined to conclude that it was wisest to term the axes of both male and female flowers 'sporangio-phores', but as has been said in the case of the male flower there is little to support this terminology, and the direct evidence as to the foliar nature of the flattened and bifid male sporangiophore in *Ephedra*, which is emphasized by the fern-like veneration of the organ in *E. fragilis* when in bud, is on the

¹ Sykes, 1910.

whole against it, and supports the view that the male flower represents an axillary strobilus.

Attempts have been made by various authors¹ to show that the coverings of the ovules represent fused bracts, and that the female flower is consequently an axillary bud bearing one or two whorls of bracts and terminating in an ovule. Some have also tried to prove that the ovule is not the termination of the axis of this bud, but is borne on one of the surrounding bracts, which represents a carpel.

Strasburger, in 1872, put forward the view that the outer covering in *Ephedra* and *Welwitschia* is the equivalent of a pair of leaves arranged, like the first leaves of an axillary shoot, transversely to the subtending bract. Jaccard also held the same view. According to it (Plan I, Text-fig. XXI) each half of the nut represents a leaf with a single median bundle instead of the pair of bundles formed in the normal vegetative leaf. But this suggestion is rendered unlikely by the fact that there is often a third bundle, situated in a position which would correspond to the fused margins of the leaves. Strasburger changed his opinion in 1879 and came to regard both coverings of the ovule as integuments.

Van Tieghem regarded the outer covering as composed of two leaves, corresponding in position to the second pair of leaves of an axillary bud, in the same plane as the subtending bract; the flattened surface of the nut with its two angles representing one leaf, traversed by two vascular bundles, the rounded, sometimes angled, outer portion representing the more or less abortive second leaf, sometimes supplied with a single vascular bundle. He regarded the ovule as borne on the inner leaf of the pair, a suggestion for which there is no evidence.

Lignier attempts to overcome the difficulties involved in demonstrating that the outer covering of the ovule represents a pair of leaves by the suggestion that it represents three leaves, the three vascular bundles belonging each to one of the three leaves; the female flower would thus become trimerous, the outer of the three leaves being more or less abortive. The inner covering he also regards as representing a whorl of three bracts, forming a tricarpellary ovary, the inner bract being the most developed, the two outer more or less abortive. There is no evidence to support the latter suggestion, and trimery is very infrequent in *Ephedra*. His attempts to

TEXT-FIG. XXI. Plans of the ovule of *E. distachya*. I. According to the view of Strasburger (first pair of leaves). II. According to the view of Van Tieghem (second pair of leaves). III. According to the view of Lignier (whorl of three leaves).

¹ Strasburger, 1872; Van Tieghem, 1869; Jaccard, 1894; Lignier, 1901; Arber and Parkin, 1908.

use the four-angled ovules of *Ephedra altissima* to support his view are not successful in the light of the anatomical investigations described in the current paper; for so far from it being possible that the outer covering in these cases represents only two of the leaves composing the outer covering in one of the ovules of the biovulate cones, it is found that it represents the fused outer coverings of both ovules, and its four vascular bundles represent the six bundles of the two ovules.

All theories which attempt to explain the outer coverings as composed of leaves do not meet the difficulty of the different method of vascular supply. Each of the bundles supplying the integument originates as the centre one of a group of three bundles formed from one of the bundles in the ovular base, the two lateral bundles remaining in the axis (Text-figs. II, 11, and III); the integumental bundles of *Welwitschia* are commonly formed in the same manner, but leaf-trace bundles do not arise in this way.

It appears to us that all attempts to compare the outer covering to leaves requires some distortion of the evidence, and that it is more correct to regard it as an integument in the ordinary sense of the word—a covering of the ovule of problematical origin. This is still more true of the inner covering, which with its micropylar tube is obviously comparable with the integuments of other Gymnospermous ovules. The complex structure of the outer covering is also unlike that of the ordinary leaves and is much more comparable, not only with that of the outer covering in *Welwitschia* and the middle one of *Gnetum*,¹ but with that of the outer covering of other ovules, more especially those of the Bennettiales. The resemblance² between the outer covering of *Gnetum* and the integument of *Bennettites* to which attention has already been drawn is still further emphasized in *Ephedra*; for here the three or four fibrous strands representing the star-like rays of the fibrous layer in *Gnetum* and *Bennettites* each correspond to an external angling of the seed, such as is present in *Bennettites*.³ The remarkably detailed resemblance in the structure of their outer integuments between the three members of the Gnetalean alliance, their leaves being so different, is alone a striking fact, and suggests that the coverings of the ovule are independent structures, less plastic than the leaves.

The ovule with its two integuments thus remains an isolated structure in the axil of the bract. There is no evidence to suggest that the ovule was ever borne on the subtending bract, and there is no direct evidence, except the analogy between its vascular supply and that of a vegetative bud, that

¹ It is clear from the structure that it is the middle covering of *Gnetum* which is homologous with the outer covering of the other two forms; Thoday (Sykes), 1911.

² Berridge, 1911; Thoday (Sykes), 1911.

³ Wieland's recent figures of the ovule in *Cycadeoidea turrita* (1911, p. 458, Fig. 15 c, and 1912, p. 90) still further strengthen the comparisons which have been made between the ovules of *Gnetum* and *Cycadeoidea*, though his comparison with *Gnetum*, 1911, p. 458, Fig. 15, a and b, is evidently based on some misapprehension.

the little axis on which it is borne represents an axillary bud, for it bears no leaves. But the male flower has already been compared with a little strobilus, and it seems probable in view of the evidence of reduction in the family that the female flower also represents a very reduced strobilus. If like the male flower it is to be compared with the strobilus of the Bennettiales, then the single ovule must represent the whole ovulate cone in that family; the comparisons which have been made by other authors between the male flower of *Welwitschia* and the Bennettitean strobilus necessitate this presumption, and direct evidence of such a fusion of ovules and their coverings has here been recorded in *E. altissima*, where the single terminal ovule represents the two fused axillary ovules of other species.

It seems that while there is strong evidence that the male sporangia are foliar, we are driven to the view that the ovule terminates an axillary shoot. In the Bennettiales also the male sporangia are undoubtedly foliar, but we are still not certain as to the seed, though the view that the seed pedicel is the equivalent of an interseminal scale and therefore foliar appears to be gaining ground. If the single ovule in *Ephedra* and *Welwitschia* represent the mass of foliar ovules and scales in *Bennettites*, being derived by reduction and fusion from a strobiloid condition probably more simple than that actually found in that family, this difference between male and female sporangia would be accounted for.

The single ovule now differentiated direct from the plastic apex of the axillary bud would thus be the equivalent of more than one ovule, each originally borne on a foliar organ, but now fused together at the apex of an axis, much as the apical pair of synangia in *E. altissima* and perhaps the single trilocular synangium of *Welwitschia* are the equivalent of several pairs of synangia originally borne on foliar appendages, but now fused together at the top of what falsely appears to be a cylindrical axis since it shows so little trace of its primitively bifid and leaf-like condition. It may be that there is as yet insufficient evidence for this analogy between micro- and megasporangia, but at any rate the great amount of reduction which the microsporophyll has undergone, even among existing forms, as evidenced by its variation from a leaf-like organ bearing eight synangia to a small cylindrical axis carrying only two, renders it quite probable that in the female flower also we have the final stage of a long series of reductions, the last trace of which is still to be seen to-day in the fusion of ovules in *E. altissima*.

IV. COMPARISON OF THE INFLORESCENCES OF THE THREE MEMBERS OF THE GNETALES.

Of the three genera of the Gnetales it appears from their anatomy that *Ephedra* and *Welwitschia* are most closely related to one another. The dichasial branching of the male inflorescences of all species of *Ephedra*

and the more or less regular dichasial branching of the female inflorescences of *E. altissima* is a point of similarity with both the male and female inflorescences of *Welwitschia*. In *Welwitschia* the individual strobilus is elongated and produces numerous fertile bracts and flowers, fifty or thereabouts in the female and still more in the male¹ with a few sterile bracts at the base.² In *Ephedra* the male strobilus bears only ten to fifteen whorls of fertile bracts, and the female strobilus is of still more limited growth. It has already been remarked that the strobili of the *Alatae* with their numerous membranous bracts are suggestive of an originally greater development than is found at present, and even the bracts themselves in these species bear a close resemblance to those of *Welwitschia*.

In *Gnetum* also the male inflorescence is dichasially branched and both male and female inflorescences would seem from their general arrangement to be comparable with those of *Ephedra* and *Welwitschia*. But when we come to examine the individual strobili we find that the cupule at each node is the equivalent of the pair of bracts at the node in the other genera, subtending not two but a cushion bearing six or more ovules in the female inflorescence and numerous antherophores and abortive ovules in the male. There are many more points widening the gap between *Gnetum* and the other two genera: the ovule has an extra covering and both this and the outer integument are radially symmetrical and supplied by numerous vascular bundles; the micropylar tube has a complex mechanism for closing it; the membranous appendages of the male flower have a vascular supply. The complicated method of bundle supply³ of the ovule and antherophores in *Gnetum* is also peculiarly characteristic, while the method of supplying these organs in the other two genera is very simple and quite comparable, there being, however, no median axillary bundle in *Welwitschia*.

In comparing the individual flowers of the three genera, it is again found that *Ephedra* and *Welwitschia* show most resemblance to one another, though here the signs of relationship are sufficiently clear to justify the placing of all three forms in the Gnetales.

In *Welwitschia* the male flower consists of an abortive ovule, surrounded by a disc of six male sporangiophores fused at their base, and four membranous appendages. In *Ephedra* the male flower bears two membranous appendages, and evidence has been brought forward to show that the antherophore probably consists of a disc of two fused sporophylls surrounding an abortive apex.⁴ With respect to the form of its microsporophyll (as also in its gametophyte) *Ephedra* appears the more primitive of the two; each

¹ Pearson, 1906.

² The lowest pair of sterile bracts is distinguished from the others by their acute apices; the same characteristic also occurs in the lowest pair of sterile bracts in the male strobilus of *Ephedra* (p. 953).

³ Thoday (Sykes), 1911, and Pearson, 1912.

⁴ Thibout, 1896, Part III; Arber and Parkin, Part I, p. 502.

half of the antherophore with its paired bilocular synangia resembling far more closely one element of the disc of a *Williamsonia* than the microsporophyll of *Welwitschia* with its trilocular stalked synangium.

The ovules of *Ephedra* and *Welwitschia* being in similar compressed positions differ in some respects from the freely projecting ovule of *Gnetum*, but in other ways they show remarkable similarity. They all have an inner thin membranous covering, fused with the nucellus below, free above, and prolonged into a narrow tube, lined in *Ephedra*, *Welwitschia*, and some species of *Gnetum* by a thick cuticle. The inner ring of vascular bundles, which in *Gnetum* is prolonged into the free part of this inner integument, in *Welwitschia* terminates at the level at which it becomes free from the nucellus, and in *Ephedra* at a still lower level.

They all also have a thick outer covering. In *Ephedra* it is angled, and in *Welwitschia* it has two well developed wings; in *Gnetum* it is smooth. The stony layer of this outer covering is always strongly developed at points corresponding to the external angles, and even in the smooth seed of *Gnetum* it is angled.

Ephedra and *Gnetum* both have pollen-chambers, one of the signs of their greater primitiveness than *Welwitschia*, but even in *Welwitschia* there is some disorganization at the apex of the nucellus.¹

The above evidence as to the reduced nature of *Ephedra* and its closer relationship to *Welwitschia* cannot be taken as indicating that it is reduced from *Welwitschia*. Its gymnospermous gametophyte and its well-developed pollen-chamber prohibit such a conclusion. But *Ephedra* and *Welwitschia* together appear to have retained in common numerous points which separate them off from *Gnetum* with its many singular characteristics.² Both genera show many signs of reduction, and *Welwitschia* has also, while retaining a less reduced strobilus than *Ephedra* and more primitive male flowers, undergone many remarkable vegetative modifications and a special elaboration of its ovules in the great growth of the nucellar apex correlated with its peculiar methods of fertilization.

V. SUMMARY.

1. The vascular system of the inflorescences and flowers of various species of *Ephedra* is described. It is found that the method of supply of the axillary flower buds is similar in essentials to that of the vegetative buds in the axils of the ordinary leaves. Each vegetative bud and each flower receives three bundles: a median abaxial bundle (afterwards branching into two in the vegetative bud), intimately connected with the bundles of the subtending leaf, and two adaxial bundles which originate partly or entirely from the adjoining bundles of the main stem.

¹ Pearson, 1906, Fig. 28, Pl. XIX, pp. 289-90.

² See also Pearson, 1912, p. 614; the male gametophyte, on the contrary, is most closely comparable in *Gnetum* and *Welwitschia*; l.c. p. 618.

2. The three bundles entering the axillary ovule branch each into three. In some species (*E. Torreyana*, *E. alata*, *E. fragilis*) the median bundle of each trio passes out into the outer covering; in other species (*E. distachya*) the abaxial trio does not provide any contribution to the outer covering, which thus receives only two bundles. A special case is afforded by the uniovulate species, *E. altissima* and *E. trifurca*, in which the two fertile bracts enclose only a single ovule. This receives either four or three bundles, which clearly represent the fused vascular systems of the two ovules of the biovulate species.

3. That the single terminal ovule of these species is actually the product of the fusion of the two axillary ovules of the biovulate species is clearly demonstrated by a long series of intermediate forms in *E. altissima*; among which occur biovulate cones, each ovule having two coverings, biovulate cones with a common outer covering, and uniovulate cones in which an abortive nucellus is more or less fused at the apex with a fertile one.

4. The structure of the outer covering and its method of vascular supply do not support the view that it represents the first whorl of leaves of an axillary shoot. It is here regarded as an integument. It is more or less angled in the various species and is composed, roughly, of an outer brown-celled layer and an inner fibrous layer. The vascular bundles traverse the angles and are accompanied towards the apex of the ovule by strands of fibres; they terminate in transfusion tissue. The structure of the outer integument is thus very similar to that of *Gnetum* (middle covering), except that there is here no palisade layer and that the angling of the inner fibrous layer corresponds to the outer angling of the seed which does not occur in *Gnetum*, but is present in *Welwitschia*. The comparison formerly drawn between *Gnetum* and *Bennettites* is thus further emphasized by the study of *Ephedra*.

5. The inner covering has no vascular supply, the ring of bundles entering the ovule terminating near its base. It is free from the nucellus for the upper third of the ovule and is prolonged upwards as a micropylar tube with a very strongly cuticularized lining. The opening of the micropylar tube is closed in the fertilized ovule by a hardened plug of mucilage, and the chink between the two integuments is closed by papillae which grow out from the epidermis of the outer covering and firmly clasp the inner. The fertilized ovule is thus as efficiently protected as in *Gnetum* with its complex mechanism. Both arrangements are, physiologically, abortive attempts at Angiospermy.

6. The different species of *Ephedra* exhibit much variation in the number of male sporangia. In *E. distachya*, *E. fragilis*, *E. nebrodensis*, &c., the sporangiophore is clearly bifid, and each half bears four bilocular synangia. In some species such as *E. aspera*, *E. Torreyana*, &c., there is no clear separation into two halves, and the upper pair of synangia are fused

together. Other species exhibit further stages in this reduction process, more and more synangia fusing together, often forming in the process trilocular or even quadrilocular synangia, until *E. altissima* is arrived at with only two bilocular synangia. The formation of trilocular synangia as a result of fusion affords a link with *Welwitschia*, where terminal trilocular synangia are normally produced. In most species the synangia are nearly sessile, but in *E. Torreya* and a few others they are borne on a stalk of some length, reminiscent again of the stalk freely projecting above the fused portion of the staminal whorl in *Welwitschia*.

7. From the evidence available it is concluded that the structures in the axils of the fertile bracts in the male cone are to be regarded as flowers, or little strobili, each consisting of one axis bearing four leaves. The first pair of leaves, which, except in *E. fragilis*, receive no vascular supply, are orientated like the second pair borne by a vegetative axillary bud, and the two flattened halves of the fertile organ thus appear to represent the third pair of leaves fused with one another back to back. In *E. fragilis* they exhibit circinnate vernation in the bud.

8. This bipartite sporangiophore with its paired bilocular synangia is compared with the six-partite disc of sporophylls in *Welwitschia* and with the multipartite disc in the Bennettitales. It is thought that we can trace the steps of a reduction series from the disc of *Cycadeoidea* with its bipinnate sporophylls, through such stages as *Williamsonia whitbiensis*, in which the segments are small and simple, and each bears a row of paired bilocular synangia, the lower of which are abortive; and the disc of El Consuelo in which the freely projecting portions of the disc are no longer flattened but bear stalked synangia; to *Ephedra*, where the disc is reduced to two segments, each bearing two pairs of bilocular synangia, and *Welwitschia*, where it is composed of six segments, each with a stalked terminal trilocular synangium. From the reduction series in *Ephedra* itself it is seen how from the fusion of bilocular sporangia a single trilocular stalked synangia can be produced.

9. Whether the female flower also in *Ephedra* and *Welwitschia* is, like the male, morphologically a little strobilus and the equivalent of an axillary bud, it is not easy to decide, since it consists of an isolated ovule; the more complicated relations occurring in *Gnetum* make the matter still more difficult. The male sporangiophores having been related with some show of probability to the disc of sporophylls in the Bennettitales, it seems justifiable, considering the many signs of reduction in the Gnetales, to suggest that the single ovule now developed at the apex of the axillary structure in the male and female flowers of *Welwitschia* and in the female flower of *Ephedra* represents the many ovules and interseminal scales of such a flower as *Cycadeoidea* fused together. This is rendered the more possible by the discovery that fusion of ovules actually occurs in *Ephedra*, resulting in the production of a uniovulate from a biovulate cone.

Fig. 11*b*. External view of nut of *E. distachya*, showing small angles. $\times 16$.

Fig. 12. Longitudinal section of apex of nucellus of *E. fragilis*, showing deep pollen-chamber. $\times 90$.

The Structure of the Female Strobilus in *Gnetum Gnemon*.

BY

EMILY M. BERRIDGE, B.Sc., F.L.S.

With four Figures in the Text.

VERY full and detailed accounts of the vascular supply to the flowers of various species of *Gnetum* have recently been published,¹ but in no case apparently do the ovules investigated show a certain series of complexes which constitute a striking feature in the vascular system of the female 'flower' of *Gnetum Gnemon*.

In this species, as in other Indo-Malayan forms,² the 12-14 bundles which traverse the base of the female flower all spring from the bundles which supply the cupule, and only a very few late-formed branches originate directly from the main vascular system of the inflorescence. Each of these bundles, on reaching the level of insertion of the outermost of the three coats of the ovule, becomes very broad and gives off two traces to this outer coat or 'perianth'; then turning inwards and upwards each passes on to supply the two inner coverings, which are probably best regarded as integuments.

Just above the point of departure of the two traces to the outermost coat (Fig. 1, p_1 , p_2) each main bundle gives rise to a curious complex of vascular strands.

Fig. 2 shows a tangential section of one of these, while Figs. 3 and 4, representing two sections through a single complex, show more clearly the relative positions of the main bundle, m , the traces p_1 , p_2 passing to the outermost covering of the ovule, the complex, c , and the main bundle, int , passing on towards the integuments.

Although, as in this case, the complexes often take the form of loops, they also frequently consist of three or four vascular strands, which end

Thoday, M. G. : Note on the Inflorescence Axis of *Gnetum*. Ann. of Bot., xxvi, p. 621.

FIG. 1. Longitudinal section through young seed of *Gnetaum Gnemon*. p_1 , p_2 , bundles supplying outermost coat; oi , bundle supplying outer integument; ii , bundle supplying inner integument; c , complex of vascular strands. The bundles indicated by dotted lines do not lie in the plane of the section.

FIG. 2. Tangential section of a single vascular complex. x , xylem; ph , phloem.

FIG. 3. Longitudinal sections through a single vascular complex. m , main bundle; p_1 , p_2 , bundles to outermost coat; c , complex; int , bundle to integuments.

FIG. 4. Transverse section through half the base of a flower. P_1, P_2, P_3, P_4, P_5 , &c., bundles to the outermost coat; $int_1, int_2, \&c.$, bundles to the integuments; C_1, C_2, C_3, C_4, C_5 , &c., vascular complexes.

blindly in the tissue below the groove between the second and third coats of the ovule.

In Fig. 4 the vascular complexes are shown as they appear in a cross-section through the base of the flower. They always contain a considerable mass of phloem, but the xylem tends to break up into separate strands, and in some cases, as at x , independent bundles are formed.

This whorl of twelve or more complex groups of vascular tissue, constantly appearing in the same position below the ovule, can hardly be dismissed as a mere irregularity of the bundle system. It seems not improbable that we have here the vestiges of the vascular supply of some whorl of organs which was situated between the outermost covering and the outer integument of the ovule.

It seems justifiable to assume that these complexes did at one time serve a whorl of organs surrounding the ovule, for although in the process of reduction the vascular bundles seem usually to dwindle and disappear before the organ itself is lost, as in the case of the perianth of the male flower of *Ephedra* or the abortive ovule of that of *Welwitschia*, yet these complex vascular structures may have survived, as has been suggested by Dr. Scott, because they were adapted to the storage of water. Also a very clear and somewhat similar case of the presence of vestigial bundles has been met with in the oak. In some cross-sections of a young flower the stamens were found to be represented by small outgrowths alternating with the stigmatic lobes. Just below these minute outgrowths, small branches from the vascular bundles supplying the perianth end in little irregular masses of reticulately thickened cells. In another flower of about the same age, the outgrowths are absent, but the small branch bundles persist.

The position of these vascular complexes in the base of the female flower of *Gnetum Gnemon* recalls that of 'the small complexes of four or more bundles' which Prof. Pearson describes as supplying the male flowers in other species of *Gnetum*.¹ In both cases they spring from bundles which pass on to form the vascular supply of an ovule, and they are situated just above the junction of these ovular traces with the traces of the protective bracts which in one case form the so-called perianth, in the other the cupule of the male inflorescence. If the presence of these vascular structures in *Gnetum Gnemon* is evidence for the existence, originally, of a whorl of male flowers surrounding the base of the ovule, the primitive form of the strobilus would have been an axis terminated by a female flower and bearing a single ring of male flowers, the whole protected by a cupule—the so-called perianth. This closely resembles the type of inflorescence suggested by Prof. Pearson as possibly the ancestral form; in his study of the structure of the male inflorescence he draws the following conclusion: 'Since the inflorescence may consist of as few as two flowering nodes and a terminal segment (which in some cases is an ovule with appendages) it is conceivable that the ancestral type of inflorescence was an axis bearing a single lateral ring of male flowers and a terminal female flower.'

The vascular knots may possibly have supplied a whorl of microsporophylls rather than complete male flowers; the female flower of *Gnetum* would then be comparable to the male flower of *Welwitschia*, and the presence

¹ Ann. of Bot., vol. xxvi, p. 614.

of these vascular structures might be taken as evidence for the hypothesis that the whole family originally possessed bisexual flowers. There are indications that the organs in the whorl were grouped in four sets of approximately three members, for the main bundles just above the insertion of the complexes are linked together by anastomosing strands in this manner. Hence the whorl may have consisted of four members of threefold nature similar to the microsporophylls of the *Welwitschia* flower. The structure of the male inflorescence in *Gnetum*, however, points to an association of male flowers rather than of microsporophylls with the ovule; hence it seems best to regard the female flower as representing at the present day a partial inflorescence and not a proanthostrobilus.

It follows from such a view that the apparently simple spike now constituting the whole female inflorescence of *Gnetum* is really of compound nature, consisting primitively of a central axis with a series of cupules from the axils of which sprang secondary axes bearing a ring of male flowers and a single terminal female flower. From such a compound inflorescence, moreover, could be derived an inflorescence closely resembling, both morphologically and anatomically, the male spikes of *Gnetum Gnemon*, *G. scandens*, and other Indo-Malayan species. Suppression of the first internode of the secondary axis, a modification which constantly occurs in many species of *Ephedra*, would bring the terminal female flower and the ring of male flowers into the axil of the cupule, and the outermost protective covering of the partial inflorescence, being now unnecessary, would disappear. The shortening of the first internode of the vegetative branches is accompanied in *Ephedra altissima* and frequently in *E. nebrodensis* by a shifting of the axillary buds of the first node from their normal lateral position to the abaxial side of the branch. The suppression of the internodes in the branches of the primitive inflorescence of *Gnetum* may have been similarly accompanied by a shifting of the male flowers so that they have become crowded together in the axil of the cupule below the abortive ovule, and reduced in number.

In the vegetative branches of *Gnetum Gnemon* suppression of the first internode is not clearly evident, but the presence of small buds in the axil between the branch and its subtending leaf, basipetally developed and deriving their vascular supply from the bundles of the branch alone, may indicate that the same thing occurs here also.

It seems probable therefore that *Gnetum* originally bore compound bisexual inflorescences from which both male and female spikes have been derived. The former have preserved in certain Indo-Malayan species their bisexual character, but the latter have as a rule lost all trace of it, for the strobilus of *Gnetum Gnemon* alone, as far as is known, retains in its series of vascular complexes surrounding the base of the ovule some vestige of its original complicated structure.

SUMMARY.

The presence of a ring of complex groups of vascular strands arising from the bundles in the base of the female 'flower' of *Gnetum Gnemon* may indicate that the ovule was primitively surrounded by a whorl of male flowers. If this were the case the female inflorescence of *Gnetum* would have been originally compound and bisexual, and from such a form the existing male inflorescence can easily be derived.

Somatic Mitoses in *Oenothera*.

BY

R. R. GATES, M.A., PH.D.

Imperial College of Science, South Kensington.

With Plate LXXXVI.

THE purpose of the present paper is to record certain facts regarding the somatic mitoses in the *Oenotheras*. For several years I have made incidental observations on the somatic divisions, particularly in flower tissues. But recently, in connexion with a study of the formation of the megaspores in *O. lata*, certain peculiar phenomena were observed in the rapidly dividing cells of the nucellus. In order to understand these peculiar appearances, which stood in various possible relations to the phenomena of reduction, it was found to be necessary to make a special study of normal somatic mitoses.

A brief account of normal nuclear division in the cells of the nucellus will therefore be given, followed by a description of the few rare cases in which the shape of the chromosomes differs from the normal, and certain instances in which an actual reduction division is apparently taking place in somatic tissue.

The slides from which these observations were made were all prepared from material collected in July, 1909, from a single plant of *O. lata* for a study of oögenesis. The fixing fluid used was a chrom-acetic solution which gave excellent fixation of the nuclei, and the stains employed were Heidenhain's iron-alum-haematoxylin and the triple stain. My actual acquaintance with the somatic mitoses is much wider, including several years' observations on a large number of forms.

CHROMOSOME NUMBERS.

It may first be stated that the sporophyte number of chromosomes in this *O. lata* plant was 15. Several counts were made in various mother-cells, which yielded incontestably 15 in every case. A large number of counts made in the nucellar tissue showed that 15 was the characteristic number here also, though certain variations from that number were found to

occur. Thus, in over fifty cells of the nucellus the number was determined to be certainly 15, in three cases it was impossible to determine whether the number was 14 or 15 owing to the relative position occupied by certain chromosomes, in one cell only 12 chromosomes could be found though the cell was undisturbed by the knife, in two cells the number was certainly 16, and in one cell 20 or 21 chromosomes were found.

These counts were all made with great care, nothing short of certainty with regard to the number being considered satisfactory. The counts were made chiefly in two stages of mitosis, (1) the late prophase just before the spindle begins to appear, and (2) the metaphase in polar view. In the former case only nuclei were considered which could be shown with certainty to be uncut. This stage is a peculiarly favourable one for counting the chromosomes, because the latter are never in contact. They apparently repel each other, as they are invariably found at this time distributed just within the periphery of the nucleus (cf. Pl. LXXXVI, Fig. 11). In the equatorial plate stage nuclei only were chosen for counting when the chromosome group was in a plane parallel to the plane of section and undisturbed (cf. Fig. 17).

I mention these circumstances to show the care with which the counts were made. They show that the sporophyte number of chromosomes in this plant of *O. lata* was undoubtedly 15, although in nucellar tissue there are occasional variations to a lower or a much higher number. The significance of such variations is not at present clear. The smaller variations may be due to the temporary fusion or the fragmentation of certain chromosomes, though it was impossible to obtain evidence for this from the size of the chromosomes themselves. Or they may be due, as E. B. Wilson has suggested, to the occasional failure of a chromosome to condense from the resting nucleus. In the single case in which about 21 chromosomes were to be seen in the equatorial plate (Fig. 21), the chromosome group appeared certainly larger than in normal nuclear plates, the cell also being larger than its neighbours. It seems probable that in this case the increase in the number of chromosomes occurred in some other way. Careful examination showed that all the chromosomes occupied approximately one plane, so that the increase in number could not have been due to precocious fission of certain chromosomes, unless, possibly, it had occurred in the prophase before the nuclear membrane disappeared and the equatorial plate was formed. We can, therefore, conclude that, whatever their significance or manner of origin, variations in the chromosome number in the nucellus do occasionally occur.

The fundamental number of chromosomes, both in the somatic cells and the germ cells of this individual, is evidently 15—one more than is found in *O. Lamarckiana*. Miss Lutz ('09) has also reported 15 chromosomes in the root tips of certain plants of *O. lata* as well as in several individuals of certain other mutants. As I pointed out (Gates, '08, p. 28), these deviations of one chromosome from the number (14) in *O. Lamarckiana*

very probably arise during meiosis, for one of the striking features of diakinesis in *O. Lamarckiana* and its mutants is that the chromosomes are but loosely paired (cf. Fig. 38), and there is, therefore, exceptional opportunity for the occurrence of irregularities in the distribution of the meiotic chromosomes. I further showed that during meiosis in the pollen mother-cells such distributional irregularities actually do occur.

From all the counts thus far made of the chromosomes in *O. lutea* it appears that the number 15 occurs at least in most individuals, though the counts are perhaps not yet numerous enough to show that 15 is the number for all individuals, and that the *O. lutea* characters are therefore constantly associated with the extra chromosome. The inconstancy of this mutant when self-pollinated (in a fertile race) or crossed may perhaps be accounted for by the presence of the extra chromosome, for it is probable that part of the megaspores produced will have 8 chromosomes, and part 7.

SOMATIC MITOSIS.

Prophase.

Though the somatic cells of *Oenothera* are relatively small, yet the nuclear structures are very clear, and in any meristematic tissue it is easy to get a complete series showing every stage of mitotic division within a small area. It is not to be expected, however, that the finest details of the chromatin in the earliest prophase stages can be depicted as minutely as in larger nuclei, so that such questions as the earliest stages of the transformation of the nuclear reticulum into the prophase chromosomes will not be critically considered here. The later prophase stages are, however, remarkably clear, and admit of no doubt in interpretation. The following description and figures refer only to the cells of the nucellus, though in other tissues the processes are essentially the same.

When in the complete resting condition (Pl. LXXXVI, Fig. 1) the nucleus contains a delicate reticulum whose meshes are equally distributed through its whole cavity. Several nucleoli of varying sizes usually are present, and a small area more or less free from threads is usually found around the nucleoli, especially the larger ones, in fixed material. The reticulum in fixed preparations consists of the usual delicate interwoven threads, having a more or less beaded appearance owing to the presence at intervals of deeper staining and sometimes thicker portions of the threads, the same structures occurring also where threads cross. This moniliform appearance of the threads becomes more conspicuous at the beginning of the preparations for prophase (Fig. 2). The threads also begin to lose their uniform character, some threads becoming visibly thicker and more conspicuous, while others retain the delicate character of the completely resting nucleus. Very soon this differentiation becomes more marked (Fig. 3), a few of the threads retaining their original delicate character, but most of them becoming

progressively thicker and more conspicuous. This is accompanied in some threads by an intensification of the moniliform character, while other portions of the threadwork become thicker and quite homogeneous in appearance (Fig. 3), having a rather loose texture and presumably formed by the fusion of several threads. This is, frequently at least, accompanied by a movement of material towards the periphery of the nucleus, for the thicker threads are usually more conspicuous in this region. They are also more strongly moniliform, thus giving the periphery of the nucleus a more densely chromatic appearance.

At a slightly later stage than that of the last figure the chromosomes begin to be sufficiently definite so that they can be counted approximately. There is some variation at this time in the manner of their first appearance as definite chromosome bodies. Sometimes they first appear as very long and narrow, deep-staining, twisted threads in the nucleus (Fig. 4). In this figure only a portion of the chromosomes are drawn, in order to show the complete outlines of certain ones. In other cases the bodies which are destined to become chromosomes are shorter and thicker, and much less twisted when they can first be observed (Figs. 3, 5, and 6).

The formation of the body of the chromosome seems, therefore, to be the result of progressive parallel fusion of numbers of strands in the original reticulum. The threadwork is thus swept up into a few thick strands which from the first show a marked tendency to occupy the periphery of the nucleus. The finer threads visible in Figs. 5 and 6 finally all disappear, presumably by absorption into the denser masses, and the chromosomes meanwhile continue to shorten and thicken progressively. In Fig. 7 this process has proceeded farther than in Figs. 5 and 6, and the chromosome number can now be definitely counted—15.

During these processes the nucleoli remain unchanged, floating freely in the nuclear cavity until the nuclear membrane disappears, when they are suddenly dissolved and vanish.

It will be seen from the preceding figures that nothing even remotely resembling prochromosomes is to be found in the resting nucleus. I have sought for these bodies, using a variety of depths of stains, and am convinced there are no such bodies present in the resting nucleus. The nucleoli and the bead-like thickenings of the threads of the nuclear reticulum are the only dense bodies to be observed. The latter are very numerous, and, as can be seen from Figs. 1-3, a number of them occur along any length of thread equal to that of the chromosome. I can only conclude that there is no evidence whatever for the persistence of denser chromosome centres or prochromosomes in the completely resting nuclei of these cells. The passage into a moniliform threadwork or reticulum is complete, no denser aggregations except the easily recognizable nucleoli, which are usually only 3 or 4 in number, remaining in any part of the nucleus.

At the stage represented by Fig. 7 the last threads of the reticulum have been withdrawn, and the nuclear cavity is now occupied only by karyolymph in which the chromosomes and nucleoli float. They are peripherally arranged and undergo progressive condensation as shown in Figs. 7-10. This is the best stage of all for counting.

In a previous paper (Gates, '11*b*, p. 931) I reached the conclusion, after a preliminary examination of somatic prophase in *O. gigas*, that a continuous spireme is produced, which segments to form the chromosomes. A study of the earlier prophase stages shows that this conception requires modification. The chromosomes are coiled spirally round and round the nuclear cavity in diakinesis in such a way as to give frequently the appearance of an end-to-end arrangement. But they do not originate in an end-to-end position, as shown by Figs. 4-7. They originate, as already described, by a progressive condensation of the threads in certain portions of the reticulum, in a manner similar in some respects to that described by Stomps ('10) in the pollen mother-cells of *Spinacia*. When first differentiated from the reticulum they are neither end to end nor side by side, but are irregularly arranged with regard to each other, a single chromosome in the earliest stage of its appearance sometimes extending across the whole diameter of the nucleus (Fig. 4). They are also at first much coiled and very irregular in shape, often forming a loop, though usually of nearly uniform thickness throughout. They thus correspond to Boveri's ('09) conception of the origin of the chromosomes from the resting reticulum as shown in the blastomeres of *Ascaris*. While we may consider that each portion of the resting reticulum represents in general an alveolated chromosome, yet anastomoses between adjacent parts, as well as perhaps movements between parts of the nucleus, must cause more or less intermixture of portions of the reticulum derived from separate chromosomes. This may perhaps account for the manner in which the chromosomes are intermingled when they first appear, but it of course assumes a more strict individuality of the resting chromosomes than can be visibly demonstrated.

I was unable to obtain any satisfactory evidence that the chromosomes are paired at all in arrangement when they are first differentiated from the reticulum. Later, in Figs. 8-11, indications of a side-by-side pairing begin to appear. In these figures each nucleus is drawn in two parts, representing the chromosomes seen in upper and lower focus. In each case the full number of 15 chromosomes is present. In Figs. 8*a* and 8*b* the chromosomes are still considerably looped and twisted. In Figs. 9 and 10 they have condensed to a shorter and thicker, more rod-like shape. Delicate (linin?) connexions are still to be seen attached to some of the chromosomes in Fig. 9.

In a former paper (Gates, '11*b*) I mentioned that the chromosomes in somatic prophase usually undergo a longitudinal split. A single

chromosome in the nucleus of Fig. 9 shows such a split precociously. Fig. 10 represents the definitive shape of the chromosomes just before this split usually appears, and in Figs. 11 *a* and 11 *b* the fission is clearly visible in nearly every chromosome. At about this time the chromosomes also take up a more uniformly distributed peripheral position, and they may frequently have the appearance of an end-to-end arrangement, though they are not actually in contact, and their original arrangement was quite different. At the stage represented by Fig. 11 the chromosomes have also usually reached entire uniformity as regards size and shape. There are usually one to several nucleoli at this time, but occasionally, as in Fig. 10, no nucleolus is present. All the Figs. 1-11 are drawn from nuclei which were uncut by the knife.

The first definite indications of lateral chromosome pairings appear at about the same time as the longitudinal split. Such a feature cannot be shown satisfactorily when the chromosomes are lying in three planes, but there are indications of such pairs in Fig. 11.

The stage of the prophase in which the chromosomes are longitudinally split appears to last for some time. But it is soon followed by a stage (Fig. 12) in which the nuclear membrane has disappeared, the spindle has made its appearance as a delicate web of fibrillae in the cytoplasm immediately surrounding the nucleus, and the split in the chromosomes is no longer visible. The chromosomes are still grouped around the periphery of a sphere, as in the last stage, but the cavity of the nucleus has decreased somewhat, so that the chromosomes are more closely grouped, but they still partly retain the shape of curved rods, a shape assumed by the diakinetid chromosomes (Fig. 11) in accommodating themselves to the periphery of the nucleus. This stage is of short duration. Fig. 13 shows a later prophase, in which the spindle is beginning to assume a bipolar shape, and the chromosomes are being arranged on the equatorial plate. In this particular cell the chromosomes vary considerably from their usual shape, and the difference is not merely due to foreshortening. In studying large numbers of somatic mitoses, such variations in the shape of the chromosomes are occasionally found. Their significance is not at present understood.

Another case in which the shape of the chromosomes differed markedly from their normal shape in nucellar tissue is shown in Fig. 14. In this metaphase side view the chromosomes are short and thick, dumb-bell-shaped bodies, and they are also peculiarly distributed on the spindle, although the cell was undisturbed in cutting. All the chromosomes are not represented in the figure, and the full number could not be exactly determined. Fig. 15 shows the position of this cell (*b*) in the ovule near the megaspore mother-cell (*a*), in which the heterotype mitosis is just completed, but no cell-wall has been formed. Such cases of variation in chromosome shape in particular

cells occur only occasionally, and no explanation of their occurrence is to be offered in the present paper.

Metaphase.

Fig. 16 represents a normal metaphase in slightly oblique view. The chromosomes are not all represented, but the longitudinal split can be clearly seen. Figs. 17–21 represent equatorial plates of the metaphase in polar view. Figs. 17 and 18 each contain 15 chromosomes, while 16 chromosomes are present in Fig. 19, 12 in Fig. 20, and 20 or 21 in Fig. 21, though for the sake of clearness only 18 are drawn in the figure. As already stated, the regular number in this plant is undoubtedly 15, and the departures shown in Figs. 19, 20, and 21 represent rare cases. Such wide fluctuations as 12 and 20 were particularly surprising to find, but accurate study of other somatic tissues will probably disclose equally striking cases of occasional variations in number in certain stages of mitosis.

Farmer and Shove ('05) described similar variations in the root tips of *Tradescantia virginica*. After a large series of counts they found the chromosome number to vary from 26 to 33 (p. 562). They also (p. 565) found the number inconstant during the heterotype mitosis, varying from 12 to 16. This may be connected with the fact that the plant commonly fails to set seed.

Wilson ('09, p. 185), in his study of the chromosomes in the Hemipteran genus *Metapodius*, also found occasional variations of one in the number of chromosomes in the spermatogonia and ovaries.

It will be seen that in Fig. 20 two of the chromosomes, and in Fig. 21 one chromosome, show a precocious split. As a possible suggestion regarding the origin of the increased number of chromosomes in Figs. 19 and 21, we may assume that the fission which regularly occurs in the prophase chromosomes in diakinesis, instead of closing up, becomes accentuated, resulting in the separation of those daughter chromosomes and their regular orientation in a single plane afterwards, on the equatorial plate of the spindle. Of course it does not follow that such chromosomes will undergo another fission on the spindle, and thus perpetuate the increased number. It might well be, and is indeed perhaps more probable, that those chromosomes which, on our hypothesis, completed their precocious fission and separation in the prophase, would merely travel to opposite poles of the spindle and thus restore the normal number. The determination of this possibility by observations of fixed material is practically an impossibility, for the moment such chromosomes pass towards the poles in anaphase, there remains no evidence that they separated immediately after the precocious split in the prophase. The probability of this explanation is, however, increased by the fact that the aberrant numbers were, all but one, found in metaphase groups.

Critical examination of these figures will show clear evidence of pairing between the chromosomes on the equatorial plate. The paired arrangement first begins to be seen in the late prophase (Fig. 11) at the time of the precocious chromosome split. The pairing naturally becomes much more evident to an observer when the chromosomes arrange themselves in one plane on the equatorial plate. Figs. 17, 18, and 20 show indisputable evidences of it. Nearly all the chromosomes in these figures are clearly arranged in pairs. It is often impossible, however, to determine any definite pairing at all. In Figs. 17 and 18 the chromosome number is odd, from which it follows of necessity that one chromosome is unpaired. In Fig. 18 any observer would scarcely hesitate to decide that all the chromosomes are in pairs except the one marked *a*, while in Fig. 17 there are several equally clear pairs, and the chromosome marked *a* is probably the odd one. The twelve chromosomes in Fig. 20 are all evidently arranged in pairs.

Anaphase and Telophase.

The anaphases of mitosis are represented by Figs. 22-5. Figs. 22 *a* and 22 *b* are polar views of the two chromosome groups of the early anaphase from the same cell, just after the daughter chromosomes have separated. Each group contains 15 chromosomes, and the great apparent variation in size and shape of the chromosomes is a result of the varying positions they occupy in their movement towards the poles. Fig. 23 is a side view of a later stage of anaphase, in which the chromosomes, in the form of rods or loops, are just reaching the poles. The poles of the spindle have lost their sharp-pointed character, and have become broad with the fibres of the spindle nearly parallel throughout.

In Fig. 24 a more compact group of the daughter chromosomes is being formed, the spindle is somewhat shortened and broadened, and the first indication of a cell-wall has appeared in the median plane of the spindle. In Fig. 25 are found the first indications of coalescence between parts of chromosomes which are in contact. The first thickening of the spindle fibres in the median region gives a shadowy appearance to this part of the spindle. In Fig. 26 the process of condensation of the chromosome group has proceeded farther, until a compact and apparently almost solid mass of chromatin is formed at each pole. The thickenings on the spindle fibres in the median plane are more definite and sharply localized than in the previous figure. The nuclear membrane has not yet begun to appear.

In the telophase stages the chromosomes frequently change their shape in an important manner. The origin of the nuclear membrane has not been studied, but it doubtless agrees with the method already known for the nuclei of the pollen mother-cells of *Oenothera* and many earlier-described forms. Fig. 27 represents an early stage in the reconstruction of the two daughter nuclei. One of these nuclei shows clearly 15 chromosomes,

while in the lower nucleus the full number could not be seen owing to the angle from which the lower nucleus was observed. It will be seen that in this figure and the following (Fig. 28) the chromosomes nearly all have a characteristic dumb-bell shape. This was first observed several years ago in other floral tissues (Gates, '07, p. 19). In Fig. 28, also, 15 chromosomes are present and can be counted very easily. These chromosomes are in the form of tiny loops, or in many cases have a median constriction which gives them the appearance of dumb-bells. It will be seen from the figures that the size of the chromosomes varies strongly, not only according to the size of the cell and nucleus in which they are found, but according to the stage of mitosis. The mass of chromatin at the poles in the stage represented by Fig. 26 is frequently greater than that in the early telophase after the nuclear membrane has been formed. These telophase stages also show that the chromosomes retain their individuality as independent bodies during the period represented by Fig. 26, during which they are closely massed together. The slightly later telophase in Fig. 29 also contains 15 chromosomes. A nucleolus has not yet appeared. The nucleus has grown in size (its larger size in this figure also depends partly upon its presence in a larger cell); the chromosomes also are larger, have mostly lost their median constriction, but are still sharply individualized. It is not certain that the median constriction always appears, although it is of frequent occurrence. The increase in size of the chromosomes appears to be due at first to a process of swelling, which is often accompanied (Fig. 30) by the chromosome becoming less deeply staining, and sending out processes which begin to anastomose with those of adjacent chromosomes. In Fig. 30 both daughter nuclei of a nucellus cell are shown in the same stage of alveolization. Figs. 31-3 show other nuclei in the same condition. The chromosomes can still be counted, at least approximately. The chromatin content of the nucleus is here, as in the prophase, frequently coiled, though quite irregularly, round the periphery of the nucleus. Before this stage has been reached the new cell-wall is formed, but these stages can of course be easily distinguished from prophases by the comparative size as well as position of the nuclei and cells.

Fig. 34 shows the two daughter nuclei in a still later stage. The nuclei have markedly increased in size, and their anastomosis and transformation into a threadwork has proceeded farther. The chromosomes can still be counted, however, the whole 15 being shown in Fig. 34 *b*; and the median constriction still remains in some of them. Nucleoli have also appeared. This telophase stage is easily distinguished from the prophase stages represented by Figs. 5-10, not only in the size of the nuclei but in the shape of the chromosomes. If Fig. 34 were mistaken for a prophase the dark bodies might then easily be considered 'prochromosomes'. In Fig. 35, though the nucleus has passed still farther into the resting condition, and

a delicate network of threads fills much of the nucleus, yet the chromosome centres are still visible and can be approximately counted. It is possible that when the mitoses follow each other very rapidly the nucleus begins a new division before it has passed much farther than this stage into the resting condition. But if the growth is not too rapid, a completely resting nucleus is formed (Fig. 36), corresponding exactly with Fig. 1 except in its smaller size. In the subsequent growth of the nucleus up to the size of Fig. 1, its chromatin content remains in the form of a uniformly distributed reticulum. It is impossible to see in these facts any support for a theory of pro-chromosomes. That each section of the resting reticulum is derived, in large part at least, from a given chromosome is probable, but there is no centre or core of the chromosome which retains its condensed form through the completely 'resting' nucleus.

OTHER OBSERVATIONS.

For comparison, I have shown in Fig. 38 a single megaspore mother-cell in *O. lutea* in metaphase of the heterotype mitosis. Not only the cell, but the spindle and chromosomes are enormously larger than in the surrounding nucellar tissue. Fifteen chromosomes can be counted, though they are rather closely grouped. As is well known, allotypic chromosomes generally differ from somatic or typical chromosomes, not only in size but in shape. The heterotypic chromosomes of Fig. 38 are not slender rods or loops, but are short and stout or almost spherical. But for unknown reasons the chromosomes in occasional somatic cells may approach the shape of the heterotypic chromosomes, as in Fig. 13, or may take other forms, such as that of Fig. 14, which resembles the ordinary shape in early telophase of somatic mitosis (Figs. 27, 28). It should be stated that the cells represented by Figs. 13 and 14 were both surrounded by dividing cells in which the shape of the chromosomes was normal, so that the variations in shape cannot be attributed to the fixation or subsequent treatment.

Another observation which is worth recording here, as showing the relative stability of the spindle as a structure in the cytoplasm of the cell, and that it is not merely a reflection of osmotic stresses or electro-magnetic lines of force, is the following. By an accident which occasionally happens to every cytologist, a preparation which had been mounted in Canada balsam some time previously was slightly crushed, so that the cell-walls of a small area of tissue were destroyed by the pressure. On the margin of this area were several cells which were burst open and their contents extruded. One such cell contained a spindle in metaphase, and this was pressed out of the cell through the broken cell-wall. The spindle itself remained perfectly intact, with the chromosomes attached and undisturbed, though the spindle had been moved out of the ruptured cell and turned through an angle of 90°. This spindle remained floating freely in the

Canada balsam, and permanently unchanged as regards the arrangement of its fibres and the attachment of the chromosomes. Even were it not already abundantly evident from other sources, one could not fail to be convinced by this simple observation that the spindle is a structure more stable than the rest of the cytoplasm, and that the chromosomes are definitely attached to the spindle fibres.

In this connexion certain observations of Lillie ('08) on the eggs of the annelid worm, *Chaetopterus*, are worth citing because they lead to exactly the same conception of the relations between spindle and cytoplasm. Eggs of *Chaetopterus* suspend their maturation processes in the metaphase of the first reduction division to await the entrance of a sperm, the spindle being attached by one pole to the periphery of the egg. If eggs in this condition be centrifuged, the spindle with its attached chromosomes is frequently torn loose and displaced by the centrifugal force to one side of the egg. But the chromosomes remain attached, though the spindle may be more or less distorted by too rapid centrifuging or by the impact of the heavy yolk globules thrown against it. It was further found that if such centrifuged eggs are afterwards fertilized and allowed to develop, the spindle migrates back to its original position in order to complete the maturation processes.

REDUCTION DIVISIONS (?) IN SOMATIC TISSUE.

The primary purpose of the preceding account of normal mitosis in nucellar tissue was to afford a basis for comparison with certain cases which appear to represent actual reduction divisions in the same tissue. Two such cases were carefully observed which agreed in all essentials, and one of them is represented in Fig. 37. The cell containing this spindle occurred near the margin of the nucellus of an apparently normal ovule. Adjacent cells were in various stages of normal mitosis. As will be seen from the figure, this spindle was exceptionally large. Comparison with Fig. 38 shows it to be nearly as long, though not so broad, as the heterotypic spindle, though the containing cell was not conspicuously larger than surrounding cells of the nucellus. The spindle is conspicuously larger than in normal nucellus cells such as are represented in Figs. 14, 16, 23-6.

As regards the chromosomes, which are not all represented in Fig. 37, they could not all be determined with certainty, owing to the crowded positions occupied by some. But as far as could be determined, there were certainly two very clear pairs or bivalents in which the individual chromosomes could be seen, one pair in which the two chromosomes appeared to be closely appressed or fused, two pairs less clear owing, apparently, to partial fusion, one other probable pair, one certainly single chromosome, and probably another single chromosome. This makes 14 chromosomes. The presence of the fifteenth could not be determined.

The two very clear pairs are shown in Fig. 37, the members of each pair having the shape of normal somatic chromosomes (i. e. long, somewhat curved rods), but lying clearly in longitudinal pairs and oriented quite differently from their normal position on the equatorial plate. These are separately represented by *a* and *b* in Fig. 37 *a*. The partly fused pair are represented by *c* in Fig. 37 *a*, while *d* represents a chromosome which is clearly single.

Critical study of this and one other similar spindle demonstrates that a portion, at least, of the chromosomes are closely paired with each other. Such cases are evidently rare, and it will require much further study to demonstrate the actual fate of the chromosomes in such mitoses. Even the loosest pairs are much more closely associated than the pairs of an ordinary somatic metaphase (cf. Fig. 37 with Figs. 18, 19, 20), while in several pairs the chromosomes appear to be partly fused. Their peculiar orientation on the spindle also reminds one of the heterotypic mitosis (Fig. 38) in which the chromosomes are always irregularly scattered in the median region of the spindle and not in regular alinement. On the whole, it seems probable that this pairing in the equatorial region of the spindle (Fig. 37) will be followed by the separation of the pairs, and hence by a reduction division. It is impossible not to be struck by the numerous differences between this figure and a normal somatic metaphase. While the inference that this intimate pairing is to be followed by a reduction or segregation division is as yet unproven by actual observation, yet it seems more probable than any other explanation I can offer.

DISCUSSION.

The present paper is meant to be a record of facts rather than a discussion of literature, but a few points may be briefly referred to.

A paired condition of the chromosomes was first found in the somatic tissues of plants by Strasburger in 1905. References to subsequent papers, showing the undoubted occurrence of regular somatic chromosome pairings, were made in my paper on the mode of chromosome reduction (Gates, '11 *a*). It is undoubtedly true that this condition in the metaphase of each somatic division is widespread in the sporophytic tissues of plants. It is obvious from Figs. 4–10 that in the early prophases of sporophytic mitoses in *Oenothera* the chromosomes are at least less evidently paired than in the metaphase. Whether they remain associated throughout the whole intermitotic period, or whether they go through a regular series of evolutions leading to fresh pairing in each mitotic cycle, must therefore remain undecided, though it is certain that chromosomes which are paired on the spindle in metaphase are more likely to be closely associated with each other during the passage into the resting condition than those which occupy

widely separated positions in the equatorial plate. It is, therefore, uncertain whether the pairing of chromosomes in the metaphase is but a part of a constant association between homologous maternal and paternal chromosomes of the sporophyte, or whether in each mitotic cycle there is a re-entering into a paired arrangement of chromosomes which in the resting nucleus are less closely or but little associated with each other. The fact that in heteromorphic chromosome groups, as in *Funkia*, *Galtonia*, *Yucca*, &c., the pairings are always between chromosomes of similar morphology is a strong argument for the belief that the paired arrangement represents an actual association of homologous maternal and paternal elements. However, until it is definitely shown that the chromosomes in gametophytic mitoses, such as in pollen grains or in Fern prothallia, have no paired arrangement, too much stress cannot be laid upon the general significance of the pairing in sporophytic tissue. Meantime, the evidence from the chromosome behaviour in animals, both in spermatogonial divisions and in synapsis, very strongly supports the hypothesis of homologous pairing. If the gametophytic chromosomes of plants should prove to be also paired in metaphase (a view for which I am not aware that any evidence exists at the present time), then the explanation would necessarily be a mechanical one, and the same explanation would then apply to sporophytic pairings. It seems improbable, however, that a purely mechanical explanation of these pairings will ever be necessary.

Another point worth emphasizing is that in the late prophase of somatic mitoses a split occurs, just as frequently occurs in the heterotype prophase, and may afterwards close up, again as in the heterotype prophase. This serves to emphasize a fact which I referred to in a previous paper (Gates, '11 a), namely, that the only essential difference between the behaviour of the somatic and the heterotypic chromosomes is that the latter merely segregate in metaphase, while the former undergo a split. In other words, this removes one more of the differences which were formerly supposed to exist between the somatic and the heterotype mitoses.

Again, though the chromosomes usually show a median constriction in the telophase, yet this is only of transient duration, and apparently bears no relation to the appearance of a split in the succeeding prophase. The chromosomes of the telophase pass into the resting condition without any indication of a split in their substance, such as has been described for certain forms. The earliest appearance of any split in the chromosome structure is in the rather late prophase of mitosis.

Variations in the shape of somatic chromosomes have been comparatively little studied. Němec ('10, p. 263) has shown that the chromosomes in root tips of *Allium montanum*, *Vicia faba*, and *Galtonia candicans* become much shorter and thicker after treatment with benzine vapour, and Kemp ('10) in a careful paper has shown that chloral hydrate produces

a marked change in the shape of the chromosomes of the root tip, often producing chromosome shapes closely resembling heterotype tetrads.

The results, particularly of Němec, in producing tetraploid and octoploid nuclei by subjecting growing root tips to chloral hydrate, are too well known to require discussion here. The question whether such tetraploid cells afterwards undergo reduction divisions which restore the normal number of chromosomes, or whether the disappearance of tetraploid cells from the root tips (which gradually takes place after subsequent growth) is wholly due to other causes, such as division into several smaller cells, fragmentation, and passing into permanent tissue, has been much disputed. Kemp found nothing in her studies which could be interpreted as true reduction figures, and she evidently, like Strasburger, doubts the existence of such. Němec ('10, pp. 63-5) describes two types of reduction figures in chloralized roots: (1) indirect reduction figures which differ from the typical (*a*) in that the chromosomes are longitudinally split at the poles of the spindle, and (*b*) in their occurrence in abnormally large (tetraploid) cells; and (2) direct reduction figures, which also occur in large (tetraploid) cells, and in which a segregation of the chromosomes takes place, half going to each pole of the spindle.

If my interpretation of Fig. 37 of this paper is correct, the pairing of chromosomes in metaphase will be followed by a direct reduction division. Němec ('10, p. 245) describes somewhat similar pairings with partial fusion of the chromosomes as occurring frequently in the root tips of *Ricinus zanzibariensis* (cf. his Figs. 92, Pl. III, and 97, Pl. IV). The possibility therefore remains that an actual reduction will not take place, though the large size of the cell and spindle suggests that something exceptional is occurring in the cases I have described.

SUMMARY.

The results recorded in this paper may be briefly summarized as follows:

The individual of *O. lata* from which the figures for this account of the somatic mitoses were drawn contained 15 chromosomes in its megaspore mother-cells and in the cells of the nucellus. In the nucellus, however, there were occasional cells containing a different number. Thus over 50 cells were shown to have 15 chromosomes, one contained only 12, two contained 16, and one 20 to 21. These aberrant numbers were all, with one exception, observed in the metaphase equatorial plate, and it is possible that the higher numbers are to be accounted for by separation of certain of the daughter chromosomes immediately after their formation by the prophase split. If this is the real explanation of such cases, it does not follow that the increased chromosome number will be perpetuated, for the chromo-

somes which separated precociously may merely segregate in metaphase instead of dividing again, and thus restore the normal number.

From the various counts now made it is evident that more individuals of the mutant *O. lata* contain 15 chromosomes than 14, and it may be that the *O. lata* characters are constantly associated with the presence of an extra chromosome.

The account of somatic mitosis is taken entirely from the nucellus, though the phenomena are closely similar in other tissues. The resting nucleus contains a uniform reticulum of somewhat moniliform threads. There is no evidence whatever of prochromosomes or denser chromatic centres in the completely resting nucleus.

The chromosomes first appear in early prophase by a thickening in certain threads of the reticulum. They are at first long and narrow, much twisted, and are not evidently paired in any way, but are scattered irregularly through the nucleus, being connected by a meshwork of finer threads.

The chromosomes then shorten and thicken, the finer threads gradually disappear, and the chromosome bodies can easily be counted.

A conspicuous longitudinal split then, usually at least, appears in the chromosomes in the late prophase shortly before the nuclear membrane disappears. The first evidence of lateral pairing of the chromosomes also appears about this time.

In the latest prophase stage, after the nuclear membrane has disappeared and the spindle has begun to form, the split in the chromosomes may close up entirely.

In metaphase the chromosomes are often in evident pairs on the equatorial plate, it being possible in some cases to determine with a high degree of probability the particular chromosome which is odd and unpaired.

Certain cases are described in which the chromosomes in metaphase differed from the normal in shape, being shorter and thicker and more like the heterotype chromosomes, or dumb-bell shaped like the somatic chromosomes in one stage of the telophase.

In the very early telophase, after the nuclear membrane is formed, the chromosomes, at least in many cases, assume a characteristic dumb-bell shape owing to a median constriction. The chromosomes continue to be countable until a later stage, but finally pass into a completely resting condition in which no remnant of a central denser core of the chromosome remains.

It was discovered accidentally that if the wall of a cell in a preparation be ruptured and the contents squeezed out, the spindle may be isolated and retain its shape and the chromosomes remain attached, showing that it has greater stability of structure than would be produced by osmotic or electromagnetic forces.

Finally, two cases were observed in which the spindles were exceptionally large and the chromosomes were many of them closely joined in pairs to form bivalents, though retaining the shape of the somatic chromosomes. These bivalents were peculiarly oriented on the spindle, and from all analogy it seems very probable that this pairing would be followed by an actual reduction division in somatic tissue.

In conclusion, I am greatly indebted to Professor J. Bretland Farmer, F.R.S., for suggestions and criticisms in connexion with this work.

Note added Aug. 29.—In a paper which has just appeared ('Triploid Mutants in *Oenothera*,' *Biolog. Centralbl.*, 1912) Miss Lutz affirms the incorrectness of certain of her earlier counts of 14 chromosomes for *O. lata*, and finds 15 chromosomes in the root tips of all the *lata* plants she has examined. In a re-examination of the preparations of *O. lata* (now somewhat deteriorated) described in my first paper on the subject ('Pollen Development in Hybrids of *O. lata* and *O. Lamarckiana*, and its Relation to Mutation,' *Bot. Gaz.*, Feb., 1907) I was unable to determine with certainty whether this *lata* plant contained 14 or 15 chromosomes. But from all the evidence now at hand, it is safe to conclude that *O. lata* nearly always contains 15 chromosomes, though it is quite possible there may be exceptions in the case of certain forms of *lata* which produce plenty of pollen. It is probable that the almost complete sterility of the pollen in typical *lata* is concerned with the presence of the extra, unpaired chromosome.

EXPLANATION OF PLATE LXXXVI.

Illustrating Dr. Gates's paper on Somatic Mitoses in *Oenothera*.

The figures were all drawn with an Abbé camera lucida, using a 2 mm. Zeiss apochromat. objective, ap. 1.40, and an 18-compensating ocular, and reproduced natural size, giving a magnification *circ.* 3,800 diameters; except Fig. 15, which is drawn with a low power. The figures were all taken from the nucellus of *Oenothera lutea*, except Fig. 38, which represents a megaspore mother-cell.

Fig. 1. Completely resting nucleus, containing a uniform moniliform reticulum.

Fig. 2. Cell showing the earliest prophase stage of the nucleus. Certain threads of the reticulum are becoming thicker and more markedly moniliform.

Fig. 3. Slightly later than last figure. The distinction between the thicker and more delicate threads is becoming more apparent.

Fig. 4. Prophase stage, showing the first appearance of definite chromosomes. They are long and irregularly coiled. For the sake of clearness only part of them are represented in this figure, the fine threads being omitted.

Figs. 5 and 6. Slightly later stage in which nearly all the chromosomes can be counted. The chromosomes are shorter, thicker, and less coiled than in the previous figure, and portions of the fine threads of the original reticulum still remain.

Fig. 7. Later prophase, in which the remnants of the reticulum have disappeared and only the chromosomes (fifteen) and the nucleoli are left floating in the cell-sap.

Figs. 8-11 each represent two views of a single uncut nucleus, showing all the chromosomes (fifteen) in two planes of focus.

Figs. 8 *a*, 8 *b*. A single (uncut) nucleus in two foci, showing all the chromosomes (fifteen). The latter are still thin rods, somewhat coiled.

Figs. 9 *a*, 9 *b*. Showing all the chromosomes (fifteen) of another nucleus slightly later than the last. The chromosomes are shorter and thicker, one showing a precocious split. Fragments of 'linin' remain attached to some of them.

Figs. 10 *a*, 10 *b*. Same stage as last. Chromosomes peripherally arranged, full number (fifteen) present, no nucleolus.

Figs. 11 *a*, 11 *b*. Later stage of diakinesis than last, in which the chromosomes all show a clear longitudinal split.

Fig. 12. Last stage of prophase. The longitudinal split in the chromosomes has closed up, the nuclear membrane has disappeared and the first indications of the spindle appear as a web of delicate fibrillae surrounding the nucleus. The full number of fifteen chromosomes is present.

Fig. 13. Slightly before metaphase. The chromosomes are just being drawn into the equatorial plate. In this cell the chromosomes are somewhat abnormal in shape. Only twelve are represented in the figure.

Fig. 14. Another abnormal nucleus in metaphase, side view. The chromosomes are arranged in two series on the spindle, and are in the shape of dumb-bells. Nine are shown in the figure.

Fig. 15. An ovule (integuments not shown); *a* represents the megaspore mother-cell which has just undergone the heterotypic division; *b* is the cell represented in Fig. 14.

Fig. 16. Normal metaphase, side view, slightly oblique. The chromosomes have split for the anaphase. The spindle is sharp-pointed.

Fig. 17. Metaphase, polar view. The chromosomes (fifteen) probably all in pairs except *a*, which is unpaired.

Fig. 18. Same as last. Chromosomes (fifteen) clearly paired, except *a*, which is the odd chromosome.

Fig. 19. Equatorial plate, showing (exceptionally) sixteen chromosomes with some indications of pairing.

Fig. 20. Equatorial plate, showing (exceptionally) only twelve chromosomes. They clearly form six pairs. The two outermost show the beginnings of a precocious split.

Fig. 21. Equatorial plate showing (exceptionally) eighteen chromosomes. The whole number present was twenty or twenty-one. One chromosome shows the beginning of a precocious split. See text.

Fig. 22. Early anaphase, showing the two daughter groups of chromosomes (fifteen each) in equatorial view, from different foci of the same cell.

Fig. 23. Later anaphase, showing the chromosome loops being drawn to the poles. Spindle poles now broad, and spindle fibres nearly parallel.

Fig. 24. Later stage than last. The chromosomes have reached the poles and the thickenings of the fibres in the median region of the spindle have already appeared.

Fig. 25. Same stage as last. First indications of cell-wall.

Fig. 26. Slightly later stage. The chromosomes have formed a compact group at each pole.

Fig. 27. Telophase. The membrane has been formed around the daughter nuclei, and the chromosomes—now very small—have mostly taken on the shape of dumb-bells owing to a median constriction. The full fifteen chromosomes can be counted in the upper nucleus.

Fig. 28. Same stage as last, showing the fifteen chromosomes, nearly all having a clear median constriction.

Fig. 29. Later telophase than last. The nuclear cavity has increased in size, the chromosomes are larger and have mostly lost their constriction. Fifteen chromosomes present.

Fig. 30. Later telophase, showing both daughter nuclei. The drawing-out and anastomosis of the chromosomes has begun.

Figs. 31-33. Same stage as last. Not all the chromosomes represented.

Figs. 34 *a*, 34 *b*. Two telophase nuclei from one cell. The centres of the chromosomes still remain condensed. In 34 *b* the full fifteen chromosomes are shown, several of them still showing the median constriction.

Fig. 35. Later stage than Fig. 34. The reticulum is becoming better developed, but portions of the chromosomes still remain in the condensed form.

Fig. 36. The completely resting condition, like Fig. 1 but smaller. A uniform, slightly moniliform reticulum fills the nuclear cavity.

Fig. 37. An abnormal cell from the nucellus. The spindle is much larger than in an ordinary nucellar cell, being nearly as long—though not so broad—as the heterotype spindle (Fig. 38). The chromosomes are mostly in close pairs, lying side by side but irregularly oriented on the spindle. The members of these pairs are much more closely associated than in normal mitoses (cf. Figs. 17-20), and it seems probable that this will be followed by a reduction of the chromosome pairs. In Fig. 37 *a* several of these chromosomes are drawn separately; *a* and *b* are two chromosome pairs, *c* a partly fused pair, *d* a single chromosome, and the other three represent partly fused pairs.

Fig. 38. Megaspore mother-cell drawn on same scale, showing heterotype mitosis with fifteen chromosomes present. The chromosomes differ sharply in size and shape from those of the somatic cells.

The Structure of *Mesoxylon Lomaxii* and *M. poroxyloides*.

BY

D. H. SCOTT, F.R.S.

With Plates LXXXVII-XC.

THE genus *Mesoxylon* was established by Mr. Maslen and myself in 1910 for certain Palaeozoic stems, intermediate in structure between the genera *Poroxylon* and *Cordaites*. *Mesoxylon Sutcliffii*, one of the five species briefly characterized in our original Note, was very fully described by Mr. Maslen last year (Maslen, '11). His admirable account of this typical form, of which very ample material was available, enables me to deal somewhat more briefly with the two species now to be described, which are not so richly represented. The question of the specific value of the anatomical characters by which we distinguish the fragmentary remains of petrified Palaeozoic plants is a difficult one; we have thought it advisable to give distinct names to well-characterized forms, even though we cannot in all cases be certain that the distinction may not be bridged, as more numerous specimens come under observation.

It will be well to begin by recalling the characters assigned to the genus *Mesoxylon*:

Pith relatively large, discoid. Wood dense, with narrow, usually uniseriate medullary rays, and relatively narrow tracheides. Leaf-traces double where they leave the pith, the two strands uniting at a lower level, but undergoing further subdivision in the pericycle and cortex, before entering the leaf.

Centripetal xylem present in the stem, where it forms part of the leaf-traces at the margin of the pith and throughout their course outwards into the leaves.

Outer cortex strengthened by a system of sclerenchymatous bands of the *Dictyoxylon* or *Sparganium* type. Wood of the kind usual in Cordaitales, the bulk of the secondary tracheides having multiseriate bordered pits on the radial walls. Tracheides of the leaf-traces, spiral or scalariform.¹

¹ The generic character is very slightly abridged from that given in our Note (Scott and Maslen, '10, p. 237).

Mr. Maslen has pointed out that '*M. Sutcliffii* (as well as the other species of *Mesoxylon*) exhibits structural characters intermediate between those of *Cordaite* and *Poroxyton*, but on the whole stands much nearer to the former genus' (Maslen, '11, p. 409).

I think this opinion is justified; the chief character in which *Poroxyton* is approached is the very definite one of the presence of centripetal wood in the stem. It was on this ground that I at first put *M. Sutcliffii* provisionally in the genus *Poroxyton* (Scott, '09, p. 511). As regards most, if not all, of the species referred to *Mesoxylon*, the characters common to *Cordaite*s are more numerous, if less important. The relation of our genus to certain other genera, recently established, will be briefly considered at the close of the paper.

MESOXYLON LOMAXII, Scott and Maslen.

The specimens of *M. Lomaxii* are larger than most of the others. The three fragments known at present, which may possibly have come originally from a single stem, measure respectively:

5.5 × 2.3 cm. (Slide 2325)

6.0 × 3.5 cm. (Slide 2326)

and 5.0 × 4.0 cm. (Slides 2327 and 2328).

These rough measurements are probably rather under the mark, owing to the difficulty of allowing accurately for the partial destruction of the cortex.¹

All the specimens are from roof-nodules at Shore, and the preservation is of the usual roof-nodule type: much tissue has been lost altogether, but the remaining portions are often well preserved, though not remarkably so in this case. Fortunately the inner margin of the wood is one of the best preserved regions (Pl. LXXXVII, Figs. 1 and 2).

The pith is large: in the least distorted of the specimens (see Fig. 1) it measures 22 × 17 mm. in diameter. There is a continuous and persistent outer zone of pith, while the central region is in the usual discoid condition (Pl. LXXXIX, Fig. 17).

The other striking features of the species are the dense zone of wood, with numerous prominences, corresponding no doubt to the position of the leaf-traces, on the side towards the pith (Figs. 1 and 2); the evident groups of centripetal xylem in the primary strands of the wood (Pl. LXXXVII,

¹ The longitudinal sections, from the same specimen as the transverse section 2326, are numbered 2375-2383. There are five more sections in the Collection at University College, London, lent me by Prof. F. W. Oliver, F.R.S. Q 6 m is a transverse section cut immediately above my 2328, while Q 6 n, also transverse, belongs to the same fragment as 2326, and was probably cut below that section. Q 6 o-Q 6 q are three longitudinal sections cut from the same specimen as my transverse section 2325. All the University College sections are good, and of quite equal importance to those in my own collection.

Fig. 5; Pl. LXXXIX, Fig. 18): the phloem-zone with its large and conspicuous secretory sacs (Figs. 6 and 7), the broad cortex, mostly of secondary origin, and the rather narrow external, Dictyoxylon zone (Figs. 1, 2, and 6), which, however, is seldom preserved.

The Pith.

The persistent zone of the pith shows little differentiation; the outer portion has somewhat thicker walls than the inner layers, which consist of a delicate tissue; the cells of both portions are short.

The diaphragms constituting the central, discoid part of the pith are made up of thin-walled cells, similar to those of the inner portion of the persistent zone; they have the form usual in Cordaiteae; the diaphragms are thickest at the outer end, where they abut on the persistent zone, and thin out towards the centre of the pith, where they are usually broken and distorted (see the radial section, Pl. LXXXIX, Fig. 17).

The Leaf-traces.

As regards the course of the leaf-trace strands our data are incomplete, for no serial sections are available; the characteristic points, however, are clear. Traced inwards through the secondary wood the twin bundles of a leaf-trace converge (Pl. LXXXVII, Fig. 4), and fuse as soon as they reach the margin of the pith (Fig. 5). This rapid convergence and fusion of the twin strands may be taken, provisionally, as a specific character. As a result, the numerous circum-medullary primary strands are, in the case of *M. Lomaxii*, single bundles (Pl. LXXXIX, Fig. 18), with perhaps some slight indication of recent fusion. The tangential section shown in Fig. 3 passes through a pair of bundles (at *l.t.*), where they have not yet fused. If we now follow the trace outwards, we find that its course approaches the horizontal in passing through the wood, as is necessarily the case, where much secondary growth has taken place. In the phloem the two bundles reappear in approximately transverse section (Fig. 6). In passing through the cortex further subdivision goes on. Thus the four bundles of a single trace are seen in Fig. 7. Later stages of subdivision are not clearly shown, but it is evident that the bundles of the trace increased in number, for at least five are seen in a tangential section through the secondary cortex (slide 2376). Probably the ultimate number was eight, as in the other species.

The outgoing leaf-traces observed are not numerous. Though the loss of tissue, both in the wood and cortex, has no doubt often led to their being missed, it is probable that the leaves to which they ran were really more scattered than in the three species, *M. Sutcliffii*, *M. poroxyloides*, and *M. multirame*. At the most not more than four traces have been observed outside the wood, nor more than three in the wood itself, in

any one transverse section. It must, however, be remembered that the great development of periderm in the cortex must give the bundles a more horizontal course in this region, so that the conditions, even apart from the state of preservation, are not so favourable for observing them in transverse section as in specimens where there is less secondary growth.

On the other hand, the single primary xylem-strands, formed by the fused pairs, are present in large numbers around the pith; in each transverse section there are about twenty which show evident centripetal xylem, while other prominences, which are without this tissue, no doubt represent the lower ends of similar leaf-trace strands or the products of their anastomosis. Thus the whole inner margin of the wood is strongly undulated (Fig. 1), the intermediate secondary xylem only reaching the pith in the bays between the prominences. From the great number of primary xylem-strands it is evident that the phyllotaxis was complex.

In the structure of the leaf-traces, the first point to be noticed is the centripetal xylem. This is well developed, both in the bundles passing through the cortex (Pl. LXXXVII, Figs. 6 and 7), and in those which are approaching or have reached the edge of the pith (Pl. LXXXVII, Fig. 5; Pl. LXXXIX, Fig. 18). It forms, as seen in transverse section, an arc or crescent of considerable thickness; its irregularly grouped elements are sharply distinguished from the radial rows of the centrifugal wood (Fig. 18). The tracheides of the centripetal xylem are spiral or finely scalariform. It appears that the tissue persisted with little diminution for some distance downwards after the bundle reached the pith, for many of the circum-medullary strands have a well-developed centripetal portion. In others, however, it is extremely reduced, while it is altogether absent from many of the prominent xylem-strands. There can thus be no doubt that the centripetal wood eventually died out in a downward direction, as in other species of *Mesoxylon* and in *Poroxylon*, *Calamopitys Beinertiana*, &c.

The position of the protoxylem appears to have been, as is usually the case in this group, in contact with the centripetal wood (Pl. LXXXIX, Fig. 18, *px*). Here, as in other species, it is accompanied by some thin-walled parenchyma, which partially separates the centripetal from the centrifugal xylem.

A characteristic feature of the circum-medullary strands is the presence, in many cases, of a definite bundle-sheath separating the xylem from the pith. The sheath is limited to those strands which are seen in the upper part of their course; it dies out lower down. In a transverse section the sheath is found in about two-thirds of the strands which still have definite centripetal xylem. The simplest form of sheath occurs low down in the course of the strand. Here it consists of an arc, not more than two or three cells in thickness, of more or less radially elongated cells, with walls a little thicker than those of the adjacent pith-cells (Pl. LXXXIX, Fig. 18, *sl*).

The sheath encloses the whole prominent part, both centripetal and centrifugal, of the xylem-strand. Following the strand upwards in its course to the point where it is about to leave the pith, the sheath is here a much more important structure, consisting of numerous layers of radially arranged thick-walled cells, which have evidently increased in number by secondary divisions (Pl. LXXXVII, Fig. 5, *sh*). The double bundle shown in the photograph is in the act of fusion, or rather of separation, for we are tracing it in the upward direction. Still higher up, where the twin bundles are beginning to pass out into the wood, the sheath forms a double arc, corresponding to the two strands (Pl. LXXXVII, Fig. 4). In this region the cells of the sheath have reticulate, tracheoidal markings, which may be seen in Fig. 4 on using a lens. As we follow the trace on its outward course, we find that the sheath becomes merged in the secondary wood which here closes in behind the outgoing strands; in the transitional region the short cells of the sheath are interspersed with the long, sinuous tracheides.

The Wood.

The structure of the wood, apart from the centripetal xylem of the leaf-traces, is of the usual Cordaitan type. In the parts corresponding to the primary strands a considerable amount of the inner centrifugal wood consists of scalariform tracheides, or in some cases elements with crossed spirals; in the case of an entering bundle, fifteen layers of such elements were counted, and in one of the blunter prominences, representing a bundle lower down in its course, there were ten such layers.

In places, however, where the strictly secondary wood abuts on the pith, as in the depressions between the bundles, the pitted tracheides may extend right up to the inner margin. The scalariform elements are, as a rule, sculptured on all sides, while in the pitted tracheides the pits are limited to the radial walls. Transitional elements sometimes occur.

The tracheides of the secondary wood are rather small, ranging from 30 to 60 μ , the usual dimensions being 40 to 50 μ . The medullary rays are very narrow, 12 to 18 μ in width. As the tangential sections show, they may reach a considerable height, up to about twenty-five cells. They range from this down to a height of two cells or even one. Only in quite rare cases do we find a radial division, making the ray locally biseriate; otherwise the rays are uniseriate throughout (Pl. LXXXIX, Fig. 19). In certain places the pits are well preserved. They form two or three series on the radial wall of the tracheide, and have the somewhat angular outline usual in Cordaitales. In a few cases the border of the pit is sufficiently perfect to show the inclined, elliptical slit, but usually the pore appears round (Pl. LXXXIX, Fig. 21). On the walls of medullary ray-cells in contact with tracheides the pits are arranged in two or three horizontal rows on the

ray-cell; they are less regular in form than elsewhere, and seem to be unbordered, though the preservation leaves this uncertain.

In the outer secondary wood the position of a double leaf-trace is marked, in tangential section, by the presence of two knots of irregularly interwoven tracheides, enclosing in their meshes the tracheides of the outgoing strand.

The Phloem and Pericycle.

The phloem-zone is traversed by long, sac-like elements, possibly of a secretory nature. In one of the specimens especially (slide 2325), they are very conspicuous; they are from 100 to 200 μ in diameter; their thick walls appear black and their contents brown (Pl. LXXXVII, Figs. 1 and 6). These elements extend into the pericycle, which may be distinguished from the phloem in longitudinal section by the fact that only short cells are present between the sacs.

In the phloem proper, which is imperfectly preserved, there are long tubes, about 40 μ in diameter, which in tangential section are seen to form a kind of mesh-work, enclosing the phloem-rays (LXXXIX, Fig. 20). Transverse or oblique walls appear to occur at long intervals. These tubular elements may probably be the sieve-tubes.

The Cortex.

The inner cortex is remarkable for the great development of secondary tissue, resembling periderm (Pl. LXXXVII, Figs. 2 and 6). The whole of the thin-walled zone has its cells radially arranged; the radial cell-rows, however, are not continuous throughout; the tangential divisions appear to have gone on in more than one layer, and not to have been limited to a definite phellogen. The zone in question, which reaches a thickness of at least 5 mm., may perhaps be more properly called secondary cortex rather than periderm.

In the hypodermal zone the radial sclerotic bands are usually narrow, and vary much in depth. There is no extensive tangential section of this zone, but some cases of anastomosis between the bands have been observed. Hence we may speak of the mechanical hypoderm as of the Dictyoxylon type. Towards the exterior the sclerotic bands unite in a continuous zone of moderately thick-walled tissue. The outer tissues are very imperfectly preserved, but the contour, as far as shown, appears to prove that the leaf-bases were scattered, and not crowded as in *M. Sutcliffii*.

Diagnosis.

An amended diagnosis of the species may now be given:
Mesoxylon Lomaxii, Scott and Maslen, 1910.
Leaf-bases scattered.

Pith large and discoid, with a persistent outer zone.

Twin-bundles of the leaf-trace converging rapidly in the wood, and fusing immediately on reaching the edge of the pith.

Centripetal xylem well developed, persisting for a long distance below the fusion of the twin-bundles.

Xylem-strands at the margin of the pith with a distinct and wide sheath in the upper part of their course.

Spiral and scalariform tracheides constituting the whole of the leaf-trace xylem and the inner part of the corresponding secondary wood, but almost absent from the intermediate secondary wood.

Bordered pits in two or three rows.

Medullary rays (with rare exceptions) uniseriate, 1-25 cells in height.

Secondary inner cortex or periderm of great thickness.¹

Dictyoxylon zone relatively narrow.

Roof-nodules; Shore, Littleborough. Lower Coal Measures.

This species is named after Mr. James Lomax, to whom its discovery and that of the other species of *Mesoxylon* is due.

MESOXYLON POROXYLOIDES, Scott and Maslen.

This species, like the last, was first named and shortly described in 1910, in the joint Note by Mr. Maslen and myself. It had, however, already been referred to, together with *M. multirame*, in the second edition of my 'Studies in Fossil Botany' (Scott, '09, p. 526), where I mentioned the occurrence of stems from Shore, in which the centripetal wood of a *Poroxyylon* co-existed with the discoid pith and other characters of a *Cordaites*. *Mesoxylon poroxyloides* is a fossil from the ordinary coal-balls or seam-nodules of Shore; in this respect it is like *M. multirame*, and differs from *M. Sutcliffii*, *M. Lomaxii*, and *M. platypodium*, which are all roof-nodule specimens. The preservation of *M. poroxyloides* is consequently more complete than that of the species last mentioned, for it is free from the patchiness which is the peculiar defect of specimens from the roof-nodules. The detailed investigation has been carried out on one specimen, represented in my collection by seven sections (slides 2352-2358), of which four are transverse and three longitudinal. This may be called the type specimen.²

¹ This character must, of course, vary with the age of the specimen.

² There are six more sections of this specimen in the University College collection, for the loan of which I am indebted to my friend Prof. F. W. Oliver, F.R.S. Two of the sections, Q 6 a and Q 6 b, are transverse, and four, Q 6 c-Q 6 f, longitudinal. I have been able to determine the order of four of the transverse sections, which, from below upwards, run thus:

S. Coll.	2352
"	2353
Univ. Coll. Coll.	Q 6 a
"	Q 6 b

The other two transverse sections are not in series with the above, but 2355 comes below 2354.

Another stem, incompletely shown in slide 2397, may probably belong to this species, and is interesting from its close association with numerous leaves of the so-called 'Cordaitean' type (see p. 1022). A third stem (slide 2609) closely resembles the type, though not so well preserved. These are rather small stems from 2 to 3 cm. in diameter. A much larger specimen (slide 2608), of which the *radius*, measured only to the outer edge of the wood, exceeds 4 cm., has some points in common with *M. poroxyloides*, but in such large and incompletely preserved stems specific identification becomes very uncertain.

In the type specimen (Pl. LXXXVIII, Fig. 8), the pith measures about 12×4 mm. (8 mm. mean diameter), that of the whole stem being about 2.5 cm. In slide 2397 (the second specimen) the stem is too incomplete to measure accurately: the diameter may have been about 2 cm.; the stem is young and the pith therefore proportionately larger than in the type. The stem in slide 2609 approaches 3 cm. in diameter, that of the pith being little more than 6 mm. It thus appears that a comparatively small pith may be regarded as characteristic.

The pith, as in other species, has a persistent outer zone and a discoid middle (Pl. LXXXVIII, Fig. 13; Pl. XC, Fig. 22). In the convergence and early fusion of the twin-bundles of the leaf-trace as they reach the pith (Pl. LXXXVIII, Figs. 9 and 10) *M. poroxyloides* comes nearest to *M. Lomaxii*, from which it differs in the absence of a definite sheath round the primary xylem.

The centripetal xylem is well developed and is retained for some distance below the point of fusion of the strands (Pl. XC, Fig. 23). The secondary wood has the small tracheides and narrow medullary rays usual in the genus.

The phloem, chiefly secondary, forms a broad zone, well preserved in the type-specimen. The pericycle contains numerous large elements with dark contents, which may have been secretory sacs.

The Dictyoxylon zone of the cortex is wider than in other species. The leaf-traces subdivide in passing through the cortex, and on entering the leaf-base the full number of eight bundles is attained (Pl. XC, Fig. 24).

No axillary shoots or steles have yet been observed.

The Pith.

The pith is decidedly well preserved in places; the most favourable section for showing it as a whole is slide Q 6 c in the University College collection. The section illustrated in Pl. LXXXVIII, Fig. 13, and Pl. XC, Fig. 22, is not quite radial and the pith is somewhat broken and displaced, but the discoid structure is sufficiently evident. It is of rather a peculiar kind and may be described as compound, for the thick horizontal plates stretching inwards from the persistent zone subdivide towards the

middle into a number of thin discs (Pl. XC, Fig. 22; Pl. LXXXVIII, Fig. 13). Thus the rupture of the pith appears to have taken place in two stages. It is possible that this may have only happened locally.

The external, persistent zone of pith is about 0.8 mm. thick, and consists for the most part of thin-walled, fairly isodiametric cells. In the inner layers, the cells appear empty or have light-brown contents; those next the central cavity are sometimes flattened (Pl. LXXXVIII, Fig. 10). In the outer half of the zone the cells are a trifle smaller, and many of them have almost black contents. In contact with the wood a few narrow, vertically elongated, delicate-looking cells may be distinguished (Pl. LXXXVIII, Figs. 10, 11, and 14).

The diaphragms are composed of larger cells than those of the persistent zone; they appear round or somewhat hexagonal in transverse section, and when seen in longitudinal section are found to be much flattened (Fig. 13). The tissue of the thin central diaphragms has collapsed; connecting shreds of membrane show that the diaphragms have been torn apart by the growth of the stem (Fig. 13). The excellent preservation of the persistent zone is a clear proof that the partial destruction of the central tissue was a natural process occurring during life. It will be seen that the structure of the pith in *M. poroxyloides* agrees very closely with that of *M. Sutcliffei*, described by Mr. Maslen (Maslen, '11, p. 391).

The Leaf-traces.

In the zone of wood, as shown in a complete section, Pl. LXXXVIII, Fig. 8, three pairs of bundles are seen passing in, and seven more leaf-traces can be recognized at the margin of the pith, either in course of fusion or already fused. In all these strands the centripetal xylem is well developed.

As the twin xylem-strands come in through the secondary wood they converge (Pl. LXXXVIII, Fig. 9), and almost immediately on reaching the border of the pith they prepare to fuse. At this level the two centripetal xylem groups open out towards each other (see the right-hand bundle in Fig. 9), the xylem-parenchyma of the two strands becoming continuous across the medullary ray between them. At a slightly lower level the two centripetal arcs of xylem unite, so that the joint strand now has a single primary xylem-mass. The photograph in Pl. LXXXVIII, Fig. 10, shows a double strand in the act of fusion; the two centripetal groups of xylem have just become continuous. The drawing (Pl. XC, Fig. 23) shows a similar strand lower down in its course, where union is complete. That this is the actual course of the changes, as traced from above downwards, is shown on comparing the same strands in successive sections. Other strands around the pith have reduced remains of centripetal xylem, or the smallest elements are quite on the inner edge, showing that the structure has become endarch.

As regards the outward course of the leaf-traces, there is no essential difference from *M. Sutcliffii*. The bundles, however, run very obliquely through the secondary wood, the phloem zone, and the inner cortex; they are seldom seen well in transverse sections of these regions. We know, however, that the original pair divided up into eight, for all the eight bundles of a trace are seen in the section shown in Pl. XC, Fig. 24, where they are entering a leaf-base. Some sections show the strands passing almost horizontally through the wood, and subdividing as they enter the cortex.

The structure of the primary strand is essentially the same as in *M. Sutcliffii* and other species. The centripetal xylem is perhaps rather specially well developed; here also the protoxylem, where it can be clearly seen, is in contact with the centripetal part of the xylem, abutting on the internal parenchyma of the strand (Pl. XC, Fig. 23). Longitudinal sections show that the centripetal wood is composed, apart from the protoxylem, of close-wound spiral elements. The somewhat oblique tangential section from which the photograph (Pl. LXXXVIII, Figs. 11 and 12) is taken shows a pair of bundles approaching the pith. In the right-hand bundle the plane of section passes obliquely through the island of parenchyma and protoxylem (Fig. 12, *px*).

No actual sheath is developed round the xylem-strands as they reach the pith. There is, however, a very near approach to this structure, for, where the double strand is entering through the wood and getting near the pith, the adjacent cells on the inner side have divided tangentially, and some of them show tracheal markings, just as in *M. Lomaxii* (Fig. 9, *sh*). The differences between the two species as regards the bundle-sheath is thus only one of degree.

The Wood.

The inner part of the centrifugal wood is composed of spiral, reticulate, or scalariform elements. The reticulate markings are often evidently formed by crossed spiral bands, such as are shown at one or two places in Mr. Maslen's figure from a leaf-trace bundle of *M. Sutcliffii* (Maslen, '11, Pl. XXXV, Fig. 14). The reticulate condition often forms the transition to the regular pitted sculpturing of the main mass of secondary tracheides. The zone of spiral and transitional elements is of considerable width, twelve to fourteen layers in the leaf-trace, and about six layers even where the wood appears to be purely secondary. This seems to be a specific difference from *M. Lomaxii*.

The typical, pitted, secondary tracheides have only two rows of pits on the radial wall, and sometimes only a single row (Pl. LXXXVIII, Figs. 14 and 16). Where a medullary ray is crossed, the pits are more numerous, narrower, and markedly oblique. The tracheides are about 20 to 40 μ in

diameter, most of them over 30μ . The rays are almost invariably uniseriate, ranging in height from one to about ten cells; the diameter of a ray is commonly from 20 to 25μ , the cells being about 36μ in height. At the end towards the pith the rays become broader, and radial divisions of their cells are frequent. The wood of *M. poroxyloides* thus differs from that of *M. Lomaxii* in the somewhat smaller size of the tracheides, with a corresponding diminution in the number of rows of pits, and, so far as observed, in the absence of very high medullary rays. There is pretty close agreement with the wood of *M. Sutcliffii*, as described by Mr. Maslen. The greater development of the inner spiral and scalariform zone of tracheides in the secondary wood is characteristic of *M. poroxyloides*.

The Phloem and Pericycle.

The phloem in the type specimen forms a zone 0.8 mm. to 1 mm. in breadth (Pl. LXXXVIII, Fig. 15). Nearly the whole thickness is made up of radially seriated, secondary elements. The phloem is very fairly preserved, and is closely similar in structure to that of *M. Sutcliffii*, of which Mr. Maslen has given a full description (Maslen, '11, p. 400). The elongated elements with dense contents are very conspicuous; in some the contents are black, in others light brown, but the two appear to pass over into one another, and I cannot find any sharp distinction between the two forms. It may be mentioned that cells with dark contents also occur in the phloem rays, which are often dilated towards the exterior. It is probable, as suggested by Mr. Maslen in the case of his species, that the long elements with no obvious contents are the sieve-tubes. I postpone, however, any detailed account of the phloem to a later paper, as I have recently received from Mr. Lomax a series of sections from a remarkably well preserved stem, closely similar to *M. poroxyloides* as regards the phloem, though differing in some other details. Beyond the phloem comes another fairly broad zone, which may best be regarded as the pericycle. This contains a number of large sacs with dark contents (Fig. 15, s.s.). In longitudinal section the sacs often appear to be divided up into cells, but this may only be due to a breaking up of the contents.

The Cortex.

On the outer border of the pericycle is a layer of internal periderm, very unequally developed, and in some places reaching a thickness of about a dozen cells. Many of the periderm cells are flattened and rather thick-walled, suggesting a true cork. There is, however, no sign of any general desiccation of the outer tissues, so it is evident that they had not yet been completely cut off by cork from communication with the water supply of the stem. At many places the periderm is double, an outer layer or arc having formed in the adjacent cortical tissue. On general grounds one would

expect the outer periderm to have been formed before the inner ; the latter, however, is sometimes the more developed of the two, and as the whole cortex appears to have been living up to the time when the plant itself met its fate, we cannot be certain as to the order in which the peridermal layers appeared.

The inner cortex, like the pericycle, contains large sacs with dark contents, though they are not so numerous here. Except where a leaf-trace is passing out, the inner cortex is little developed ; we almost immediately reach the Dictyoxylon zone, which attains a considerable thickness—quite 2 mm. in places. The radial bands of fibres do not, however, extend quite to the outside of the stem ; the fibres are little thickened, and the differentiation of the mechanical tissues, as seen in transverse section, not very marked.

The outer surface of the stem is incompletely preserved, and hence the arrangement of the leaf-bases is obscured. At first sight they appear to be scattered, but further examination shows that they must have been fairly close together. Thus, in one section (slide 2353) two leaf-traces are seen in the outer cortex ; both consist of a number of bundles—probably eight in each case—though all are not preserved. The adjacent bundles of the two traces are only about 4 mm. apart.¹ The corresponding leaf-bases are not complete, but there can have been no great extent of stem-surface between them. The leaf-bases, however, were probably somewhat less closely set than in *M. Sutcliffi*.

As in other species, where a leaf-trace passes out through the cortex into the leaf-base it is surrounded by a large mass of parenchyma, which encroaches upon the Dictyoxylon zone. This is consequently considerably thinner opposite the outgoing leaf-traces than elsewhere.

It may be mentioned that the 'Cordaitean' leaves associated in slide 2397 with a stem, probably referable to *M. poroxyloides*, are of the type recently described by Prof. Margaret Benson under the name *Cordaites Felicis* (Benson, '12). This is shown by the well-developed sheath, the presence of complete longitudinal fibrous partitions between the bundles and of thickened masses of hypoderm between the bundles and the partitions, the partial 'inner sheath', and the arrangement of the centripetal and centrifugal xylem, which is often identical with that shown in Prof. Benson's text-figure (l. c., p. 204). Some of the leaves associated with the stem in question are, however, thicker (i. e. cut, no doubt, nearer the base) than any of Prof. Benson's specimens ; one fragment reaches a thickness of 1.8 mm. In these thickest parts some of the partitions are missing ; their absence may be correlated with a recent division of the bundles.

¹ The distance between the centre lines of the two traces would be about 8 mm.

It thus appears very probable that *Cordaitea Felicis* was the leaf of a *Mesoxylon* of the *poroxyloides* type. Direct evidence from continuity may perhaps be hoped for. At any rate this probability may serve to call closer attention to the British specimens of 'Cordaitean' leaves, which had been much neglected until the appearance of Prof. Benson's paper. Many excellent specimens are now available.

Diagnosis.

The following is an amended diagnosis of the species :

Mesoxylon poroxyloides; Scott and Maslen, 1910.

Leaf-bases moderately crowded, not quite covering the surface of the stem.

Pith not very large, discoid, with a persistent outer zone.

Diaphragms sometimes splitting into finer plates towards the middle of the pith.

Twin-bundles of the leaf-trace converging and uniting soon after reaching the pith, subdividing in the cortex to form eight bundles.

Centripetal xylem very distinct, persisting below the fusion of the twin strands.

Xylem-strands without a sheath, or with only a rudimentary one, limited to the region where they first reach the pith.

Tracheides of the inner part of the intermediate secondary wood, as well as those of the leaf-traces, spiral, reticulate, or scalariform.

Bordered pits in one or two rows.

Medullary rays (with rare exceptions) uniseriate, 1-10 cells in height.

Dictyoxylon zone of cortex very broad, fibres not much thickened.

Seam-nodules; Shore, Littleborough. Lower Coal Measures.

COMPARATIVE CONSIDERATIONS.

Important forms of *Mesoxylon* still remain to be described, but the three species which have now been dealt with by Mr. Maslen and myself are sufficient to make the position of the genus clear. The existing classical accounts of the structure of the stem in *Cordaitea* (Renault, '79 and '96) are not so full as we could wish, and a reinvestigation is desirable; so far as the stem is concerned we are now better acquainted, in some respects, with the anatomy of *Mesoxylon* than with that of the type-genus of the family. On the available data, however, it is evident that the affinity between *Mesoxylon* and *Cordaitea* is a close one, and I agree with Mr. Maslen that our genus may best be included in the family Cordaiteae (Maslen, '11, p. 411). This is, of course, a departure from the position which I took up in the second edition of my 'Studies in Fossil Botany' (Scott, '09, p. 511), when I provisionally included what is now *Mesoxylon Sutcliffei* in the genus *Poroxyylon*, though at the same time I referred to other forms, since added

to *Mesoxylon*, under Cordaiteae (l.c., p. 526). The centripetal wood of the stem, no doubt, died out gradually; in *Mesoxylon* it is still sufficiently well developed to justify generic separation from *Cordaitea*, but not, I think, a position in a distinct family. The point, however, is of little importance; what really matters is, that the two families Cordaiteae and Poroxylae are now closely linked together.

The points of resemblance and difference between *Mesoxylon*, *Cordaitea*, and *Poroxylon* have been well summarized by Mr. Maslen (l.c., p. 410). They hold good essentially for all the species investigated. It will be noticed that no definite distinction between *Mesoxylon* and *Cordaitea* is given, beyond the presence of centripetal xylem in the stele of the former. In other respects there appears to be agreement, but we do not know enough about the exact course of the leaf-traces or the detailed structure of the phloem in *Cordaitea*, to be certain how close the agreement really was. At any rate, we have the large, discoid pith, the dense wood with narrow rays,¹ and the histology of the xylem-elements, especially the great development of spiral and scalariform tracheides in the leaf-trace region, as definite characters common to the two genera. The species of *Mesoxylon* would have been left in *Cordaitea* if it were not for the presence of centripetal wood in the stele. I feel no doubt that most of the British specimens of 'Cordaitean' leaves really belong to *Mesoxylon*, which is a much commoner type of stem in the Coal-Measure petrifications than that of *Cordaitea* itself. If this belief is confirmed, we shall have the close agreement in foliar characters as another proof of the near affinity of the two genera.

I thus regard *Mesoxylon* as the last term in the series of forms leading up from the Seed-Ferns to the typical *Cordaitea* described by Grand'Eury and Renault.

Some additions have lately been made to the Cordaitales and their allies by Dr. Zalesky, who has founded no less than five new genera, partly for new forms, partly for plants already described under other names (Zalesky, '09, '11¹, and '11²).

The new forms are: *Callixylon Trifilievi*, Zal. (Zalesky, '09 and '11¹), and *Caenoxylon Scotti*, Zal. (Zalesky, '11²). The other new genera are: *Eristophyton* (Zalesky, '11¹), based on *Calamopitys Beinertiana* (Göpp.), and *C. fascicularis*, Scott; *Mesopitys* (Zalesky, '11¹), based on *Dadoxylon Tschihatcheffi* (Göpp.); and *Parapitys* (Zalesky, '11¹), based on *Dadoxylon Spenceri*, Scott.

Callixylon Trifilievi (Zalesky, '09) from the Upper Devonian of the Donetz basin in Russia is a very interesting fossil, evidently allied to the Lower Carboniferous genus *Pitys* (Scott, '02). Numerous (26) small, mesarch

¹ As a matter of fact somewhat wider rays occur in *Cordaitea* than have yet been observed in *Mesoxylon* (Renault, '96, p. 334).

strands of primary xylem surround the pith, most of them in contact with the secondary wood, though some are separated from it by 1 to 3 rows of cells. These strands anastomose freely. At a distance from the pith the rays are usually uniseriate. The pith is horizontally ruptured (imperfectly discoid), and the pith-cells surrounding a primary xylem-strand are elongated radially with respect to it. Tangential pits occur in the secondary wood, as in *Pitys antiqua*. The agreement with *Pitys* seems to be decidedly nearer than with the other genera (*Parapitys* and *Eristophyton*) with which the author compares it. He separates the plant generically on the ground of its narrow medullary rays, the wedge-like segments of secondary wood, and the arrangement of the pits, on the radial walls of the secondary tracheides, in groups (Zalessky, '11¹, p. 28). At any rate this new form, of which a fuller description is promised by the discoverer, finds its place in the family Pityeae, and has no near affinity with *Mesoxylon*.

The fragment named *Caenoxylon Scotti* by Dr. Zalessky is of uncertain origin; it is of Upper Palaeozoic age, and possibly comes from the Permian of the Ural (Zalessky, '11²). The pith is 2 cm. in diameter, and the zone of wood, so far as preserved, about 13 mm. thick. The presence of distinct annual rings in the wood is an interesting feature, indicating a relatively late age. The pith is not stated to be discoid, but is described as consisting of distinct outer and inner regions, with a meristematic layer between them.

The primary xylem is divided into a number of bundles of various sizes and shapes, separated by medullary tissue with occasional signs of meristematic division. Some of the strands may be a considerable distance apart from the main mass of primary xylem, of which they are ramifications; in all, the structure is endarch. The leaf-traces are double, and the medullary rays uniseriate. The author regards *Caenoxylon* as undoubtedly allied to *Eristophyton*, *Pitys*, *Parapitys*, and *Mesopitys*, and more remotely to *Cordaitea*, *Poroxyton*, and *Mesoxylon*. He suggests, on the ground of the arrangement of the primary xylem and the character of the double leaf-trace, that the fossil may possibly be on the line of descent of *Ginkgo*.

At present we have only a preliminary communication from Dr. Zalessky on this form. Except that I cannot recognize any but the most remote affinity to his *Eristophyton*, I have nothing to add to the author's remarks.

In connexion with *Caenoxylon* we may shortly refer to Dr. Zalessky's new genus *Mesopitys*, founded on the *Araucarites Tchihatcheffi* of Göppert. This, again, is a Permian plant, and was the first stem of that age in which the presence of annual rings in the wood was observed. The pith is small (3 mm. in diameter in one case), the stems (without cortex) ranging from 5 × 3 to 13 × 8 cm. No mesarch xylem-strands were observed; the primary wood, as in *Caenoxylon*, is all centrifugal, forming groups of irregularly

arranged tracheides with the smallest elements always on the inner side. The whole of the primary wood is composed of spiral or rayed tracheides which abut immediately on the pitted elements of the secondary wood. Unlike *Caenoxylon*, *Mesopitys Tchihatcheffi* has a single bundle constituting the leaf-trace, where it passes out through the wood. The medullary rays are uniseriate. The genus *Mesopitys* is established for stems with secondary wood of the *Dadoxylon* type, characterized by the arrangement of the feebly developed primary wood in bundles of endarch or even mesarch structure, and by the single bundles traversing the secondary wood (Zalessky, '11¹, p. 28). The author regards his new genus as forming the final term of the group of stems of the *Dadoxylon* type described by me in 1902, and considers it to be closely allied to his *Eristophyton Beinertianum* (*Calamopitys Beinertiana* (Scott)).

It is interesting to note that Dr. Zalessky is prepared to include stems with mesarch as well as those with purely endarch primary xylem in the same genus. I have no objection to this in principle, for the one structure, no doubt, passed over gradually into the other, nor do I dispute a certain degree of affinity between my *Calamopitys Beinertiana* and *Mesopitys Tchihatcheffi*. At the same time, the presence of very highly developed mesarch strands in the former plant (though they become endarch lower down in their course) appears to me a more important difference than Dr. Zalessky recognizes. I quite agree with the author that his *Mesopitys Tchihatcheffi* requires a new genus.

Another of Dr. Zalessky's new genera is *Parapitys*, founded for the reception of *Dadoxylon Spencersi* (Scott, '02). It was inevitable that sooner or later this form should acquire generic rank. It is characterized by the double leaf-traces, the small mesarch strands of primary xylem, and the relatively small pentagonal pith, the wood being of the ordinary Cordaitan type. Of all the forms discussed by Dr. Zalessky, *Parapitys* seems to me the nearest to *Mesoxylon*, from which it only differs (so far as we know at present) in the characters of the pith. It seems to be widely separated from the species of *Calamopitys* placed by Dr. Zalessky in *Eristophyton* by the double leaf-traces and the great reduction of the primary mesarch strands.

Dr. Zalessky devotes a good deal of space to an argument against my inclusion of *Calamopitys fascicularis* and *C. Beinertiana* in the genus *Calamopitys* of Unger, founding the new genus *Eristophyton* for their reception (Zalessky, '11¹). I do not propose to enter fully into the question in this paper, because, from my point of view, these plants have very little to do with *Mesoxylon*. It is possible that the various, not very important characters, on which Dr. Zalessky lays stress, may in the aggregate justify generic separation. The author, however, has not quite realized what the characters are which I regard as essential to *Calamopitys*. As I stated (Scott, '02, p. 360): 'The *Calamopitys* group is characterized by the

relatively large dimensions and distinct mesarch structure of those primary xylem-strands which are about to pass out from the pith, while the same strands, lower down in their course, are reduced in size, and in some cases assume endarch structure, owing to the dying out of the centripetal xylem. A single strand passed out from the pith to form the leaf-trace.'

The really characteristic point in *Calamopitys* is the presence of the quite peculiar large, round mesarch xylem-strands, which are unlike those of any other plant I have seen. Their structure in *C. Saturni* and *C. fascicularis* (to take an example from each group) is identical, as I hope to show more in detail on another occasion. The only differential character of any weight between *Calamopitys* and the new *Eristophyton* is the width of the medullary rays, which are generally wide in the former and narrow in the latter. This, however, appears to be inconstant, for, in a section of *C. annularis*, very kindly lent me, among many other preparations, by Count Solms-Laubach, the rays are only one or at most two cells in width, thus differing from the pluriseriate rays usual in *C. Saturni* and even in other specimens of *C. annularis*. There is no reasonable doubt that the species of *Calamopitys* described by Count Solms-Laubach were Pteridosperms, as indicated by their *Kalymma* petioles. The important question at issue between Dr. Zalesky and myself is whether the species *C. fascicularis* and *C. Beinertiana* were likewise Pteridosperms, or belonged to a higher group. This goes much beyond the mere question of generic separation, which is of secondary importance.

At present I must adhere to my view that the agreement in the primary characters of the wood, between the species placed by Dr. Zalesky in *Eristophyton* and the type species of *Calamopitys*, is so close as to prove a very near affinity. The question will not, however, be finally decided until the cortex and leaf-bases of the former species are known.

One argument used by Dr. Zalesky must be shortly dealt with, as it appears to me somewhat misleading (Zalesky, '11¹, p. 27). He says that, if my view is just, we must suppose that the species *fascicularis* and *Beinertiana* had fern-like foliage. He regards his *Callixylon Trifilievi* as certainly allied to these species. He finds reason to believe that the latter plant may have had a stem reaching about a metre in diameter, and thinks it improbable that such trunks could have borne the foliage of a Fern.

Now, to begin with, *Callixylon Trifilievi* shows no close affinity to *Calamopitys fascicularis* and *Beinertiana*. It is practically a *Pitys*, and no one has attributed filicoid foliage to *Pitys*, which was more probably of Cordaitan habit. Secondly, there is no reason to doubt that in Palaeozoic days stems of great girth bore fern-like foliage. A specimen of *Medullosa stellata* discovered by Weber (Weber und Sterzel, '96, p. 25), though decorticated, measured nearly $\frac{1}{2}$ a metre (48 × 45 cm.) in diameter. It is well known that the foliage of *Medullosa* was fern-like (e.g. *Neuropteris*,

Alethopteris). Whether *Calamopitys fascicularis* and *Beinertiana* attained a very large diameter or not we cannot say; if they did so, the fact would certainly be no argument against their Pteridospermous affinities.

SUMMARY.

The characters of *Mesoxylon Lomaxii* and *M. poroxylodes* have already been summarized in their specific diagnoses (pp. 1016 and 1023). The genus comes very near *Cordaites*, as shown by the characters of the pith and wood, and further indicated by those of the associated leaves. The affinity with *Poroxylon* is somewhat more remote, and the genus is best placed in the family Cordaitaceae; it is at present definitely distinguished from *Cordaites* only by the presence of centripetal wood in the stele of the stem. *Mesoxylon* thus forms the last link in the chain of fossil types connecting the Pteridosperms with the typical *Cordaites* of the Upper Palaeozoic.

Of the new genera recently established by Dr. Zalesky, *Callixylon* is very near *Pitys* and should be placed in the same family. *Caenoxylon* and *Mesopitys* are advanced forms, and had reached an anatomical level corresponding to that of *Cordaites* itself, but on somewhat different lines.

Parapitys is best regarded as a near ally of *Mesoxylon*. *Eristophyton*, even if generically separable from *Calamopitys*, is closely allied to it, and both may provisionally be regarded as probably belonging to the Pteridosperms rather than to the Cordaitales. It is possible, however, that further discoveries may show that the Calamopityaceae were an important transitional group.

The results already attained by Dr. Zalesky and others are very satisfactory, as demonstrating a considerable variety among the stems of Palaeozoic age, referable or allied to the Cordaitales.

DESCRIPTION OF PLATES LXXXVII-XC.

Illustrating Dr. Scott's paper on *Mesoxylon*.

The photographic figures require to be examined with a lens.

PLATE LXXXVII.

Mesoxylon Lomaxii.

Photographs by Mr. W. Tams.

Fig. 1. General transverse section of the stem, showing the patchy preservation characteristic of roof-nodule specimens. \times nearly 2. Slide 2328.

Fig. 2. Half of another transverse section, better preserved. *d*, Dictyoxylon zone; *pd*, periderm. \times about 3. Slide 2325.

Fig. 3. Tangential section from inner part of wood, showing the twin-bundles of a leaf-trace (*l.t.*) and their junction below. \times 10. Slide 2380.

Fig. 4. Somewhat oblique section, showing the converging twin-bundles of a leaf-trace (*l.t.*). *sh*, bundle-sheath; *p*, pith. \times about 30. Slide 2325.

Fig. 5. Leaf-trace in the act of fusion. *x*, centripetal xylem; *sh*, bundle-sheath; *p*, pith. \times about 40. Slide 2328.

I. INTRODUCTION.

THE fossil plant described in the present paper was obtained from the colliery at Dearnley near Littleborough in Lancashire in 1910, and is of Lower Coal Measure age. It occurred in a nodule from the roof of the workings, as is shown by the presence of *Goniatite* shells scattered through the sections, and probably was obtained from the same seam as the type specimen, *Sutcliffia insignis*, which came from a roof-nodule from the adjacent mine at Shore Littleborough.¹ The specimen, which was about 10 inches long, was cut by Mr. James Lomax, and thanks are due to the 'Committee of British Fossil Plants' of the British Association for the Advancement of Science for a grant which partially defrayed the cost entailed in cutting the specimen. In September, 1911, the series of fifty-eight transverse and nineteen longitudinal sections, labelled 'new *Medullosa*, probably *Sutcliffian* type', was handed over to me by Professor F. W. Oliver, F.R.S., for investigation. I cannot allow this opportunity to pass without gratefully acknowledging the never-failing help and advice which

¹ Scott, D. H. : IV. On *Sutcliffia insignis*, a New Type of *Medulloseae* from the Lower Coal Measures. Trans. Linn. Soc. London, vol. vii, Pt. 4, ser. 2. Sept. 1906.

he has extended to me during the progress of the work. Dr. Scott has also kindly examined three of the sections, and I have thus had the advantage of his valuable opinion as to the identification of the specimen.

My thanks are also due to W. H. Sutcliffe, Esq., who kindly lent me three of his sections of *Sutcliffia insignis* for purposes of comparison.

Though the fragment of stem was, as stated, about 10 inches long (25.5 cm.), the series of transverse sections only cover a distance of about 7 inches (18 cm.). The maximum transverse dimensions were $9\frac{1}{2} \times 3\frac{1}{2}$ cm.; it is, however, most probable that the form has been considerably altered by lateral pressure, though it is doubtful whether it ever possessed a circular

contour. A comparison with the stem described by Scott¹ shows the size to be distinctly less than in his fossil, in which the dimensions were 12×6.5 cm. The specimen was cut into three blocks, and the further treatment of each of these is shown in Text-fig. 1.

Owing to the complexity of the vascular structures present in the stem, it appeared desirable to construct a model to better elucidate the course of the strands. In preparation for this the outline of the different xylem-strands (including both primary and secondary tissues) was traced from the sections, and

TEXT-FIG. 1. Block A represents the upper end of the specimen, as will appear during the course of the paper.

the tracings were then enlarged to twice the size by the pentagraph. The average distance between each section was determined, and wax plates of this thickness were prepared,² two sheets being used for each section, so that the correct proportions as far as possible were maintained. The method employed in building up the model from these wax plates was,

¹ Loc. cit., p. 46.

² Bees-wax softened with vaseline until the consistency desirable was attained was used; the dental wax commonly employed for this purpose being inappropriate on account of the thinness of the sheets.

in other details, similar to that described by Farmer and Hill,¹ so that further description is unnecessary. In the preparation of this model great assistance was given me by Mr. T. G. Hill, who not only suggested the method, but helped me during the progress of the work; I should also like to express my appreciation of his unstinted help in connexion with some of the diagrams which illustrate this paper.

II. GENERAL STRUCTURE.

The specimen appears to consist of a protostele associated with 'meristeles',² in all of which considerable secondary thickening has taken place; a few small leaf-trace strands are also present. Extrafascicular strands of wood and bast surround the protostele and 'meristeles', and the whole of the vascular tissues are invested by a discontinuous sheath of secondary

TEXT-FIG. 2. Outline tracing of the vascular strands of Section O. Dotted areas represent the primary wood, shaded areas the extrafascicular strands, the broken line the limit of the tissues, and the triple broken lines the arcs of secondary cortex; phloem is omitted. cortex. The basal portion of the stem is represented by Section O, the apical section being LVIII; the structure is, on the whole, best seen in the lowest sections of the series.

Practically nothing but the vascular system is represented, and it appears probable that in places this is not present in its entirety (at X, Text-fig. 2, it is almost certain that some strands are missing).

In the lower sections a somewhat discontinuous zone of periderm-like tissue occurs at a short distance outside the vascular strands. The entire absence of cortex (except in small isolated patches) and the lack of any

² The term 'meristele' is used in order that the descriptive parts of the present paper may conform to the terminology employed by Scott in his description of *Sutcliffia insignis*, so that comparison may be facilitated. No morphological significance is attached to the term by the present writer.

trace of the decurrent leaf-bases which form so distinctive a feature in the specimen described by Scott are, in all probability, due to the formation of cork, which resulted in the sloughing off of the exterior tissues. In the upper sections of the series the beginning of cork cambium formation can be traced (see Text-fig. 18, A and B), but in this region, as in the lower part of the specimen, the outer tissues are absent. It is possible, of course, that as the fragment of stem drifted out to sea,¹ the vicissitudes of the journey partly destroyed and tore the more delicate outer tissues, and there can be no doubt that some parts of the stem have been injured in this way ;

TEXT-FIG. 3. Transverse section of a very small concentric leaf-trace strand. x' = primary wood; ph = phloem; le = large elements of the phloem; $f.s.$ = fibrous strands; $s.c.$ = secretory cell. $\times 70$.

at the same time it appears probable that some part of the cortex has been lost naturally. The suggestion is put forward that the phellogen was a short-lived tissue, and was replaced by successively deeper seated cambiums, a phenomenon which is not uncommon in many vascular plants at the present day. Where traces of the cortical tissue are found, here and there throughout the series, it is seen to be composed of delicate, thin-walled parenchyma cells, with numerous secretory elements scattered

TEXT-FIG. 4. View of one side of the model of the vascular system of the new *Satellia*. The model faithfully embodies the actual data, except that in places where these were obviously defective the missing parts have been restored. Such restorations are in all cases indicated by dotted lines on the drawing. Nat. size.

e = extrafascicular strands; α , β , and γ = 'meristeles' (compare with Text-figs. 8 and 9); $l.t.$ = leaf-trace strands; M = protostele.

throughout, the resemblance to the internal cortex of *Sutcliffia insignis* being very close. Small leaf-trace bundles occur in groups of two or three sparingly scattered throughout the series; the extraordinarily few bundles present compared with the size of the stem are accounted for by the fact that, owing to the deep-seated nature of the periderm, the bundles become cut off immediately they enter the cortex. In all cases where the phloem is preserved the leaf-trace strands are seen to be concentric in structure (Text-fig. 3).

Each of these ultimate leaf-trace bundles is partially surrounded by three or four strands of fibrous elements, differing in size, and where in the upper sections of the series the cortex is preserved, similar strands occur. In intimate connexion with the sclerenchyma strands secretory elements are frequently found; these appear to be of the same type as those prevalent in the ground tissue. A similar association of secretory elements with fibrous strands is seen in *Sutcliffia insignis*,¹ and has also been described by Seward as characteristic of *Sutcliffia Williamsoni*² (= *Rachiopteris Williamsoni*).

The vascular system of the stem is essentially similar to that of *S. insignis*; there are, however, two important additions. The main stele and all the vascular strands with the exception of the small leaf-trace bundles are characterized by a wide zone of secondary wood and bast. In addition to this numerous extrafascicular arcs of wood and bast encircle the vascular system proper. The preservation of these arcs leaves much to be desired in many cases, but there is little doubt that in life they formed a complete, irregular, anastomosing network around the cylinder, strongly recalling the extrafascicular strands of certain genera of Cycads (Pl. XCI, Fig. 1, and Text-figs. 4 and 5).

The single main stele, which is roughly triangular in outline, varies but slightly in size throughout the series, except where vascular strands are given off, or where fusion of a neighbouring strand with the main stele is taking place.

The primary wood is in all essentials precisely similar to that of *Sutcliffia insignis*, that is, the tracheides mixed with parenchyma extend to the centre, and the protoxylem occupies the exarch position (cf. Text-figs. 6 and 7).

The dimensions of the primary wood are somewhat smaller than in Scott's specimen, as would be expected from the smaller size of the fossil as a whole. The maximum dimensions of the primary wood of the new specimen are 1.4 × 1.1 cm. as compared with 4.7 × 1.8 cm. in *S. insignis*. Secondary growth has added considerably to the thickness of the wood, so that the total wood measurement amounts to 2.9 × 1.9 cm.

¹ Scott: loc. cit., p. 48.

² Seward, A. C.: On *Rachiopteris Williamsoni*, sp. nov., a New Fern from the Coal Measures. Ann. Bot., vol. viii, 1894, Plate XIII, Figs. 3 and 8.

The vascular masses subsidiary to the main stele, called by Scott 'meristeles', are far less numerous than in the original specimen, a fact which may be again accounted for by considering the small size of the new stem compared with the old; they are moreover distinctly smaller (cf. Pl. XCI, Fig. 1, with Pl. VII of Scott's paper). As very considerable crushing and collapse has taken place—so that except in occasional patches, where the preservation is excellent, the elements are more or less flattened in the plane of the long axis—the dimensions given for the meristeles are

TEXT-FIG. 6. Transverse section of the primary wood of *Sutcliffia insignis*. University College, London, Collection (Scott's section V). $\times 37$. x^1 = primary wood; $x.p.$ = xylem parenchyma; $s.c.$ = secretory elements.

TEXT-FIG. 7. Transverse section of the primary wood of the new *Sutcliffia*. $\times 37$. x^1 = primary wood; $x.p.$ = xylem parenchyma.

only approximately correct. Disregarding the secondary tissues, so that more ready comparison may be made with Scott's figures, the following results were obtained for the dimensions of the meristeles figured in Text-figs. 8 and 9 :

$$\begin{array}{ll} \gamma = 7 \times 1.5 \text{ mm.} & \alpha^1 = 2.5 \times 1.5 \text{ mm.} \\ \beta^1 = 5 \times 1.5 \text{ ,,} & \beta^2 = 2 \times 1.5 \text{ ,,} \\ \gamma^2 = 4 \times 2.5 \text{ ,,} & \gamma^3 = 2 \times 1.5 \text{ ,,} \\ \alpha = 2.5 \times 1.5 \text{ ,,} & \end{array}$$

The measurements made by Scott¹ in *Sutcliffia insignis* were $\alpha = 7 \times 4.5$ mm. and $\beta = 14 \times 4$ mm. The structure of the 'meristeles' is, in all cases, precisely similar to that of the main stele, with the exception that the zone of secondary thickening does not attain to so great a thickness, and occasionally does not entirely surround the primary wood. It

¹ Loc. cit., p. 49.

may be remembered that in Scott's fossil the structure of the 'meristeles' was similar to that of the main stele, and, like it, sometimes showed a slight indication of the beginning of secondary growth.

III. COURSE OF THE 'MERISTELES'.

In order to elucidate the behaviour of the 'meristeles' as completely as possible, the course of three strands, designated α , β , and γ , will be traced. In Text-fig. 2, taken from the lowest section of the series, the main stele (M) has a large hook-shaped projection at its left-hand side (α); it consists almost entirely of secondary wood, but embedded within it are two groups of primary xylem (Text-fig. 8, Fig. II); these groups are respectively labelled α and α^1 .

In III¹ a slight indentation appears at the extreme left of this projection; it occurs immediately opposite a deep incision present on the opposite side of the mass, and lies just above one of the groups of primary wood; the end of the hook is evidently preparing for detachment. In IV the process is almost entirely complete, while in V α^1 is quite independent (Text-fig. 8, Figs. IV and V, and Pl. XCI, Fig. 1). Very rapidly, secondary wood almost, but not quite, encloses the detached end of α^1 , while α soon shows no sign that disturbance has taken place. No further change occurs in α^1 —it never becomes entirely surrounded by a zone of secondary wood—until Section XXXIX, $3\frac{3}{4}$ inches higher up (9.5 cm.).

At this level its primary wood is beginning to divide into two portions, a division which is completed by XLVI. It is difficult to say with certainty what is happening in this upper part of the stem, for the tissues have been subjected to considerable crushing and the preservation is poor; but in Sections XLV to XLIX, though the 'meristele' α^1 appears to be fusing with α , the appearance is in all probability deceptive and due to mechanical pressure;² moreover, α^1 is dividing up into ultimate leaf-trace strands.

Returning to the 'meristele' α , in II a group of primary xylem elements can be traced passing from the stele M to join the isolated cluster already present; in V it has passed nearly through the secondary wood of M and the 'meristele' is detaching itself from the main stele (Pl. XCI, Fig. 1); it becomes entirely free in VIII (Text-fig. 8, Figs. II–VIII). As soon as these changes are completed the secondary wood immediately closes round it, and also round M; this condition is maintained for a distance of $3\frac{1}{4}$ inches (8.2 cm.) (Text-figs. 4 and 5). From Section XXXVIII upwards the sequence of events cannot be given with absolute certainty owing to the crushing which has taken place, but the primary xylem of α undoubtedly divides into two parts; the smaller portion is passing out through the

¹ The Roman numerals refer to the number of the slide.

² In the model this strand is necessarily represented as fusing with α (Text-fig. 4).

secondary zone, but the sections are insufficient to trace the behaviour of the larger. The larger agrees, so far as the size and appearance are concerned, with the radially symmetrical leaf-traces which will be described later (p. 1047), while the smaller is probably a leaf-trace strand of the

TEXT-FIG. 8. Tracings showing the breaking up of the 'meristeles' α and β . The dotted areas indicate the primary wood; only xylem is included in the tracing. Slightly under nat. size. The numbers refer to the numbers on the slides. M = main stele. All vascular tissues except the main stele, and the 'meristeles' α and β , are omitted.

unilateral type. The evidence is not absolutely satisfactory, but it would appear to justify the conclusion that the hook-shaped projection seen in Section O is an outgoing foliar strand, which divides into smaller strands,

which in turn break up completely into leaf-trace bundles. Further evidence in favour of this conclusion is provided by the behaviour of the other 'meristeles'.¹

The course of the 'meristele' β will next be traced; in the lowest section of the series (see Text-fig. 2) it is already entirely free from the main stele M; it lies on the side of the stele remote from the 'meristeles' α and α^1 which have just been described. It is entirely though somewhat unevenly surrounded by secondary tissues, and contains two groups of primary tracheides. In IV the 'meristele' is preparing to divide into two parts, each containing one primary xylem group; this division is completed in V (see also Pl. XCI, Fig. 1). One of these two parts, β^1 , shows no secondary tissues for some considerable distance on the side remote from β^2 (Text-fig. 8); this is probably due almost entirely to injury in this region. β^1 shows no further change until XXVIII, when a portion of the primary wood at its upper end shows signs of detachment; this separation is completed by XLI, and the rounded mass of primary xylem β^3 has passed out from the secondary wood. It cannot be traced above this level, so that its exact significance cannot be stated definitely. From its size, and the position of the protoxylem elements, β^3 probably represents a radially symmetrical leaf-trace strand such as was indicated as occurring during the breaking up of the 'meristele' α . Returning to the other half of the divided 'meristele' β , namely β^2 (Text-fig. 8, Fig. V), almost immediately after its separation from β^1 the secondary wood on the outer side opens out, exposing the primary xylem. This 'opening out' of the 'meristele' is undoubtedly partly the result of injury, but there can be little doubt that some movement of the vascular mass took place in life, in order to prepare for the fusion with the main stele M, which occurs immediately above this level. The course of events is shown in Text-fig. 8, Figs. II-XX; comparison with Pl. XCI, Fig. 1, shows that the portion of the stele M with which β^2 finally fuses has been considerably injured, though how far the absence of secondary wood at this part of M is a natural feature it is difficult to say—in all probability a break in the secondary tissues of M occurred preparatory to the entrance of β^2 , thus allowing for the fusion of the secondary and primary tissues of the former with the corresponding ones of the latter. During the process of fusion, a small arc of secondary wood with two or three primary tracheides attached to its margin became isolated. The ultimate fate of this arc could not, however, be determined. This instance of fusion of a 'meristele' with the stele, the only one occurring in the series, is of considerable interest; it is unparalleled in *S. insignis*, for Scott decided that what appeared to be a case of re-fusion in that stem was due to

¹ The ultimate breaking up of the 'meristeles' α and α^1 is not shown in Text-figs. 4 and 5. The model ends with Section LIV, for the last four sections were too fragmentary to include.

mechanical pressure;¹ he was unable to trace a genuine case of re-fusion of a 'meristele' with a stele.

As neither of the meristeles α or β , which have hitherto been considered, give really conclusive evidence of the breaking up of the 'meristeles' into foliar strands, for this purpose the changes undergone by the remaining 'meristele', γ , will be described. The 'meristele' γ is a vascular mass lying on the remaining free side of the stele M and almost equalling it in

TEXT-FIG. 9. Tracings showing the breaking up of the meristele γ . Slightly under nat. size. A slight restoration has been necessary in Sections XLIV-L.

size (Pl. XCI, Fig. 1), giving the stem the appearance of having two almost equal steles in the lower half of the series, but that γ is only a large 'meristele' and not a stele is abundantly proved by its subsequent behaviour.

The primary wood in this 'meristele' occurs in two masses, one at either end, and the secondary wood extends completely to the middle in the central region. In Section O a small strand of primary wood shows evidence of detachment,² in XVIII it begins to pass outwards through the

¹ Loc. cit., p. 52.

² Shown still more clearly in Plate XCI, Fig. 1.

secondary wood, and in XXI it has become entirely free from it. The secondary xylem closes up immediately after the exit of this bundle, and none of it accompanies the strand during its outward passage. Immediately it becomes free from the 'meristele' it turns vertically upwards and can be traced as far as XXXI (Text-fig. 4); after this level it is no longer present in the series. The strand consists of a small group of primary tracheides mixed with parenchyma, and only one protoxylem group appears to be present. Its preservation is far from satisfactory, but it is certainly concentric in structure, though how the phloem was gained could not be ascertained. In the upper sections in which it appears the phloem has associated with it the ring of the large elements which are so characteristic a feature of the phloem of the leaf-trace bundles; bundles of fibres also occur immediately beyond the phloem. There can be no doubt that this strand is a leaf-bundle of the unilateral type, passing out directly and prematurely from a 'meristele'.

In tracing the course of the 'meristele' γ the central region of it shows signs of injury quite early in the series, and in XIX there is a complete break at the middle part. A division of the 'meristele' into two portions in all probability occurred in life, but the appearance in the fossil is considerably emphasized by crushing and injury (Text-fig. 9, Figs. XII, XXVII, and XXIX). A small portion, γ^3 , is soon cut off from γ^2 , and subsequently γ^1 and γ^2 appear to fuse. The evidence for this re-fusion is however doubtful, for considerable crushing has taken place in the upper portions of the stem, and added to this there is further injury in preservation at the critical region. In any case, by the time XLVIII is reached (Text-fig. 9, Figs. XXXIII-XLVIII) γ has divided into two larger and one small portion, γ^1 , γ^2 , and γ^3 . Above this level the primary wood of γ^1 is dividing up into smaller portions, which do not leave the 'meristele' in the course of our series; so far as one can judge from this stage, the 'meristele' γ^1 is dividing into radially symmetric leaf-trace strands. Division also begins in γ^3 , and three small strands of primary xylem—each with a single protoxylem group—are produced; they begin to pass out through the secondary wood, but they cannot be traced to the stage where they gain the phloem zone. On this account the unqualified statement that the 'meristele' γ^3 is used up entirely in the production of unilateral leaf-trace strands cannot be made, but comparison with the similar bundle given off by the 'meristele' γ in Section XVIII leaves little room to doubt that it is correct.

In summarizing the evidence provided by the course of the three 'meristeles' α , β , and γ , it appears evident that large masses of vascular tissue are cut off from the central axis, that these run parallel to the latter for some distance, giving off leaf-traces and ultimately dividing up into smaller strands, often unequal in size, and that the primary wood of these strands was ultimately entirely used up in the production of leaf-trace

bundles either radially symmetric or unilateral in type. It could not be determined whether the radially symmetric foliar strands ever divided further to produce the smaller unilateral traces. Unfortunately neither Scott's fossil nor the new stem enables the question to be definitely settled as to whether the whole vascular mass which separates from the main stele is completely used up in the production of leaf-traces, but the great probability that they were has already been shown by a comparison of the behaviour of the 'meristeles' α^1 , γ^1 , and γ^3 .

The very interesting cases recorded by Scott of the 'occurrence of fusion between meristeles probably of quite distinct origin' do not occur in the new stem, though instances of re-fusion of 'meristeles' of similar origin, and of a 'meristele' with the main stele, have been already described. The distribution of the 'meristeles' around the central strand appears to be in the form of parallel cords of vascular tissue rather than in the state of 'a kind of network round the stele';¹ the network in the new stem is provided by the extrafascicular arcs which will be described later (compare Text-figs. 4 and 5). One further question still remains to be considered. Are the 'meristeles' to be considered as a leaf-trace system, or are they to be considered as part of the stelar system proper to the stem? In discussing this question Scott points out the marked agreement between the meristeles of *Sutcliffia insignis* and the large concentric strands which leave the stele in *Medullosa anglica*; in both there is the same close agreement between the steles and the large strands given off from them. In *M. anglica* these main foliar strands, which are concentric at first, break up entirely into collateral bundles which enter the bases of the leaves, that is, they represent a leaf-trace system only. Scott concludes that they cannot 'be directly compared to the meristeles of *Sutcliffia*' because in *Medullosa anglica* 'there is no evidence of fusion with neighbouring strands, nor any indication that part of the strand remained behind in the stem after the foliar bundles were given off', and for these reasons he interprets the vascular structure in *Sutcliffia* as a protostele giving off a peripheral system of subsidiary steles which form the points of departure of the actual leaf-traces. The discovery of a portion of a second stem tends to show, though the evidence is unfortunately not absolutely complete, that the meristeles were completely used up in the formation of leaf-traces; in all probability none were left behind exclusively cauline in nature; further, fusion of neighbouring strands was not of common occurrence, and may have been merely a consequence of the crowding together of numerous 'meristeles'. In connexion with this point, moreover, it must be remembered that fusion of leaf-trace bundles is a not uncommon occurrence in the Medulloseae. The 'meristeles' of our stem appear to offer a close comparison with the leaf-trace strands which leave the stele in *Medullosa anglica*; in both a large

¹ Scott: loc. cit., p. 53.

concentric bundle, partially or completely surrounded with secondary tissues, leaves the stele—the main stele repeated on a small scale. In the new *Sutcliffia* this strand divides more or less unequally into smaller strands, of which the primary wood breaks up ultimately into concentric leaf-trace bundles, the secondary tissues being lost during the process. In *Medullosa anglica* the strand passes gradually outwards, and then divides up into collateral leaf-trace bundles, the secondary tissues also being lost during the breaking-up process.¹

On the grounds of the additional evidence afforded by the new stem it would appear justifiable to regard *Sutcliffia* as possessing for its main vascular axis a protosteles, from which was given off vascular strands varying in size, but in every case similar in structural details to the protosteles; these strands divided irregularly into smaller bundles which were ultimately completely used up in the production of leaf-trace bundles. This interpretation of the structure connects the fossil more closely with the genus *Medullosa* through such a type as *M. anglica*, and still further supports Scott's view of its primitive position in the *Medulloseae*.

IV. HISTOLOGY.

1. *Structure of the Wood.* The structure of the primary wood is in all essential characters similar to that of *Sutcliffia insignis*, as can be seen by comparing Text-figs.

6 and 7, which represent portions of the primary wood of each drawn on the same scale. The tracheides are of the ordinary elongated form, with multiseriate bordered pits on the radial walls; they are of large size, varying in diameter from 216 to 400 μ , the average being about 281 μ ; their size is thus slightly greater than in *S. insignis*, in which, though the diameter may reach 350 μ , the range lies between 170 and 320 μ .

TEXT-FIG. 10. Part of a radially symmetrical leaf-trace bundle. $\times 70$. s.c. = secretory elements; xy' = primary xylem; par. = parenchyma.

¹ Scott, D. H.: On the Structure and Affinities of Fossil Plants from the Palaeozoic Rocks. III. On *Medullosa anglica*, a New Representative of the Cycadofilices. Phil. Trans. Roy. Soc., Ser. B, vol. cxci, 1899, p. 92.

Thin-walled xylem parenchyma forms a continuous network among the primary tracheides; its cells are elongated transversely parallel to the tracheide walls just as in Scott's fossil (compare Pl. XCI, Fig. 2, with Pl. IX, Fig. 13, of Scott's paper). On the whole the parenchyma is less abundant than in the latter stem, giving an appearance of somewhat greater 'woodiness' to the new fossil. A very characteristic feature in *S. insignis* is the presence of numerous elements with dark contents scattered throughout the xylem parenchyma (Text-fig. 6); in the new stem these secretory elements are apparently absent except in the case of one 'meristele' (Text-fig. 10), in which such elements occur.

The xylem parenchyma is, in most places, very badly preserved, so that the apparent absence of secretory elements may be due to this cause. Here and there, however, in both transverse and longitudinal series, are

elements of a lighter colour, some giving an appearance of vacuolation; these may quite possibly represent the secretory cells, so abundantly present in the much better preserved wood parenchyma of *S. insignis*.

The position of the protoxylem is always exarch, and it is very common for the prominent protoxylem groups to run in pairs (Text-fig. 11. Compare with Scott's photograph,¹ Pl. IX, Fig. 11). In longitudinal sections the protoxylem is seen to be composed of spirally thickened elements which are succeeded

towards the inside of the stele or 'meristele' by denser spiral and then multiseriately pitted elements, the latter composing the bulk of the wood. In all the vascular strands the arrangement is similar (Pl. XCI, Fig. 3).

A characteristic feature of the fossil is the presence of a broad zone of secondary wood and bast, which entirely surrounds the primary wood in the main stele, and either entirely or partially encircles the 'meristeles'. The thickness varies in the stele and 'meristeles' of different sizes; in the former it may attain a breadth of 0.9 mm., but in the latter its dimensions are usually much smaller. The secondary tracheides are arranged in regular radial series, separated by medullary rays; frequently one series of tracheides only lies between two rays, though as many as 3-5 may occur. The average breadth of the medullary rays is from 3 to 4 cells, but their vertical

TEXT-FIG. 11. Transverse section of part of the primary xylem of a meristele, showing the 'paired' protoxylem groups. $\times 70$. *p.xy.* = protoxylem; x^1 = primary xylem.

¹ Scott: *Sutcliffia insignis*, loc. cit.

height is considerable. The principal rays extend from the parenchyma of the primary wood to the external limits of the secondary phloem, but shorter secondary rays may arise in the secondary wood. In some places the secondary xylem may be locally very parenchymatous in nature, the tracheide rows or files being 1-2 cells thick, while the medullary rays are 5-6 elements in breadth. The rays are made up of thin-walled parenchyma cells, in which the longest diameter lies in the radial direction.

The tracheides of the secondary wood are of the same multiseriate type as those of the primary xylem, though they are arranged with much greater regularity; their average diameter is distinctly smaller, being only 159μ . The diameter of the first-formed secondary tracheides is much less than that of the later formed ones, being only from 33 to 67μ , the full size of the elements being only gradually attained (Text-fig. 12, and Pl. XCI, Fig. 1).

Owing to the kindness of Dr. Scott, I had the opportunity of examining a section of *Sutcliffia insignis* in which secondary growth was just beginning, and it is of great interest to note that the size of the secondary tracheides which are there forming agrees exactly with the similar elements in the new stem.¹

TEXT-FIG. 12. Transverse section of part of the wood of the stele, showing the small size of the first-formed secondary elements. $\times 70$. *p.xy* = protoxylem; x^1 = primary xylem; x^2 = secondary tracheides; *m.r.* = medullary ray; *x.p.* xylem parenchyma.

No trace of cambium could be distinguished, but the preservation was not perhaps sufficiently good to warrant such an expectation.

It frequently happens that the continuity of the secondary wood is interrupted, the radial seriation of the elements starting afresh at a certain distance outwards, so that the new series no longer corresponds with the cells previously formed; the size of the elements after the break is always considerably smaller than before. At these places there is produced a superficial resemblance to an annual ring, but that it is merely superficial is clear from the fact that the phenomenon is purely local, and never extends completely round the stele; it is evidently due to some local irregularity in cambial activity (Pl. XCI, Fig. 1). It is interesting to note that

¹ Cf. Scott, *Sutcliffia insignis*, Plate VIII, Fig. 10.

an exactly similar peculiarity has been described by Scott¹ as occurring occasionally in the secondary xylem of *Medullosa anglica*.

2. *Structure of the Phloem.* The primary phloem is not preserved around the steles and 'meristeles', but a broad zone of secondary bast, usually very badly crushed, extends entirely or almost entirely round them; here and there the preservation is sufficiently good to enable some details of its structure to be observed. In most cases the zone appears to have attained considerable thickness, though lateral crushing has undoubtedly exaggerated the appearance to some extent.

The phloem elements are arranged with great regularity, the radial rows corresponding with the tracheidal series of the wood, while the medullary

TEXT-FIG. 13. Transverse section of secondary phloem. $\times 105$. *ph.* = thick-walled elements of phloem; *m.r.* = medullary ray; *s.c.* = secretory element.

rays are an extension of those present in the xylem. The phloem elements resemble those described by Solms-Laubach² as occurring in the secondary phloem of *Medullosa Leuckarti*, and by Scott³ in *M. anglica*; they appear to have thick cell-walls, so that the lumen in transverse section appears as a dot (Text-fig. 13). For reasons detailed in his paper, Solms-Laubach regards these elements as sieve-tubes, and this conclusion Scott considers as probably correct. The latter observer offers two suggestions to account for the thick-walled appearance presented by the elements.

The cell-walls may have been thin walled during life, swelling up greatly under the influence of maceration and decay in the period before petrification;

¹ Scott: *Medullosa anglica*, loc. cit., p. 90.

² Solms-Laubach: *Über Medullosa Leuckarti*. Bot. Zeit., 1897, p. 179.

³ Scott: *Medullosa anglica*, loc. cit., p. 90.

or, the apparent 'middle lamella' may represent the whole thickness of the wall, the thick-walled appearance being delusive and depending on some change in the cell contents. In the new stem the 'middle lamella' usually appears to be quite distinct from the remainder of the apparent 'thick wall', so that Scott's second suggestion would certainly appear the more probable explanation in this case. In longitudinal section the phloem is seen to be composed of strands of long, narrow, tapering elements (Pl. XCI, Fig. 4), and the short-celled parenchyma of the medullary rays; in the latter secretory elements frequently occur.

Immediately beyond the phloem lies a somewhat narrow zone of very badly preserved tissue containing numerous large, secretory sacs; this tissue appears to be sharply marked off from the cortex and may possibly represent the pericycle.

3. *Structure of the Leaf-trace Bundles.* The number of leaf-trace strands occurring in the series is extraordinarily small, and it is evident, considering the length of stem under examination, that the leaves could only have occurred at long intervals. It is known that some of the Permian Medulloseae were fair-sized trees,¹ and doubtless *Sutcliffia* should be included among them, though it is just possible that the suggestion put forward by Göppert and Stenzel² that some members of the family were climbers may apply here, but much more evidence needs to be brought forward before any definite statement can be given.

Where leaf-trace strands occur in the series they are always in clusters of two or three closely associated together, giving further weight to the suggestion that their derivation is by the breaking up of a 'meristele'; the only exception is the isolated trace derived from γ , but this is probably to be regarded as a premature phenomenon and not as a normal feature. In one case two adjacent, distinct leaf-traces appeared to be approaching preparatory to fusion, but whether this actually occurred cannot be stated, for the leaf-traces disappeared from the series before the critical region was reached. As in *Sutcliffia insignis*, two types of foliar bundles exist; the larger have several protoxylem groups distributed around the wood, and are thus radially symmetrical; the smaller have either one or a twin protoxylem group and are unilateral; in both cases the wood is exarch (Text-figs. 3, 14, and 15).

The zone of ground tissue is too narrow to determine whether the radially symmetrical strands bifurcate during their outward passage, producing unilateral foliar bundles; from the fact that in *S. insignis*³ the former occurred near the 'meristele' zone, and the latter in the leaf-base, it is probable that this takes place.

In both types of bundle the tracheides are mixed with parenchyma as

¹ Scott, D. H.: *Studies in Fossil Botany*, 2nd ed., Part II, p. 443.

² Göppert und Stenzel: *Die Medulloseae, eine neue Gruppe der fossilen Cycadeen*. *Palaeontographica*, 1881.

³ Scott: *S. insignis*, loc. cit., p. 57.

in *S. insignis*. The phloem round the radially symmetrical bundles is unfortunately always absent, though its preservation is almost perfect in some of the unilateral strands. When present, the bast forms a complete zone around the wood, though the distribution may be somewhat unequal, the thickness being greater on the side remote from the fibrous strands

TEXT-FIG. 14. Transverse section of a radially symmetrical leaf-trace bundle, just passing out through the secondary wood xy^2 . $\times 55$. The arrow indicates the direction in which the bundle is moving. $p.xy$. = protoxylem; xy^1 . = primary xylem; par . = wood parenchyma; ty . = tyloses. (Compare with Scott's *S. insignis*, Pl. IX, Fig. 14.)

(Text-fig. 3). A very characteristic feature of the phloem of the leaf-trace strands is the presence of a ring of large elements, usually occurring in the outer zone of the bast, though it may in places abut on the wood (Text-fig. 3). These large cells may occur singly, or two or three together, in the

latter case they are separated from one another by a delicate cell-wall. Their size varies somewhat, the larger cells being usually found on the side nearest the fibrous strands. The elements in question are precisely similar in appearance to those described and figured by Scott in *S. insignis* (p. 58, Pl. IX, Figs. 14 and 15, and Pl. X, Fig. 22) and by Seward¹ as occurring in *S. Williamsoni* (p. 211, and Pl. XIII, Figs. 6, 7, 8, 11, and 12). Seward in his fossil described various stages in the organization of these elements, and concluded that 'the characteristic receptacles which accompany the vascular bundles of *Rachiopteris Williamsoni* are of the nature of small secretory

TEXT-FIG. 15. Transverse section of a unilateral leaf-trace bundle. $\times 55$. xy^1 . = primary xylem; $p.xy$. = protoxylem; $f.s.$ = fibrous strand; $c.$ = cortex; $s.c.$ = secretory element. (Compare with Scott's *S. insignis*, Pl. IX, Fig. 15.)

canals, formed as the result of a schizolysigenous process. In one slide there is a solitary instance of a bundle-canal containing dark-coloured contents similar to that in the larger canals of the fundamental tissue, and possibly representing the remnants of secretion.' Scott, on the other hand, is 'inclined to regard the large elements of the phloem as sieve-tubes', and expresses some doubt as to 'the interpretation of these structures as developing canals'. In the new specimen the ring of small cells surrounding the scattered elements, which shows so clearly in *S. insignis*, does not usually occur, but the large elements sometimes show in the interior evidence of broken-down walls, giving the impression that the ring of small

¹ Seward, loc. cit.

cells did exist, and is being disorganized ; no sign of the early stages of development, such as are figured by Seward, were to be traced. In all the secretory elements so abundantly scattered throughout the specimen evidence of the secretion is seen either in the form of black carbonaceous matter, light coloured contents, or the appearance of vacuolation, but in no case have any of these signs of contents been observed in the large elements of the phloem. Longitudinal sections were not available for examination, but from Scott's observations on *S. insignis*, they are known to be long tubes. On the whole the new specimen does not materially add to the evidence which would elucidate the question of the nature of the elements in question. The absence of any sign of secretion and the distribution of the elements in the

TEXT-FIG. 16. Transverse section of a leaf-trace bundle showing periderm formation. $\times 70$.
pd. = periderm ; *xy'* = primary wood. (Xylem slightly restored.)

phloem (where the presence of such numerous secretory elements appears to be unparalleled) would incline to the view that they represent sieve-tubes.

An interesting feature occurs in two of the leaf-traces at the upper end of the stem. The bundles are of the unilateral type, and no phloem is present ; but immediately surrounding the primary wood a zone of periderm occurs (Text-fig. 16). The tracheides of the primary wood have obviously been injured in some way, probably by fungal growth, and the leaf-traces in consequence are being isolated by means of a periderm formation. A precisely similar case of isolation of a vascular strand which had been injured by a fungal attack has been observed in the hypocotyl of a seedling of *Allionia albida*.

V. THE GROUND TISSUE AND THE SECONDARY CORTEX.

The description given by Scott of the ground tissue of *Sutcliffia insignis* applies equally well in the case of the new fossil, for where patches of the cortex are preserved, 'the short-celled ground-parenchyma contains numerous sacs with carbonaceous contents, and is traversed by secretory canals and strands of sclerenchyma.' The latter are in almost every case grouped round the leaf-trace strands, where they occur in an arc of three or four groups, varying in size, and lying on one side of the bundle only.

A distinctive feature of the stem is the presence of a wide zone of tissue, which usually forms the limiting layer of the fossil, and which may attain a thickness of 15 to 20 elements in some parts. The elements composing this layer are clearly of secondary origin, for they are arranged with some regularity in radial series. Examination of longitudinal and transverse series shows the tissue to be composed of somewhat rectangular shaped cells, thin walled, and empty of contents, while occasional secretory elements run between them (Text-fig. 17).

The development of this tissue can be traced in the upper part of the series. In the delicate tissues of the inner region of the cortex, here and there partially preserved, certain cells show obvious signs that a tangential division has just been completed (Text-fig. 18); in others further divisions have taken place. There can be little doubt that periderm formation is here beginning. A comparison of the various stages of development between this beginning of periderm formation and the wide zone of tissue of secondary origin found lower in the stem has led to the conclusion that the latter represents only the secondary cortex produced by the phellogen. Support is given to this view by the fact that no sign of cambial activity can ever be detected on the inner margin of the tissue; moreover, the cells do not show the characteristic features usually associated with cork, and finally it appears improbable that secretory elements would

TEXT-FIG. 17. Transverse section of secondary cortex. $\times 70$. s.e. = secretory elements; i.s. = direction of the stele; o.s. = direction of the cortex.

occur in the midst of dead suberized tissue. If this be the case, then, the cork, and in some cases deeper seated tissues also, must have suffered destruction.

In any one section the zone of secondary cortex never extends in a continuous band round the vascular structures, but is found in arcs of greater or less extent. The fact that, in the upper region of the series, cork-cambium formation can be traced in what is obviously an old stem suggests that the phellogen may have had only a comparatively short period of activity before it was replaced by a new, more deeply placed arc

TEXT-FIG. 18. A. Beginning of phellogen formation. $\times 70$. B. Later stage of cork cambium development. $\times 55$. c. = cambium; s.c. = secretory element; f.s. = fibrous strand; o.s. = direction of cortex; i.s. = direction of stele.

of meristem; so that by successively formed layers of cork, each more deeply placed than the last, the stem would in time be composed only of the vascular cylinder and the last formed cork formations, a condition arrived at in the new stem of *Sutcliffia*, where practically all the cortex and the leaf-bases have been sloughed off as bark.

It is of great interest to record in this connexion, that Dr. Scott,¹ who very kindly examined two or three of my sections, remarked, 'I sometimes find very distinct bands of meristem in the cortex of my *Sutcliffia*, but they look more like the beginning of periderm than of vascular tissue. The inner cortex generally is very delicate and fit to originate meristems.'

¹ In a letter to Professor F. W. Oliver on June 22, 1912.

VI. THE EXTRAFASCICULAR STRANDS.

One of the most interesting features in the vascular anatomy of the new stem is the presence of numerous extrafascicular strands around the vascular system proper. In life it is probable that these strands formed a complete anastomosing network around the steles and 'meristeles', for in the fossil they extend round three sides; their absence on the fourth is accounted for by the fact that considerable injury occurred on this side in the course of petrification. The strands appear to cluster at the ends of the long diameter of the stem, but this appearance is perhaps partly exaggerated by the lateral pressure to which the stem has been subjected (Text-figs. 3 and 4). The arrangement of these extrafascicular strands varies considerably; usually they take the form of normally orientated bands of secondary wood and bast, frequently they assume a fan-shaped appearance, incompletely concentric structures may occur, rarely nearly perfectly concentric bundles are found, while in one case a band-like strand showed inverted orientation of the vascular tissues. The size as well as the arrangement of these strands shows great diversity (Text-fig. 2 and Pl. XCI, Fig. 1). In every case, no matter what the size, arrangement, or orientation of the strands, there are found on the side of the wood remote from the phloem a number of short isodiametric tracheides (Text-fig. 19).

TEXT-FIG. 19. Transverse section of part of an extrafascicular strand, showing isodiametric tracheides (*t.t.*) on its inner margin. *xy?* = secondary xylem. $\times 84$.

These short broad tracheides have, as a rule, reticulate markings on their walls, though occasionally pitted elements seem to be present. Their average maximum diameter is about $100\ \mu$; their length, which is slightly greater, averages $66.6\ \mu$. They are clearly marked off from the long, multiserially pitted tracheides which compose the bulk of the wood of the extrafascicular strands, for the diameter of these elements only reaches about $58\ \mu$, although in some strands the dimensions are greater and may reach $115.8\ \mu$;¹ it is very difficult to determine clearly the short

¹ They are thus somewhat smaller than the secondary tracheides of the stele and 'meristeles', the average diameter in the latter case being $159\ \mu$.

tracheides of the more or less concentric strands owing to the crushing which has usually taken place.

Scattered throughout the series in the band of tissue immediately beyond the secondary phloem of the 'meristeles' (probably the pericycle) are found clusters of isodiametric tracheides with reticulate markings exactly resembling those which occur on the inner margin of the wood of the extrafascicular strands (Pl. XCI, Fig. 5). It is suggested that these strands of short tracheides may have been directly derived from the delicate parenchyma cells of the inner cortex to facilitate the storage of water. Strands or clusters of storage tracheides once having been formed may possibly have provided a starting-point or 'nucleus' around which cambial activity being initiated secondary formation of xylem and phloem began; the ultimate product of the secondary growth being the diversely organized extrafascicular arcs which form so characteristic a feature of the fossil. It may perhaps be pointed out here, though the question will be discussed later, that these strands are regarded as entirely secondary structures and are not considered to have any phylogenetic connexion with the stele or 'meristeles'.

The short tracheides at once recalled the somewhat similar, pitted, isodiametric tracheides described by Seward¹ in *Megaloxylon*, but in that genus they compose the bulk of the primary wood, and they certainly have no connexion with that tissue in *Sutcliffia*. The occurrence of parenchymatous tracheides, reticulately marked but with scattered bordered pits, has been described by Rothert² as present singly or in groups in species of *Cephalotaxus* where they represent modified elements of the pith. As in the case of *Megaloxylon*, the function of water storage is assigned to them, and a comparison is instituted with the similar cells found in *Nepenthes*, *Salicornia* sp., *Crinum*, and certain members of the Orchidaceae. Thus the conversion of parenchymatous cells into short tracheides for the purpose of water storage appears to be a not uncommon phenomenon.

In this connexion it may be noted that Lang³ observed the occurrence of short tracheides in a species of *Ophioglossum*; they were mixed with the parenchyma of the pith and 'apparently derived by the conversion of some of the medullary cells into tracheides'. A similar phenomenon may occur in *Botrychium*. Lang notes, however, that in both cases the stimulus to the development of the tracheides may have been traumatic.

The fact of the greatest interest in connexion with these extrafascicular

¹ Seward, A. C.: Notes on the Binney Collection of Coal-Measure Plants. Part II, *Megaloxylon*, gen. nov. Proc. Camb. Phil. Soc., vol. x, Part III, 1899.

³ Lang, W. H.: On the Interpretation of the Vascular Anatomy of the Ophioglossaceae. Mem. and Proc. of the Manchester Lit. and Phil. Soc., vol. lvi, Part II, 1912.

strands is the extraordinarily close parallel they afford with the successive vascular rings characteristic of certain genera of the Cycads, namely, *Cycas*, *Encephalartos*, *Macrozamia*, and *Bowenia*. Not only is the arrangement of the secondary strands in arcs, fan-shaped masses, and occasionally concentric bundles closely similar in *Sutcliffia* and in the above-mentioned genera of the Cycads, but comparison with the descriptions and figures given by Worsdell¹ in his series of papers on Cycadean anatomy shows that the intimate structure is practically identical also. Large isodiametric tracheides occur at the edge of the wood in both cases, the great development of the medullary rays results in a very parenchymatous xylem in both living and fossil stems, while in both occasional inversion of the strands is found.

One further point still remains to be considered, namely, the origin of the extrafascicular strands of the Cycads. Worsdell (loc. cit., 1900, p. 452) considers the large, irregularly-shaped, reticulately thickened tracheides of the extrafascicular rings are homologous with the reticulate tracheides of the central region of the cortical concentric strands of the stem and leaf of *Cycas*, and in this genus he was able to observe their development. In *Cycas revoluta*, Thunb., he found 'the first-formed vascular elements arose by tangential division of the large, rounded or angular, cortical or pericyclic cells resulting in the large, isodiametric, irregularly-shaped tracheides of precisely similar shape to those cells. After one or more such elements have been cut off, the parenchyma cells begin to divide radially as well as tangentially, in this way forming smaller and smaller elements with each centrifugal division, until at length the majority of the tracheides are of the same size and shape as those of the central cylinder or stele.' The displacement of the large first-formed tracheides by pressure of surrounding tissues, and the great difference in size between them and the later-formed ones, render 'the determination of their mode of origin, at an older stage of the same vascular tissues, utterly obscure. The similar reticulate tracheides in the cortical concentric strands . . . in all probability arise in precisely the same way.' [It is of interest to note that in an isolated, concentric strand in the cortex of the upper regions of the hypocotyl of one seedling of *Macrozamia spiralis*,² the central core of the bundle consisted of short tracheides which were surrounded by a zone of cambium and cambiform cells, the few immature xylem-elements present were developed centrifugally from the centre of the bundle.] Quotation at length has been made from Worsdell's paper

¹ Worsdell, W. C.: I. The Anatomy of the Stem of *Macrozamia* compared with that of other Genera of Cycadeae. Ann. of Bot., vol. x, 1896. II. ² Hill, T. G., and de Fraine, E.: On the Seedling Structure of Gymnosperms. III. Ann. of Bot., vol. xxii, 1909, p. 442.

because the description given by him appears to explain in a satisfactory manner the way in which the similar strands in *Sutcliffia* may possibly have arisen from parenchyma cells. It is, however, impossible to state the mode of origin with certainty, as no stages between the clusters of tracheides formed from cortical or pericyclic cells and fully formed arcs or strands were observed.

The investigations of Weber and Sterzel¹ have shown that in *Medullosa stellata*, var. *gigantica*, and probably also in *M. Solmsii*, var. *lignosa*, extrafascicular zones of vascular tissue occurred outside the system of steles, and that these zones were very similar to those found in Cycads of the present day. Scott² also found that in *Medullosa anglica* irregular bands may occur in the stem which are 'probably best regarded as extrafascicular new formations, comparable to . . . the irregular strands which sometimes occur in the extrafascicular region of *Macrozamia*'.

There still remains one further structure of interest to be described, a strand which appears in a few sections only, and which lies beyond the other vascular tissues. It consists of a concentric bundle of fair size, the maximum diameter being about 2 mm., the whole being slightly elongated tangentially (Pl. XCII, Fig. 6). Short isodiametric tracheides with reticulate markings form the bulk of the central region of the strand (Pl. XCII, Fig. 7), and round them lies a zone of secondary wood, completely encircled by secondary phloem; the structure of the latter appears precisely similar to that surrounding the stele and 'meristeles'. All the wood elements are smaller than those of the extrafascicular strands: the average diameter of the secondary tracheides only reaches $33.3\ \mu$, whereas in the former they are usually $115.8\ \mu$. The short tracheides have a diameter nearly twice as great as the elements of the secondary wood, and are $58.3\ \mu$ broad.

The resemblance of this strand of the accessory vascular strands of *Medullosa anglica* is very striking. Scott instituted a comparison between these latter and the cortical bundles of *Cycas*, and states that he regards them, as also the extrafascicular bands, as 'characteristic Cycadean anomalies', which comparison and interpretation might well be extended to *Sutcliffia* also.³

VII. ATTRIBUTION OF THE SPECIMEN.

The fossil stem here described has been attributed to the genus *Sutcliffia* on account of the close resemblance it exhibits to the only other stem of the genus at present known, viz. *Sutcliffia insignis*. The general structure of the vascular system is identical in the two fossils, for both have a simple

¹ Weber und Sterzel : Beiträge zur Kenntnis der Medulloseae, p. 116, and Taf. viii, Fig. 2.

² Scott, *Medullosa anglica* : loc. cit., p. 98.

³ Compare Scott, *Medullosa anglica*, loc. cit., p. 98, Pl. XII, Fig. 18, with Pl. XCII, Fig. 6 of this paper and with Worsdell, loc. cit., 1898, Figs. 6-8, 1896, Figs. 2, 9, and 10.

protostele¹ surrounded by large, irregular masses of vascular tissue, detached from or in connexion with the main stele. The origin and subsequent behaviour of these vascular masses ('meristeles') is very similar; in both cases they are derived by the separation of portions from the protostele, and in both these detached portions undergo further irregular division. In *S. insignis* the meristeles 'form the points of departure for the actual leaf-traces',² while in our specimen evidence is afforded that they are entirely used up in the production of foliar bundles.

Fusion between 'meristeles, probably of quite distinct origin', occurs only in the type specimen, but re-fusion of 'meristeles' with the meristeles of similar origin, and with the protostele, has been described for our fossil (p. 1039). In both cases the 'meristele' repeats the structure of the protostele on a small scale.

The leaf-trace strands form a further feature of comparison between the two specimens, for in both stems the foliar traces are concentric and the structure is exarch, and, moreover, two types of leaf-trace bundles are present in both, namely, the unilateral and the radially symmetric.

Finally, the agreement in histological details between our stem and that of *S. insignis* is very striking. The structure and composition of the primary wood is very similar in the two cases, and the beginning of secondary growth in *S. insignis* agrees closely with the first formed secondary tracheides in the new specimen. The primary phloem surrounding the leaf-trace bundles shows the same peculiarities in both stems. The strands of fibrous elements with the closely associated secretory elements, and the great abundance of secretory cells throughout the tissues, are characteristic features common to both.

Thus, a consideration of the general structure of the stem, the origin and behaviour of the 'meristeles', the leaf-trace bundles, and the close agreement in histological details in the two stems leaves little room for doubt that the relationship between them is exceedingly close. The question next arises whether the differences which occur are sufficient to warrant specific distinction, or whether they can be explained on any other grounds.

The outstanding feature which characterizes our stem is the great development of the secondary tissues around the stele and 'meristeles', coupled with the network of extrafascicular zones and accessory vascular strands; the absence of any leaf-base forms a further feature of difference. The latter is undoubtedly to be correlated with the formation of periderm; in *Sutcliffia insignis* cork was absent, though, as Scott has pointed out,³ arcs of meristem were in process of formation; so the absence of leaf-bases may therefore well be attributed to the greater age of the stem. It appears

Using the term in the sense in which it is employed in Tansley's 'Lectures on the Evolution of the Filicinean Vascular System'. New Phyt., 1908, p. 138.

² Scott: loc. cit., p. 54.

³ See footnote, p. 1052.

extremely probable that the presence of the secondary tissues and the extrafascicular strands may be explained on the same grounds, for in *S. insignis* slight secondary growth had taken place around the stele and 'meristele' in the lower parts of the specimen, and the resulting tracheides agree absolutely with those in the new stem.

The apparent absence of secretory elements from the xylem parenchyma constitutes the most serious difficulty in assigning the fossil to *Sutcliffia insignis*, but in one 'meristele' such elements can be readily detected (Text-fig. 10), and, moreover, it appears very probable that under more favourable preservation similar elements would be found generally distributed among the primary tracheides (see p. 1044).

Until further evidence is available it would appear desirable, therefore, to attribute, provisionally, the new specimen to *Sutcliffia insignis*; on this view Scott's specimen would be the stem in its young state, whereas the present fossil would show the complexity¹ attained in the older, though smaller, plant.

VIII. AFFINITIES.

In the original description of the genus, *Sutcliffia*² is included in the family Medulloseae, and as the reasons for this conclusion are so fully stated there, it is quite unnecessary to add further remarks on this question. The additional data afforded by the new specimen only serve to bring into still closer relationship the two genera, *Sutcliffia* and *Medullosa*, through some such forms as *Medullosa anglica*, the simplest and geologically oldest known member of its genus.³ The protostele of *Sutcliffia*, with its wide zone of secondary tissues, bears a very close resemblance to one of the three steles of *M. anglica*, the main difference depending upon the mesarch nature of the protoxylem in the latter species compared with its universally exarch structure in the former. Extrafascicular strands of wood and bast and accessory vascular bundles are present in both; and finally there appears to be no serious objection to the view that the 'meristele' of *Sutcliffia* are homologous with the leaf-trace strands which leave the stele in *M. anglica*, for both appear to be entirely used up in the formation of foliar bundles.

It remains to be considered whether the new specimen throws any further light on the affinities of the Medulloseae with other groups. Scott expressed the view that *Sutcliffia* is 'the most primitive member of the Medulloseae yet discovered', though he continues, 'it is doubtful, however, whether it lay on the direct line of descent of any of the more complex types with which we are acquainted.' He considered that its structure 'has not advanced very far beyond the simple protostelic condition' of such a form

¹ Cf. Scott, *Sutcliffia insignis*: loc. cit., p. 54.

² Scott, *Sutcliffia insignis*: loc. cit., pp. 63-5.

³ Scott, *Medullosa anglica*: loc. cit., pp. 114-15. Studies in Fossil Botany, Part II, 1909, p. 428.

as *Heterangium*; moreover, he suggests that 'the whole course of evolution from the protostele to the more elaborate dialystelic type may have been gone through within the family', i. e. 'the Medulloseae are their own interpreters.' Finally, Scott suggests the probability of a common origin for the Lyginodendreae and Medulloseae 'from a point not very far below the level of stems such as those of *Sutcliffia* and *Heterangium*'.¹ The great possibility of the origin of the Medulloseae from a group of Fern-like ancestors has thus received full treatment; it is on the probable affinities in other directions that the new specimen appears to give further evidence.

The question of the relationship between the Medulloseae and the Cycadaceae has been so fully discussed that it would seem superfluous to reopen the question, were it not for the fact that the new specimen of *Sutcliffia* appears to throw additional light upon it. Two main theories have been held with regard to the origin of the anatomical peculiarities of the Cycads. Scott² considers that 'so far as the anatomy of the stem is concerned, *Lyginodendron* appears to come near the Cycads, for the general organization is of a similar character, and the mesarch structure of the bundles is still retained in the peduncles of the cones of some recent Cycads as well as in the leaves'. He regards the Medullosean stem as anatomically different from that of recent or Mesozoic Cycadophyta 'in being polystelic (except in the protostelic *Sutcliffia*, which does not affect the question)'. The extrafascicular cylinders found in certain Cycadean genera are 'local peculiarities in the vascular system . . . due to anomalous distribution of the cambium' and are not to be regarded as of ultimate phylogenetic significance.

A second theory deriving the Cycads from the Medulloseae has been advanced by Potonié,³ and independently stated and elaborated by Worsdell.⁴ The view of Matte⁵ differs from these observers in certain respects, for he considers 'les Cycadacées comme dérivées de Lyginodendrées ou d'une famille voisine par l'intermédiaire des Médullosées'. In a recent account of the Pteridospermae Chodat⁶ summarizes his views of the relation between Medulloseae and Cycadaceae as follows: 'Les Médullosées nous apparaissent donc comme des Protocycadacées'; and he further states that 'il nous est impossible de trouver dans l'anatomie des *Lyginodendron* la moindre analogie avec celle des Cycadacées'. The main reason for the last state-

³ Potonié, H.: Lehrbuch der Pflanzenpalaeontologie. 1899, footnote on p. 168.

⁴ Worsdell, loc. cit. The paper of 1906 contains a full résumé of his views and the evidence on which they are based.

⁵ Matte, H.: Recherches sur l'appareil libéro-ligneux des Cycadacées. Caen, 1904, p. 211.

⁶ Chodat, R.: Les Pteridopsides des temps paléozoïques; étude critique. Arch. des Sci. phys. et nat., t. xxvi, 1908, p. 38 and p. 17.

ment centres round the nature of the primary strands, for in agreement with Bertrand and Corneille,¹ Chodat regards these in *Lyginodendron* as 'divergeants du type *Osmunda* en ω renversé, les deux ailes du divergeant se rebattent en arrière et finissent par se réunir par leurs pôles'; this is a not uncommon type in the Ferns, whereas in the stem of Cycads no 'divergeants' occur, the stem, as in other Gymnosperms, being composed of a 'couronne de faisceaux endarqués'. The views of Chodat thus summarized have been considered at some length by Weiss,² who concludes that the criticism seems 'sufficiently weighty to demand a careful reconsideration of the structure and affinities of *Lyginodendron*'.

The theory which would derive the Cycadaceae from the Medullosean line has been most fully discussed by Worsdell.³ He regards the normal vascular ring in the Cycad as composed in reality of 'the one-sided remnants of a number of steles', while the extrafascicular arcs and concentric bundles characteristic of some Cycadean genera are 'remnants of some ancient structure' which 'consisted of rings or layers of concentric vascular strands'.⁴ The evidence adduced by Worsdell in favour of the Medullosean ancestry of the Cycads is based upon structure observed (1) in the cotyledonary node, and (2) in the 'flowering' axis. It is not intended to enter here into a full discussion of the evidence afforded by the 'flowering' axis, but it would appear that the incurved and horseshoe-shaped bundles of *Stangeria* described by Worsdell have had far too weighty phylogenetic significance attached to them;⁵ it has yet to be proved that far-reaching conclusions of such a type can be based, legitimately, upon evidence afforded by a structure such as the 'peduncle', in which special circumstances⁶ and physiological needs must play an important part.

The evidence brought forward as supplied by the cotyledonary node is that given by the concentric structures around the main axis in certain species of *Cycas*, *Encephalartos*, *Macrozamia*, and *Bowenia*, which give the seedling an appearance of 'polystely' in this region. The strands are

¹ Bertrand, E. C., et Corneille, F.: La masse libéro-ligneuse élémentaire des Filicinaes actuelles. Travaux et Mémoires de l'Université de Lille, 1902, t. x, Mém. no. 29.

² Weiss, F. E.: Presidential Address to the British Association for the Advancement of Science, Section K, Portsmouth, 1911.

³ Worsdell: loc. cit., 1906, p. 137.

⁴ The supporters of the Medullosean ancestry for the Cycads had not, at the time they wrote, the advantage of considering a relatively simple member of the group such as *Sutcliffia*.

⁵ It may be pointed out that Scott considers that the mesarch bundles which occur in the peduncles of the cones in certain genera of the Cycads, e.g. *Stangeria*, represent the retention of a primitive character by the 'floral axis'. Scott, D. H.: The Anatomical Characters presented by the Peduncle of the Cycadaceae. Ann. of Bot., vol. xi, 1897; and Studies, pp. 365-6.

⁶ The observations of Thoday on the inflorescence axis in *Gnetum* sp. are of considerable interest in this connexion. Thoday (Sykes), M. G.: Note on the Inflorescence Axis in *Gnetum*. Ann. of Bot., vol. xxvi, 1912, p. 621.

described in detail by Worsdell,¹ Gregg,² Matte,³ and Hill and de Fraine,⁴ and are regarded by the first-named observer as giving additional weight to his view. The case of the seedling stem of *Encephalartos Barteri* is also brought forward as further evidence of its original polystelic ancestry. Matte⁵ found in one individual only of this species three practically independent, distinct steles in place of the usual endarch cylinder; this both he and Worsdell compare with *Medullosa anglica*, and regard as of the highest significance. This anomalous structure is undoubtedly of great interest, more especially when it is compared with a somewhat similar abnormal case of seedling anatomy described by Shaw⁶ as occurring in a single specimen of *Araucaria Bidwillii*. This observer correlated the abnormality with the tuberous habit of the seedling, and it is interesting to note, therefore, the somewhat similar tuberous appearance presented by the seedling of *Encephalartos Barteri* (Matte, Pl. XVI, Fig. 257). The question remains to be considered whether the cotyledonary node supplies reliable data for the elucidation of phylogenetic problems. The attention of several investigators⁷ has been directed of late years to the answering of this question, and, so far as one can judge from the evidence at present available, it is inadvisable to apply characters of seedling anatomy to solve broad phylogenetic questions. Only the main points of the evidence brought forward by Worsdell have been outlined, and no attempt at a complete discussion has been made, but it is hoped that sufficient indication has been given to show that the origin of Cycads from 'polystelic' ancestors is not yet satisfactorily proved. It is fully agreed that the probable origin of the Cycadaceae is along the Medullosean line, but from monostelic rather than from 'polystelic' forms. It is suggested that the central cylinder of a Cycadean stem was probably derived from a protostelic form, such, say, as occurred in the genus *Sutcliffia*, by the gradual disappearance of the internal tracheides. Extrafascicular zones and accessory cortical strands occur in precisely the same form in *Sutcliffia*, *Medullosa*, and recent Cycads. What the origin of these structures may be it is impossible at present to say, but there is no

G., and de Fraine, E.: On the Influence of the Structure of the Adult Plant upon the Seedling. New Phyt., Oct., 1912.

conclusive evidence to show that they were in any way connected with the original central cylinder; it is possible that they have arisen later and independently of it. Their function is evidently to provide an increased water-storing and conducting tissue for the plant, and it is suggested that as radial increase progressed in response to the increased physiological requirements, the increased vascular needs were provided for by extrafascicular arcs and strands which arose independently in the cortex, and which are not therefore to be derived by reduction from a system of steles. From such a type as *Sutcliffia*, which may be regarded as the most primitive member of the Medulloseae at present known, it is suggested that two divergent lines may have arisen. The one advanced with increasing complexity in the direction of multiplication of the number of steles, through some such form as *Medullosa anglica*, and ended blindly in the more complex Medulloseae, the extraordinary complexity of the series of steles and the anastomosing medullary and cortical 'star rings' possibly proving too cumbrous and not sufficiently plastic to allow of further evolution along these lines. The other maintained the protostelic condition, and advanced by further modification of the single vascular cylinder, and perhaps by the elaboration of the extrafascicular arcs and accessory vascular strands of the cortex, in the direction of the Cycadales.

It is to be hoped that the discovery of further fossil forms may shed additional light on this question, for the evidence connected with the reproductive organs which is at present available, tends to show that the Medullosean seeds such as *Trigonocarpus* and *Stephanospermum* are in substantial agreement in certain respects with the genera of living Cycads.¹ And in this connexion it may be noted that the recent investigation of the ovule of *Bowenia spectabilis* by Kershaw² shows that as regards structure, and development of the pollen-chamber, 'the closest parallel to the Cycads among fossil seeds is to be found in seeds of the *Trigonocarpus* affinity, and there seems to be no evidence in either of them that this structure had resulted from simplification of a more complicated type, such as that of the Lagenostomales.' Kershaw further points out that not only in the pollen-chamber, but also in respect of the integument and vascular supply, there is a very close connexion between Cycadean seeds and those of the Medulloseae.

Further, as Scott³ has already shown, 'the structure of the petiole and the organization of the leaves generally are very similar in Medulloseae and Cycadaceae.'

² Kershaw, E. M.: Structure and Development of the Ovule of *Bowenia spectabilis*. *Ann. of Bot.*, vol. xxvi, July, 1912.

³ Studies, loc. cit., p. 649.

Hence, at the present time, the balance of evidence drawn from both the vegetative and reproductive features favours the view of the Medullosean ancestry of the Cycads,¹ through some protostelic form.

IX. SUMMARY.

1. *Structural facts* (Sections II-VI, pp. 1033-56). The specimen consisted of a stem of large size and considerable complexity of structure. The vascular system was composed of a protostele, from which large leaf-trace strands ('meristeles') were given off. These large leaf-traces divided up into smaller ones and were finally completely used up in the formation of either unilateral or radially symmetrical concentric foliar traces.

The vascular strands of all orders, with the exception of the ultimate foliar traces, were surrounded by a wide zone of secondary tissue.

Extrafascicular bands of wood and bast formed a network round the stele and large leaf-trace strands; they showed occasional inverse orientation. Accessory vascular bundles also occurred.

A wide, irregular, discontinuous zone of secondary cortex surrounded the greater part of the stem; it lay immediately outside the vascular structures.

The primary xylem consisted of tracheides intermixed with xylem-parenchyma; the protoxylem, which frequently occurred in paired groups, was in all cases exarch.

The primary and secondary tracheides both showed multiseriately arranged bordered pits on the radial walls; the protoxylem consisted of spirally marked elements.

Short, broad, isodiametric tracheides occurred on the inner edge of the xylem of the extrafascicular strands, and occupied the central region of the accessory vascular bundles.

The phloem of the leaf-traces contained a ring of large elements, probably of the nature of sieve-tubes. The secondary phloem in all cases consisted of strands of narrow, apparently thick-walled elements, embedded in parenchyma.

The 'pericycle' and cortex have abundant secretory elements varying very much in size; in some cases the contents are preserved in the form of black carbonaceous matter, others present a vacuolated appearance.

The concentric foliar bundles were partially surrounded by strands of fibrous elements.

2. *Attribution* (Section VII, pp. 1056-8). The stem is included in the genus *Sutcliffia* on account of the general structure of the vascular

¹ Compare with the tentative statement in *Studies*, p. 650.

system, the origin and behaviour of the 'meristele', the leaf-trace bundles, and the close agreement in histological details.

It is provisionally attributed to *S. insignis* because the features which characterize the stem (i. e. the secondary tissues, the extrafascicular arcs, the secondary cortex, and the absence of leaf-bases) are considered to be most probably due to age of the plant.

3. *Theoretical conclusions* (Section VIII, pp. 1058–63). It is suggested that the origin of the Cycadaceae is to be sought along the Medullosean line from some such genus as the protostelic *Sutcliffia*, the central cylinder of the Cycads being probably derived from the protostele by the gradual disappearance of the primary internal tracheides. The extrafascicular arcs and accessory vascular strands are regarded as homologous in *Sutcliffia*, *Medullosa*, and the Cycads; they are not considered to be derived by reduction from a system of steles, but to have arisen independently of the central cylinder, possibly in response to increased physiological requirements.

It is suggested that two divergent lines may have arisen from some such primitive type as *Sutcliffia*, as follows:

DE FRANE—SUTCLIFFIA.

The Structure and Development of the Haustorium of *Striga lutea*.¹

BY

EDITH L. STEPHENS, B.A., F.L.S.

With Plate XCIII.

STRIGA LUTEA, Lour.² (the Witchweed or Rooibloem—'Red Flower') is a semi-parasitic annual belonging to the Order Scrophulariaceae. It occurs in scattered localities throughout Zululand, Natal, and the Transvaal, on various native grasses and also on *Zea Mays*, which is an important South African food-crop. Its life-history is now being studied by Professor Pearson, to whom I am indebted for the supply of material and for much helpful information as to its life-history and mode of growth. Most of the material investigated was collected by him on the maize crops in the Transvaal; the remainder was obtained from cultures of *Striga* on the maize reared in this laboratory.

THE PLANT.

Striga lutea is a root parasite which passes a portion of its life-history underground in the form of a slender white shoot bearing scales, leaves, and numerous adventitious roots. Later, the shoot grows above ground into a slender green-branched stem, 2 to 18 inches high, bearing decussating pairs of linear leaves and spikes of bright red flowers.³ The adventitious roots arising from the underground portion of the shoot branch freely and come into contact with the root-system of the maize plant on which the seedling parasite has established itself. The roots of host and parasite form a network in which those of the *Striga* plant are readily distinguished by the absence of root-hairs, by their transparency and paler colour (the endodermis of the maize showing through the cortex and giving the root a yellowish tinge), and often also by the presence of small patches of a reddish secretion (giving reactions for mucilage) on their surface. At points where roots of the two come in contact or approach one another

³ See figure of plant, Burt Davy ('04), Plate LXXIV A.

appearance characteristic of the developing root, which has here an ordinary endogenous development. Numbers of young lateral roots and haustoria have been seen arising side by side on the mother root, and it is clear that there is no resemblance between them in origin, development, or structure.

(c) **Connexion with Host.**

Penetration of the soft cortical tissues of the maize root is rapidly effected when once the haustorium comes into contact with it. Stages in which the tip of the haustorium has not already penetrated to the endodermis are rarely found. When the epidermal cells of the haustorium touch the host root they begin to elongate, forming papillae of a finger-like form and arranged in palisade rows, which bore their way between and through the cortical cells of the host. Their passage is effected by a ferment they secrete, which swells and ultimately dissolves the cell-walls which it touches. The margin of the advancing haustorium is marked by an irregular clear bright yellow or yellow-brown line, presumably this ferment plus the dissolved tissues of the host, and the same yellow line is often seen round individual papillae which have grown beyond the level of the rest of the haustorium. This line is represented (marked *f.*) in Figs. 5-8. It stains with safranin, but not with haematoxylin; microchemical tests to determine its nature have yielded no results. The walls of the cells of the host to a distance of several cells from the haustorium may become swollen with the action of the ferment, when they also take on this yellow colour and stain in a similar way (cf. the walls of the endodermal and cortical cells bordering the line of ferment in Fig. 7). The pressure due to growth assists in the passage of the haustorium through the tissues of the host, but to a much less degree, as is shown by the fact that very little collapsed tissue is seen in the path of its advance. Growth pressure is in evidence when individual papillae have to penetrate a hard-walled vessel, as in Fig. 7, where a papilla has evidently had considerable difficulty in penetrating into the central vessel of the maize stele. The wall of the latter has been pushed in, and the length of time that the papilla has taken to effect an entrance can be seen by the spiral thickening formed nearly down to its tip.

A series of longitudinal sections through a haustorium soon after penetration (or an optical section such as Fig. 5) shows that the central papillae have reached the endodermis, and have flattened their ends against it to form several regular palisade layers. With regard to Fig. 5, it must be remembered that it is a *median* optical section; focusing slightly above or below the level of the section, the papillae in front of and behind the layer figured as abutting on the endodermis can be seen as it were crawling over its surface trying to effect an entrance. As soon as the ferment touches the endodermis, the contents of the cells of the latter disappear, and their outer walls swell (Fig. 7). In Fig. 8 is seen an endodermal cell in longitu-

dinal section, with several papillae touching its outer wall. This has become so swollen and dissolved by the ferment they have secreted that only its inner line is distinguishable; and the inner wall has also begun to swell. The walls of the endodermal cells in the maize are thicker than those of the cortical cells, the inner considerably so, and the haustorium may enlarge to almost its mature dimensions while the papillae are trying to penetrate them.

Meanwhile, the strand of elongated cells forming the axis of the young haustorium has become converted into the line of tracheides seen in Fig. 5, running from the vessels of the parasite down through the centre of the haustorium to the stele of the host. Sometimes this line of tracheides begins to form almost immediately after the haustorium has begun to penetrate the tissues of the host; sometimes it is only laid down after some amount of cell-division has taken place in the haustorium. The latter seems to be the case when parasite and host lie close together, so that a comparatively short haustorium is formed; the former when the haustorium has had to grow out to some length, and thus is further from the water supply of its mother root. In any case, this line of tracheides is formed in the same way, and apparently always before the haustorium has penetrated through the endodermis, which it takes some time to do. Spiral markings appear in the cells of the two or three layers which lie between the vessels of the mother root and the base of the line of elongated cells forming the axis of the haustorium. The spirals run in the same direction as those of the vessels, and the tracheides thus formed make a little hump on the vascular strand, which links it with these axial cells. (These connecting tracheides can be seen at the junction of the vascular system of the mother root with the axial strand of tracheides in Fig. 5. The two lines of tracheides which appear in the figure to end blindly in the nucellus close to the vascular strand are seen at a slightly higher focus to link on to it by similar connecting tracheides.) In the lowest of these axial cells, i.e. the one contiguous with the connecting tracheides, spiral thickening now appears, and each successive cell in the same longitudinal row becomes converted into a spirally thickened tracheide. Later on, other tracheides are added to this strand by the appearance of spiral markings in the papillae that are striving to pierce the endodermis of the host, and in the cells running up behind them (cf. Fig. 8). A few tracheides have been added in this way to the axial strand of Fig. 5. Comparing it with that of Fig. 6, it will be seen that as these additional tracheides follow the line of the maize stele, the central strand is lenticular in shape, although the haustorium when mature is almost globular. Occasionally in the case of a large haustorium a branch of the axial strand may be formed later on in the 'nucleus' (cf. the left-hand haustorium in Fig. 1).

While this axial strand has been forming, active division has been

taking place in the cells surrounding it. These divide up to form a mass of small transparent nucleated cells—the 'nucleus'. It is interesting to note that this appears to be formed entirely by the renewed division of cells derived from the original subhypodermal layer of the mother root. The two outer layers of the haustorium (derived from the two outermost layers of the root) merely divide to form a cortex several layers in thickness (c., Figs. 1, 5, 6; in Fig. 5 the cortex is still only two layers thick in the lower portion of the haustorium). In the younger stages, as Fig. 5, this cortex is still clearly marked off from the small meristematic cells of the 'nucleus', but later on the outer cells of the latter enlarge, lose their slightly rounded outlines, and pass over into ordinary cortical cells (cf. Fig. 6). Around the axial strand, however, they seem to remain active until the death of the haustorium, and perhaps play some part in the transmission of elaborated food-stuffs from host to parasite.

By the time the 'nucleus' is well formed, a line or group of papillae (those which were the first to penetrate the host root) have bored their way through or between the endodermal cells, and are now tapping the vessels of the stele. They penetrate to various depths; in Figs. 6 and 7 one is just entering the large central vessel. Their ends flatten against the vessels as they did against the endodermal cells, and the ferment they secrete dissolves the wall of the vessel. Sometimes the papilla then grows on and penetrates through the opposite wall into the next vessel (cf. Fig. 7), sometimes instead its tip becomes dissolved together with the wall, so that it forms a side pipe tapping the vessel. One vessel may be tapped in this way by a longitudinal row of papillae. Spiral thickenings run up the papillae to their tips, and the tracheides thus formed constitute an efficient conducting system between the xylem of the host and that of the parasite. The further development of the haustorium is the result of the continued division of the cells of the 'nucleus', which causes the haustorium to grow down on either side of the host root till it may come to resemble an india-rubber ball with a stick (the maize root) pressing it in along one side. Several cases have been seen in which the lips of the haustorium had closed round the maize root and destroyed its cortex till its stele appeared to be almost embedded in the haustorium.

Examination of a large range of material has shown that the course of development outlined above is followed in practically every case. The very few exceptions that have been seen will be discussed later in connexion with the comparison of the *Striga* haustorium with that of other plants. The development of haustoria on the underground shoot may be mentioned here; this is occasionally seen when a maize root comes in contact with the shoot. No early stages of development of these haustoria have been found, but sections through several mature haustoria have shown them to be of the usual type, except that they are almost embedded in the

cortex of the stem, and that the tracheides, lacking the definite point of development afforded by the vascular system of the root, run in scattered lines through the 'nucleus' instead of in a central strand. The 'nucleus' seems to grow backwards through the stem, and the lines of tracheides run back with it till they meet and link on to the vessels of a leaf-trace. If they do not meet a leaf-trace, they simply end blindly in the 'nucleus'.

(d) Mechanism of Nutrition.

The whole question of the nutrition of this parasite, especially during the underground portion of its life-history, is obscure. While the water-carrying vessels of host and parasite are connected so as to allow of a free passage of water and salts, there is no such conducting system for assimilated food. No sieve-tubes are formed in the haustorium, none have been found in the mother roots, and there is apparently no connexion with the phloem of the host. It is of course possible that the parasite may absorb food by osmosis from the sieve-tubes of the host where its thin-walled cells come in contact with these, as is suggested by Peirce¹ for *Arceuthobium occidentale*. But as the haustoria fasten only upon the younger roots of the maize, in which the sieve-tubes are not easily distinguished or have not yet been formed, I have not been able to ascertain whether the conditions for such a transference are found here. Until the subaerial shoot is formed, the plant thus apparently has to depend for its supply of assimilated food on the reserve stores passed over from the phloem to the xylem of the host, and on what the haustoria may absorb from the cells dissolved by its ferment. Many microchemical tests have been made to find out what food-stuffs are transferred from host to parasite, but without result. There is no storage, even temporary, of food such as has been recorded for the haustoria of other parasites²—a fact which may be connected with the relatively short life of the haustorium in this case. It is not known just how long an individual haustorium may live, but the fact that they are never seen on the older roots of the full-grown maize shows that their life is not a long one.

DISCUSSION.

The fact that the haustorium of *Striga* may be regarded as comparatively simple in structure has already been noted. No glands are formed to assist in penetration;³ there are no arrangements of strengthening tissue;⁴ and no 'collapsed layers' are seen, such as are generally found in haustoria which have to penetrate the woody cylinder of dicotyledonous roots. All these facts may be correlated with the comparative ease with which the haustorium

¹ Peirce ('05), p. 109.

² e. g. Barber ('06), Fraysse ('06), Benson ('10), &c.

³ As formed in, e. g., *Santalum album* (Barber, '06).

⁴ As seen in, e. g., *Oxyris alba* (Fraysse, '06) and *Arameria canescens* (Cannon, '10).

can make its way through the cortex of the maize, and, once the endodermis is passed, into the comparatively slightly lignified vessels of the young root. Here it is interesting to note that several haustoria were found trying to penetrate an unknown dicotyledonous root which possessed a layer of cork about six cells thick round the stele. The haustoria had entered the root as far as the cork, and were striving to penetrate it with the secretion of much ferment, but they had not got half-way through. Though they had grown to the size of the haustorium of Fig. 6, the axial strand of tracheides had not yet been formed, confirming the opinion stated above that this is only formed after the haustorium has penetrated to the stele of the host.¹ In this case, a line of 'crushed tissue' had been formed down the centre of the 'nucleus'.

The chief interest of this investigation lies in the exactitude with which the origin and development of the haustoria can be followed up through the transparent tissues of the mother root, and in the light which is thus thrown on the disputed question of whether haustoria are to be regarded as organs *sui generis* or as much modified lateral roots, a point on which investigators have differed even in regard to the same species.² My first-hand knowledge of the literature of parasitism is not sufficient to enable me to add to the many discussions³ on this point, beyond recording the fact that in *Striga* all the lateral haustoria are clearly exogenous in origin, and show no homologies with the lateral roots. Very rarely a case is found in which the tip of a *Striga* root has apparently met a maize root and formed a terminal haustorium. I use the word 'apparently' because in every such case but two a new growing point had been formed near the apex of the haustorium (as is described for like cases in *Santalum*,⁴ *Exocarpos*,⁵ and *Krameria*⁶). When this new root had grown on, the haustorium would present the appearance of an ordinary lateral one; but it seemed clear in the half-dozen cases seen that the haustorium was originally terminal. It might of course still have had an exogenous origin from one of the layers of the very simple root-tip, but the appearance of the haustorium would suggest that the cells of the root-tip simply grew out as papillae into the host, the vessels extended down to form the central strand of the haustorium, and the inner cortical cells divided up to form the 'nucleus'. Unfortunately, no young stages in the development of such a haustorium have been seen. It may be noted that these haustoria were all formed at the ends of fairly long roots; it might have been expected that in the case of two roots running parallel, as in Fig. 1, penetration by the lateral roots of the haustorium might occur, but no such case was found.

¹ Frayse ('06) remarks of the haustoria of *Osyris alba* (p. 28): 'Dans aucun cas, l'appareil vasculaire n'apparaît complètement formé avant l'installation définitive du parasite. Dès que la pénétration est suffisante, les trachées se différencient et s'insinuent jusqu'aux divers vaisseaux...'

² Frayse ('06), p. 23.

³ Peirce ('98 and '05), Goebel ('05), Frayse ('06), &c.

⁴ Barber ('06).

⁵ Benson ('10).

⁶ Cannon ('10).

The fact that the haustoria here are clearly exogenous, and apparently organs *sui generis*, does not of course necessarily mean that in other parasitic plants they are never formed by the modification of root primordia, but it leads one to wish for more exact and detailed descriptions of their origin and development than are generally given, before coming to a conclusion on the point as regards any one plant.

SUMMARY.

1. *Striga lutea* is a semi-parasitic South African annual which grows as a root-parasite on native grasses and on the maize. It consists of a slender shoot, the underground portion of which bears many adventitious roots on which haustoria arise.

2. These haustoria are markedly exogenous in origin, being formed by the division of cells of the subhypodermal or hypodermal layer of the root, which push up the overlying layers to form a finger-like protuberance.

3. When this meets the root of a maize plant, its epidermal cells grow out as papillae and bore their way into the host, by secreting a ferment which dissolves its tissues.

4. Down the centre of the haustorium a line of tracheides is now formed, linking the vessels of root and parasite, and by division of the cells surrounding this axial strand a 'nucleus' of parenchymatous cells is formed, which gives the haustorium a globular outline.

5. The mode of nutrition of the parasite is obscure. There is free passage of water and salts from the host, but although the parasite passes a portion of its life-history underground as a total parasite, no system is formed for the conduction of assimilated food.

6. The haustoria of this plant are exogenous in development, and are probably to be regarded as organs *sui generis*.

STELE OF MAIZE

The Anatomy and Relationships of the Gnetales.

I. The Genus *Ephedra*.¹

BY

W. P. THOMPSON.

1851 *Exhibition Science Research Scholar, University of Toronto at Harvard University.*

With Plates XCIV-XCVII and two Figures in the Text.

THE question of the true affinities of the Gnetales, alluring in itself and yet hitherto so baffling, is being drawn into fresh prominence as morphologists turn to the great question of the origin of the Angiosperms. It is recognized that, aside from its own interest, a settlement of the Gnetalean affinities would mark a strategic advance in the attack on the ancestry of the dominant group of our modern seed-plants. Hitherto the chief attention of those who have added to our knowledge of the Gnetales has been focused on the reproductive structures, although even in this field much still remains to be done. The anatomical features have usually been dismissed with a bare reference to the occurrence of true vessels in the wood. There is accordingly great need of systematic study of the anatomy of the whole group, especially in accordance with the methods which have recently proven so fruitful of phylogenetic results when applied to the Conifers and lower Dicotyledones.

The results of such an anatomical study of the most primitive member of the family, the genus *Ephedra*, are given in the present contribution. It is hoped soon to complete the study of the other genera. In studying *Ephedra* the writer has had material of several species, including *E. altissima*, *californica*, *distachya*, *fragilis*, *Gerardiana*, *monostachya*, *trifurca*, *viridis*, and *vulgaris*. There is little specific variation, so that all the species may be treated together and important differences mentioned under the features concerned.

With regard to the history of the subject, it is contained chiefly in scattered references to individual features, particularly in general texts on anatomy. These will be mentioned as occasion arises.

¹ Contributions from the Phanerogamic Laboratory of Harvard University, No. 51.

PITH.

The pith of *Ephedra* is relatively very large, as may be seen in Pl. XCIV, Fig. 1, which is a photograph of a transverse section of an entire young branch. It is composed of dead, fairly thick-walled cells, many of which are filled with a hard brown substance. This substance is either homogeneous or of a foam-like structure (see Fig. 1). Often the cell-walls in certain places disappear, so that the dark masses become continuous, and, when the stem is broken, project as definite strands. This material is lacking at the node of the adult, and in both node and internode of the seedling. In a few species the pith also contains thick-walled fibres resembling those of the bast, which are confined to its periphery.

In certain places, notably in proximity to the nodes, the cells of the pith adjacent to the primary vascular bundles become differentiated. They are smaller and strongly lignified, and appear as definite strands extending inward from the protoxylem cluster. Fig. 2 gives their appearance in *E. trifurca*. It is plain that they might readily be mistaken for centripetal wood. Longitudinal sections, however, reveal their true character as lignified pith cells. It is possible, however, as Worsdell¹ holds for similar cells in *Welwitschia*, that they may represent modified centripetal wood. In *Ephedra* there is little evidence for such a view. The conditions just described emphasize the necessity for exercising the greatest care in identifying centripetal wood.

Another peculiar feature of the pith is the presence of a diaphragm of periderm-like cells a short distance above the node. In Fig. 3 the node is to be recognized by the constriction in the pith and the layer of thick-walled cells. Some distance above the node, the diaphragm may be seen extending completely across the pith and into the wood. The diaphragm is composed of vertical rows of three or more cells apparently formed by secondary divisions. It is sharply differentiated from the rest of the pith by the arrangement, size, and contents of its cells. Very frequently the branch breaks just above the node, and this layer always forms the line of separation. It serves no doubt to protect the surface exposed after the break. But on account of its extension into the wood it would also appear to be a device for cutting off young branches after the manner of an absciss periderm in leaf-fall. It recalls strikingly the similar structure found above the node in *Equisetum* and the Calamites.² In these forms, however, it is confined to the centre of the pith, not ordinarily reaching the periphery nor the surrounding wood. In the Calamites there was a diaphragm both above and below the node. Of course these peridermal diaphragms in

Ephedra and the Equisetales can have no evolutionary connexion, but they furnish an interesting case of parallel development in plants of similar habit.

PRIMARY VASCULAR BUNDLES AND LEAF-TRACES.

The bundles of the primary wood, though not large, are rather conspicuous in transverse sections. Fig. 1 gives their appearance in *E. monostachya*. They may be seen to consist of two pairs of large bundles and two groups of three smaller ones. The groups of large and small bundles alternate regularly. The number and arrangement are constant for each species, but vary in the different species. The reasons for the appearance which they present in transverse sections are readily understood when one follows their course by means of a series of sections.

1. Course.

The simplest condition is found in *E. distachya*, and is represented diagrammatically in Text-fig. 1, which is a reconstruction drawn after a study of complete series of celloidin sections through the node.¹ As we shall see, it differs considerably from the conceptions arrived at by former investigators, but owing to the exactness of the method and the number of repetitions the writer feels certain of its accuracy. The ring of bundles is represented as split and turned into one plane. In the internode there are two pairs of large bundles as in *E. monostachya*, but the smaller bundles are also in pairs instead of groups of three. There are therefore two pairs of large bundles alternating with two pairs of small ones. As the node is approached, the smaller bundles flatten tangentially, and short tracheides appear between them. By this means they are soon united, so that a continuous band of primary wood results. The appearance of this band in another species is shown in Phot. 4. The original bundles are near the end of the band. Very soon the adjacent large bundle on each side becomes included in the same way. Meantime a similar band has been formed on the opposite side of the stem. Finally, these two bands become united by the extension of their ends. There results a complete girdle of nodal wood broken only by the exit of the leaf-traces. Often the position of the internodal bundle is indicated by a slight thickening of the girdle.

The leaf-traces, of which there are two at every node to supply the pair of opposite leaves, are in all cases double. The double character is shown in *transverse* section in Figs. 5 and 6, and in *tangential* section in Fig. 7. In the latter figure the two strands of the trace are below the centre of the field which is occupied by the large branch gap. The transverse sections

¹ The sections as they came from the microtome were arranged in order on a large slide and mounted in glycerine in which they were kept indefinitely for further study. By this means the accuracy of the work is rendered just as great as with the similar paraffin series used for soft material.

also show that the two strands are inserted separately. Each arises directly above one of the smaller internodal bundles, a piece of the girdle at this point simply turning out to form a strand (see Text-fig. 1). Sometimes a thickening of the girdle runs up from the small bundle and out with the trace, indicating that the small bundle as a whole originally formed the trace.

That part of the girdle between the two strands of each trace continues up as a definite bundle, so that in transverse sections the two strands are separated by a block of wood. This feature is shown in Fig. 5. The same bundle is seen in tangential section in Fig. 7. Above the traces it divides, and each part unites laterally with the girdle to form the outgoing branch.

TEXT-FIG. 1. *E. distachya*. Reconstruction of the course of the primary fibro-vascular bundles.

The bundles of the succeeding internode are organized from the nodal wood in a definite manner and position with respect to those of the lower internode. On each side of both branch gaps a large bundle is organized. The two pairs of large bundles of each internode are thus accounted for. Between the pairs of large bundles two small ones are then formed, and the two pairs of small ones are then accounted for. The result is the same organization as in the lower internode, except that the large bundles are now in the position of the lower small ones and vice versa. At the succeeding node the story is repeated, except of course that the leaves alternate with those below.

It is obvious that the bundles of the upper internode, although their position with respect to the lower ones is definite, cannot be regarded as continuations of them. Nor can it be said that any bundle of the internode passes out definitely as a leaf-trace. It is true that in some specimens

the continuous thickening of the girdle would indicate that this was originally the case. But as a rule it may be said that the leaf-traces are organized from the ring of nodal wood.

Another species possessing this organization of the primary vascular bundles is *E. vulgaris*. In *E. trifurca* the leaves are in whorls of three, so that in each internode there are three pairs of large bundles alternating with three pairs of small ones. The girdle and traces, however, are usually organized in the same way as in *E. distachya* and *E. vulgaris*. Occasionally, however, the intercalary bundle between the two strands of the leaf-trace is absent. Such a trace with its two strands leaving the stele side by side is photographed in Fig. 6. The condition here is similar to that of other plants which have the double leaf-trace. It is no doubt the primi-

TEXT-FIG. 2. *E. altissima*. Reconstruction of course of primary fibro-vascular bundles.

tive condition, for it obtains exclusively in the traces to the reproductive bracts.

A more complicated condition of the whole primary system is found in such species as *E. altissima*. Text-fig. 2 is a reconstruction of the bundle course in this species. As the leaves occur in whorls of three, the internode has three pairs of large bundles alternating with three groups of smaller ones. But in this case each of the smaller groups contains three bundles instead of two. Accordingly the total number of bundles is fifteen. The nodal ring is organized in the same way as before. The most striking difference is that the strands of the leaf-trace arise, not above the small bundles of the internode, but above the spaces between them. The intercalary bundle is then directly above the central small bundle of the group, and the traces arise over the spaces which separate the central bundle from its fellows. In this case, at least, the traces cannot be considered as continuations of the internodal bundles. In addition to the origin of the leaf-traces, the most striking difference is the presence of three small bundles

instead of two in each group. This is no doubt a specialized feature, for in the seedling (see Pl. XCVI, Fig. 27) one finds the simpler type of organization.

The observations of former investigators differ considerably from those just outlined, and also differ materially from each other. Geyler,¹ the pioneer in this sort of work, observed the girdle at the node in *E. equisetiformis*, but did not consider it of importance. He believed that the bundles were continuous through two internodes, the leaf-traces attaching themselves laterally at that distance below their exit. In reality they run through only one internode where they are formed from the girdle. He also made the mistake of considering the large internodal bundles as the leaf-trace bundles of the succeeding node. Van Tieghem² observed the intercalary bundle between the leaf-trace strands which Geyler failed to see. He thought that it was derived from the traces and divided into two to give the proper number of bundles for the next internode. Strasburger,³ while considering that the bundles ran through two internodes, correctly observed the origin of the intercalary bundle from the girdle. All these investigators examined species, *E. distachya*, *vulgaris*, and *equisetiformis*, which belong to the simplest type described. As we have seen, the conditions existing in many other species are quite different, although intermediate stages exist.

In spite of the disagreement in regard to details the course of specialization may readily be traced. There are indications that in the ancestral form the internodal bundles were as in the simpler type, and the small bundles ran out intact to form the leaf-traces. The intercalary bundle was absent. From this condition the girdle increased, the intercalary bundle developed, and the traces lost their connexion with the internodal bundles. Finally, the third small bundle of the internode developed, and the traces came to alternate with the internodal bundles.

Some of the features just described are of importance from the standpoint of relationships. The small number and simple regular course of the bundles through the internode are quite different from the conditions in the Cycads and Bennettitales, with which there has recently been a tendency to connect the Gnetales. It is well known that all the Cycadophyta had their primary vascular system arranged in the form of an irregular trellis from which the leaf-traces departed in a haphazard manner. The conditions in *Ephedra* resemble much more closely those of the Coniferales and Dicotyledones.

The double leaf-trace is a feature on which much stress has been laid. There appears to be general agreement as to its primitive character, for it is present in the ancient Cycadofilicinean forms. In *Ephedra* it differs from the double trace of many Gymnosperms in that the two strands of which it

¹ Gefässbündelverlauf und Laubblattregion d. Coniferen. Pringsheim's Jahrbücher, 1867.

² Anatomie des Fleurs des Gymnospermes. Ann. de Sci. Nat., Bot., 1889.

³ Die Coniferen und die Gnetaceen, 1872.

is composed do not unite before entering the stele, but are inserted separately. In this respect it resembles the Cycads and *Ginkgo*. It is doubtful, however, whether any importance can be attributed to this point, for even in many of those ancient forms of which it is characteristic the two parts unite before entering the stele (*Lyginodendron*), while in others they remain separate (*Poroxylon*). On this basis the primitive Conifers can claim just as close an affinity to *Ephedra* as can the Cycads, for they also have a double trace. Furthermore, the Bennettiales, which on account of their floral organization have a much stronger claim than their modern representatives on the Gnetalean ancestry, had only a single trace, as Wieland¹ has shown. This fact has been overlooked in much recent work. For example, Miss Sykes,² in her work on *Welwitschia*, considered its double leaf-trace indicative of Cycadean affinities. It is obvious that the argument which involves the floral organization is quite contradictory to that which involves the double leaf-trace, and one or the other must be abandoned.

The bundle intercalated between the strands of the leaf-trace is a feature not found in other Gymnosperms. This fact and its absence in certain cases in *Ephedra* indicate that it is a specialization. It is possibly another condition in which *Ephedra* approaches the Dicotyledones in which the several traces to a single leaf arise at various points in the circumference of the young stele and are separated by masses of wood.

The girdle of tracheides at the node is a special feature with no significance in respect to relationship. It recalls strikingly the nodal wood of *Equisetum*, but of course this can be only a case of parallel development. This feature and the medullary diaphragm of both forms are probably correlated in some way with their similarity of habit.

2. Structure.

Each primary vascular bundle is roughly triangular, the innermost angle being occupied by the smallest protoxylem elements (Pl. XCIV, Figs. 1 and 2). The succession of elements from this point outward to the secondary wood is of the usual type. There is no centripetally developed wood, so that the bundles are of the endarch type. As has been noted above, a band of lignified elements which might easily be mistaken for centripetal wood often extends from the protoxylem for some distance into the pith (Fig. 2), but in no case was true centripetal wood found in the internode.

At the node, however, centripetally developed tracheides are occasionally to be found. They occur in the pith about the level of the exit of the leaf-traces. In this position they are not of the usual type, but bear a close resemblance to transfusion tracheides of the leaf. Fig. 8 shows one

¹ American Fossil Cycads. Carnegie Institute, 1906.

² Anatomy and Morphology of the Leaves and Inflorescences of *Welwitschia mirabilis*. Phil. Trans. Roy. Soc., B, 1910.

such element separated by at least two pith cells from the xylem. By following a series of sections one finds that they occur in strands attached to the protoxylem below, but diverging centripetally above. The lowermost elements are most like tracheides, but the upper ones rapidly assume the characters of transfusion cells. It is probable that they represent the original centripetal wood which was present universally in the ancestral types, and has been lost from the internode as in so many other plants, but in this case retained in a modified condition at the node.

At the edges of the primary bundles of the internode one often finds in *E. monostachya* and *E. vulgaris* typical transfusion tracheides like those of the leaf. They are adjacent to the pith, and often reach across from one bundle to the next. In Fig. 9 two primary bundles may be seen at the extreme right and left, and between them three or four of the scattered transfusion tracheides with their characteristic bordered pits and thickening bars. Their presence is probably due to the fact that the cortex of the young plant functions as a leaf.

Having described the origin of the leaf-traces in connexion with the course of the primary bundles, it may be well at this point to take up its structure. In all cases the trace is very small, consisting of but a few elements. Its tracheides are nearly all spiral or scalariform, although occasionally one may find a pitted element. In all cases the arrangement is endarch, i. e. the protoxylem elements are on the adaxial side of the bundle, and the metaxylem is all centrifugal. The endarch character may be distinguished in Fig. 7, in which the protoxylem elements of the trace are uppermost. In no case was centripetal xylem found. The structure is then identical with that of the trace of the Angiosperms and Conifers. It is vitally different from that of the Cycads and older Gymnosperms. In the Cycads, as is well known from the work of Scott and the earlier studies of Mettenius, there is always a large amount of centripetal wood which is considered to be retained from a primitive condition in which it occurred in the stem as well as in the leaf. At the same time the centrifugal primary wood is very small in amount and diminishes in the petiole. In *Ephedra* the conditions are exactly reversed; the centripetal wood has been completely lost and the centrifugal wood developed. In regard to the structure of the leaf-trace, therefore, *Ephedra* is as remote as possible from the Cycads, and is in agreement with the Conifers and Dicotyledones. In view of the general agreement as to the importance of the leaf-trace as a seat of ancestral characters, this is a point which should be emphasized in all phylogenetic studies.

SECONDARY WOOD.

It has long been known that the secondary wood of *Ephedra* consists of tracheides, vessels, wood parenchyma, and rays. But an intimate study of each of these constituents is necessary, especially in the light of recent

similar studies on the wood of Conifers and Dicotyledones. A transverse view in which the general characteristics and arrangement of all the elements may be distinguished is shown in Fig. 10.

1. Tracheides.

The pitting of the tracheides is usually uniseriate with the individual pits well separated (see Fig. 11). In this respect it agrees with that of all the Conifers except the Araucarians, and is sharply distinguished from that of the Cycads and Bennettitales. In the latter group the pits were almost always of the very primitive scalariform type,¹ while in the Cycads the multiseriate pitted condition is the dominant one, although the scalariform condition is not uncommon.

The structure of the individual pits presents additional points of difference. The pit mouths in *Ephedra* are circular, as in the majority of the Conifers, whereas in the Cycads they are more or less slit-shaped. The torus is also very well developed (Fig. 11), while in the Cycads it is absent.

Although the pits are usually well separated, conforming thus to the 'Abietinean' type, one often finds the mutually compressed type or 'Araucarian' condition. This is represented in Fig. 12. It is most frequent at the ends of the tracheides. Often also the more typical Araucarian condition with two alternating rows of compressed pits is to be found. Rarely are more than two rows present.

In association with the Abietinean pitting the tracheides possess a feature which has been shown recently to be of primary importance, namely, the so-called bars of Sanio. These structures, named in honour of their discoverer, are horizontal bars or folds of cellulose crossing the tracheide wall between the pits. Stained in haematoxylin they appear as dark bands. They may be distinguished in the central tracheide of Fig. 11. Miss Gerry² has shown that they are present in all Conifers except the Araucarians, i. e. wherever the Abietinean type of pitting occurs. Outside the Conifers they are to be found only in *Ginkgo*, which also has uniseriate separated pits. Naturally they cannot exist where the pits are closely compressed. Their presence in *Ephedra* serves to distinguish this genus sharply from the Cycadales, and associate it rather with the Coniferales and Ginkgoales.

The bordered pits and bars of Sanio are not confined to the radial walls of the tracheides as in most woods, but are found also on the tangential walls, as may be seen in Pl. XCV, Fig. 13. In the Conifers tangential pits, when present at all, occur only in the summer wood, but in *Ephedra* they are to be found throughout the year's growth. They are usually somewhat smaller than those of the radial wall.

¹ Wieland : loc. cit.

² Distribution of the 'Bars of Sanio' in the Coniferae. *Annals of Botany*, Jan., 1910.

The tracheide walls sometimes show tertiary spiral striations such as are characteristic of *Taxus* and *Pseudotsuga*, and according to Bailey¹ are of sporadic occurrence in all the Pineae. Fig. 14 gives their characteristic appearance in *E. californica*. They appear to be of very sporadic occurrence. Their presence is not a specific character, nor are they more frequent in young wood, as Bailey found to be the case in the Pineae. They supply one more point of resemblance to the tracheides of the Conifers.

Another type of spiral thickening to which Boodle and Worsdell² has called attention is photographed in Fig. 15. These thickenings are broader and less numerous than those of the other type. Boodle and Worsdell observed that they appear to be continuations of the mouths of the pits. The relation to the pits is plainly shown in Fig. 15, especially in the upper part of the field. In many places the relation is not so obvious on account of the fact that the section may not include the underlying pit. It is plain that these thickenings have no connexion whatever with those of the usual type. They have also been observed in the genus *Widdringtonia*, one of the Cupressineae.

Still another feature which occurs sporadically in the tracheides of the Coniferales and only in that family is present in *Ephedra*, namely, the so-called trabeculae. By this term is meant a series of lignified septa occurring all in the same horizontal line in a single radial row of elements. When seen in radial section (Fig. 16), they present the appearance of a continuous row of lignified bars crossing the field. Their occurrence is so uncommon and sporadic in any wood that little account is taken of them in the literature of wood structure. They serve, nevertheless, as another addition to the list of Coniferous characters possessed by *Ephedra*.

There is just one other point in connexion with the tracheides of *Ephedra* to which attention should be called, namely, the frequent presence of resin plates. Resin is often deposited in the tracheides in the form of spool-shaped plates. In Fig. 16 the small tracheide at the left of the large central vessel contains several of them. Although this is the prevailing form, the resin is sometimes deposited in globules or larger masses. The spool-shaped plates bear a strong resemblance to those of the wood of certain Conifers, notably the Araucarians, in which they become a characteristic feature.

All the characteristic features of the tracheides of *Ephedra* are, then, also characteristic of the tracheides of the Conifers; the arrangement of the pits, the structure of the individual pits, the bars of Sanio, tertiary spirals, trabeculae, and resin plates. No single family of the Conifers possesses all these features, so that it would be difficult to connect *Ephedra* from the

¹ The Structure of the Wood in the Pineae. Bot. Gaz., July, 1909.

² L. A. Boodle and W. C. Worsdell. Annals of Botany, 1894.

standpoint of evolution with any special members of that family. It would seem rather to be related to some generalized ancient form.

2. Vessels.

The fact that *Ephedra* possesses true vessels is perhaps its best known anatomical feature. It is also well known that the perforations of those vessels correspond to the bordered pits of tracheides. The further fact that there are interesting transitions between bordered pits and perforations has been emphasized by Strasburger¹ and by Boodle and Worsdell.² The writer's study has shown that the transitions between tracheides and vessels are much more complete than was suspected, and has revealed additional structural features. For the sake of completeness some facts already known will be briefly recapitulated.

The lumina of the vessels vary from that of a tracheide to many times that size (Pl. XCVI, Figs. 27 and 29). The pits on the lateral walls are identical with those of the tracheides, though arranged more often in two rows. In addition the vessels show the bars of *Sanio*, tertiary spirals, and trabeculae characteristic of the tracheides. The perforations of the end walls are seen in transverse section (Pl. XCIV, Fig. 10) to be simply enlarged bordered pits in which the border has become narrow and the torus has disappeared. In the radial section (Fig. 12 and Pl. XCVI, Fig. 25) these points are also visible, although the border is not so clear. The perforations may be in two or three rows which are opposite or alternate. Perhaps the clearest ideas may be obtained from the tangential section which has been photographed in Pl. XCV, Fig. 17. In this figure the slanting end wall, the open communication between the conterminous elements, and the border of the perforations are clearly shown.

From the appearances presented in these figures the conclusion is natural that the perforations represent modified bordered pits. This assumption is rendered a certainty by the fact that one frequently finds true bordered pits in series with the perforations (see Fig. 20). The latter in such cases occupy the position of the bordered pits of a normal tracheide. This condition is shown in tangential view in Fig. 18, in which the two bordered pits at the bottom of the end wall have well developed borders and tori.

The transitions between tracheides and vessels are in fact remarkably complete, especially in the first few annual rings. In Fig. 19 is represented an element which differs from a tracheide only in the absence of the torus and narrowness of the border of *one* of its enlarged central pits. The other pits, while showing a slight decrease in the border, are still true bordered pits. A further stage is represented in Fig. 20, and many other figures could have been presented showing all stages up to the completed vessel of Pl. XCVI,

¹ Über den Bau und die Verrichtungen, &c.

² loc. cit.

Fig. 25. But a single vessel is often sufficient to show clearly the gradual disappearance of the torus and border. In Pl. XCV, Fig. 20, at the end of the vessel the pits have a typical border and a deeply stained, well-marked torus. Towards the bottom of the field, i. e. towards the centre of the end wall of the vessel, the torus becomes gradually fainter until it disappears, and there results an open communication through the pits. The decrease in breadth of the border is equally gradual. Usually the conditions are not so diagrammatic as this. Sometimes the torus and border do not disappear at the same rate, but the latter may be quite well developed when the former has completely vanished. Diagrammatic cases are sufficiently numerous, however, and the various stages presented by different elements are so often repeated that there can be no doubt as to the origin of the perforations, in *Ephedra* at least.

In those cases in which the torus is only partly developed, it may have become so in one of two ways: either in the course of ontogeny it has ceased to grow at that stage in its development, or it may have continued to the complete condition, and later have been partially resorbed. The writer was unable to determine which of these alternatives is correct.

If the vessels have developed in the manner indicated it might be expected that the seedling would present primitive conditions approaching tracheides. As a matter of fact the seedling possesses very few vessels of any kind, the mass of wood consisting almost exclusively of tracheides. This fact is shown strikingly in Pl. XCVI, Fig. 27, which is a photograph of a transverse section through the base of the seedling stem of *E. altissima*. Very few vessels can be recognized, and even those which can are extremely small. The absence of vessels is also shown in longitudinal view in Fig. 28. Of course, as one examines the upper parts of the seedling it is found that they gradually increase in number. Moreover, the vessels which are present have only a single row of perforations, and these are usually of the transitional type. Such facts furnish another striking example of the recapitulation in the seedling of ancestral characteristics.

It should also be noted that in the first annual ring of adult branches the few vessels which are present usually have a single row of perforations which are often transitional to bordered pits. Evidence is thus added to that which has recently been accumulated showing that this region is also the seat of retention of ancestral features.

Boodle and Worsdell¹ state that the node also lacks vessels. For the species which the writer has examined this statement does not appear to hold good, although the number in that region may be slightly less than in the internode. The presence of vessels in the node of *E. altissima* is shown by photography in Pl. XCIV, Fig. 7, especially at the right.

We have here seen the structure of the primitive vessels of *Ephedra*

¹ loc. cit.

and of the typical ones; there remains a more highly developed condition which is occasionally to be found, but which has not yet been described. It is illustrated in Pl. XCV, Fig. 21, which is a photograph from *E. distachya*. The upper two perforations appear from their shape to have resulted each from the horizontal fusion of a pair of perforations. This inference is confirmed by the condition of the pair of opposite perforations below, for the latter are separated by an extremely thin part of the wall (compare with Fig. 20). It is clear, therefore, that a fusion of perforations sometimes occurs, resulting in the formation of still larger perforations. The resulting vessels bear a much closer resemblance to those of the Angiosperms, especially to the ones with scalariform end walls which are characteristic of the lower Dicotyledones.

In spite of this resemblance, however, it must be admitted that the vessels of *Ephedra* differ essentially from those of the Angiosperms. The perforations of the Angiospermic vessels by no means correspond to modified bordered pits. It may be stated here, however, that the vessels of *Gnetum* to a large extent clear up the difficulty.

3. Wood Parenchyma.

Wood parenchyma is very abundant in *Ephedra*, the number of its elements often nearly equalling the number of tracheides. It is sometimes scattered irregularly throughout the wood (Pl. XCIV, Fig. 10), but is more often arranged in definite tangential bands. The banded arrangement is visible in Pl. XCVI, Fig. 29, in which the parenchyma cells appear dark owing to their deeply staining protoplasmic contents. There are usually two rows of tracheides separating the successive bands of parenchyma cells, although often, especially in root wood, only a single row of tracheides intervenes. Sometimes, indeed, the bands of parenchyma cells themselves become two or three rows in thickness.

The individual cells are identical with tracheides in length and shape (Pl. XCV, Fig. 23). They are also lignified in the same way and to the same extent as tracheides. Moreover, in the vast majority of instances they have no cross-walls as do those of Conifers. Therefore, the only features which serve to distinguish them from tracheides are the character of the pitting and the possession of protoplasmic contents. When in dry material the protoplasm disappears, the distinction is often difficult to make.

As for the other distinguishing feature, namely, the character of the pits, it is usually simple. This is always true in the case of pits between adjacent parenchyma cells. In some cases, however, where the parenchyma cell adjoins a tracheide or vessel the pits show a small border on the parenchyma side as well as the usual large one on the tracheide side. The small border is shown in Fig. 22. The parenchyma cell adjoining the vessel

on the right is charged with a black resinous mass which has penetrated through the pits into the lumen of the vessel, where it remains as little globules. The deep colour of this material emphasizes sharply the doubly bordered character of the pits as well as the fact that the border on the vessel side is wider than that on the side of the parenchyma cell.

A peculiar fact in connexion with these wood parenchyma cells is that they are often multinucleate. Fig. 23 shows a parenchyma cell in the wood of *E. monostachya* which in the short extent shown in the photograph obviously contains two nuclei. This condition obtains quite frequently, although it is often hard to demonstrate. Three and four nuclei have been observed in a single parenchyma cell. It would seem that the distance from the centre to the ends of such an extremely long living cell is too great to enable the single nucleus to perform its proper functions. Accordingly the original nucleus divides and the daughter nuclei become scattered along the cell. In fact, in the proper material it is possible to observe that the nucleus is actually undergoing division. Such a case is photographed in Fig. 24. The details of nuclear divisions were impossible to distinguish.

In a few cases, as Strasburger¹ has pointed out, the parenchyma cells are further distinguished from tracheides by the presence of cross-walls such as exist in the parenchyma of most other woods. Such a wall is shown in Pl. XCVI, Fig. 25, at the centre of the field. The inclination is typical. As a rule, however, septa are rare, and in some species were never seen. They are most abundant in *E. monostachya*. In no case was more than one septum seen in a single parenchyma cell, a condition which is in sharp contrast to that of the parenchyma of most woods.

The typical wood-parenchyma cell of *Ephedra* is then, except for its pitting, merely a tracheide which has retained its protoplasmic contents. And in some cases we have seen that even its pitting resembles that of a tracheide. From these facts, and also from the entire absence of wood parenchyma in the ancient Gymnosperms, it may be concluded that the wood parenchyma of *Ephedra* has been derived from tracheides. Each parenchyma cell would therefore represent a modified tracheide.

It is to be noted that this type of parenchyma differs essentially from that of the Conifers. The latter consists of short cells, a number of which together give the shape and size of a tracheide. In fact, Bailey¹ has recently brought forward evidence to show that this type was also derived from tracheides. The real difference then consists in the presence of numerous septations in the Coniferous cells. We have seen that in *Ephedra* a single septum is sometimes present, so that the distinction is not really so profound. The Conifers appear to have carried the process of septation much further.

The cells which resemble them most closely, however, are to be found in the Angiosperms, where they have been called fibrous cells or substitute

¹ loc. cit.

fibres. In fact, de Bary¹ concluded that they fell naturally into this category. It should be noted, however, that the Angiospermic fibrous cells, as their name indicates, resemble the woody fibres rather than tracheides. They are much longer and have thicker walls. Although the lack of septa is common to the two, it is doubtful whether they are homologous structures.

4. Wood Rays.

The ray structure of *Ephedra* has hitherto been passed over with the simple statement of Strasburger² that they are multiseriate. In reality the conditions which they present are no less significant from an evolutionary point of view than those of the vessels to which the whole attention has been devoted in the past. The fact that they are multiseriate is in itself of supreme importance, for in connexion with other facts it emphasizes their close relationship to those of the Dicotyledones.

The multiseriate condition is shown in transverse section in Pl. XCIV, Fig. 10 at the left and in tangential section in Pl. XCV, Fig. 13. The number of rows of cells varies from one to ten, but the average number is four or five. There is considerable specific and regional variation in this respect. In tangential section they are found in most cases to be solid homogeneous masses which extend vertically to considerable heights. They are not so high, however, as those of the Oak, but have a more fusiform outline (Pl. XCVI, Fig. 32).

The individual cells are extremely variable in size and shape. They may be isodiametric or elongated radially or vertically. As these variations may be found within a small area, they give the ray a peculiarly irregular appearance, as is shown in Fig. 26, and especially in Pl. XCV, Fig. 13. Furthermore, in old wood, all the cells of the marginal rows often become elongated obliquely to the course of the ray, a condition which no doubt results from the slow growth of the ray in comparison to that of the surrounding wood.

Each cell is strongly lignified, resembling in this respect the ray cells of Conifers and Dicotyledones and differing from those of the Cycads and Bennettitales. The simple pits, like those of the Dicotyledones, occur on all walls and are very small, being merely fine pores. Their character may be distinguished in Pl. XCVI, Fig. 26, especially at the top of the field. All these features give an appearance in radial section strikingly like that of a large ray of the Dicotyledones.

The conditions of the rays in the young stem are quite different from those just described for the adult. At the pith one finds only uniseriate rays similar to those which are characteristic of the Conifers (Figs. 27 and 29). From this condition the broad ray of the adult is produced in two

¹ Comparative Anatomy of Phanerogams and Ferns.

² Über den Bau, &c.

ways, first by the enlargement of the uniseriate rays, and secondly, by their fusion. The first process, that of enlargement, is itself effected in two ways. The cells of a uniseriate ray may simply divide radially to produce a biseriate one, which in turn continues the process, or the adjacent tracheides may be transformed into ray parenchyma. The latter method is much more common, and indeed many rays originate by this transformation in the wood and do not extend to the pith. During the process the tracheides retain their contents and become septated irregularly. As one examines the sections from the pith outwards one finds that the compartments into which the tracheides are divided become gradually shorter and arranged irregularly. Fig. 28, which is a photograph of a tangential section near the pith of *E. altissima*, shows the formation of a number of rays in this manner. The ray cells are all very much elongated vertically, and some of them are obviously segments of tracheides. Indeed, in some places, it is difficult to distinguish the limits of the rays.

The second method in which the broad rays are formed is the significant process of fusion of small rays. Two or more small rays become joined into one large one, while the intervening fibres are either pinched out or transformed into ray parenchyma. Later, other rays may be added laterally in the same way, so that rays of various sizes are found in the compounding area. Fig. 29 shows the compounding process taking place in *E. monotachya*. Two of the large rays are obviously in the process of formation by a fusion of similar ones. Fig. 30 shows the same thing taking place in *E. californica*. The completion of the process usually requires a number of annual rings. Often it is very slow, and the included fibres remain intact for a long distance. Indeed, in some cases the fusion appears never to become complete, for tangential sections may reveal the presence of fibres and even vessels in the rays of very old wood. Such a tangential section of *E. californica* is represented in Fig. 31. The numerous included fibres show that this broad ray has resulted from the fusion of smaller ones. A similar condition from *E. trifurca* is shown in Fig. 32. Broad rays such as these containing fibres are homologous with the so-called false rays of many lower Dicotyledones, e. g. *Alnus*, *Carpinus*, *Betula*.

The formation of broad rays by the compounding process is exactly what Eames¹ has recently described as occurring in the oak. He has shown that in the seedling and in the young branch of some species the characteristic broad oak ray is not present, but develops later in a manner exactly similar to that just outlined for *Ephedra*. From these facts and from fossil evidence he concluded that the broad type of ray found in Angiosperms is not a primary structure representing the gap between the original primary vascular bundles, as has been supposed, but is really derived secondarily from an aggregation of uniseriate rays of the Coniferous

¹ Eames, A. J. : Origin of Broad Ray in *Quercus*. Bot. Gaz., March, 1910.

type. Bailey¹ emphasized the transitions in the compounding process furnished by the false rays of the Cupuliferae which, as we have seen, likewise have their counterpart in *Ephedra*. He further showed that the compounding took place primarily around the leaf-trace. The development of broad rays is obviously an adaptation for the storage of assimilates manufactured in the leaf, and the most convenient place for their storage is in the stem adjacent to the leaf-trace. From their original position around the trace he considers that the broad rays have spread throughout the wood.

Not only in the possession of broad rays, therefore, but also in their origin does *Ephedra* resemble the lower Dicotyledones. It should be noted, however, that the compounding process bears no obvious relation to the leaf-traces, but may give rise to rays which do not touch a trace at any point. In fact, it seems to be quite independent of the leaf-trace, and is likely to result in the formation of a broad ray on any radius of the stem. It is true that the trace is accompanied by a broad ray, as may be seen in Pl. XCIV, Fig. 7, but this ray is neither so broad nor so high as the usual type of compound ray. Moreover, it rarely shows the fusion process. In fact, it represents rather the leaf-gap of other woods. The reason for its poor development is probably to be found in the non-functional character of the leaves. In practically all cases the leaves are merely small scales which have little or no chlorophyll, and have given over their function of assimilation to the cortex of the young plant which is abundantly supplied with chlorophyll and stomata. Not the restricted area around the leaf-trace, therefore, but the whole circumference of the branch would feel the need for storage. Of course it is quite possible that the original position of ray development was in the vicinity of the leaf-traces, and that with the reduction of the leaves and the functioning of the cortex in assimilation the rays may have lost their original connexions. Indeed, the occasional occurrence of compounding around the trace and the constant presence of a ray in that position would justify such an inference. In any case the resemblance both in regard to the history of development and adult form between the rays of *Ephedra* and those of the lower Dicotyledones is remarkably close.

Just as in many oaks the compounding process is visible only as a passing phase in the seedling, the broad rays of other regions extending right to the pith, so in certain regions of *Ephedra* the broad ray has worked back almost or quite to the pith. This is particularly true of those regions in which storage is greatest, namely, in roots and underground stems. In these places the broad ray develops at a very short distance from the pith, and may indeed be quite continuous with the pith. Pl. XCVI, Fig. 33, which represents a transverse section of a subterranean stem of

¹ Bailey, I. W.: Relation of the Leaf-trace to the Origin of Compound Rays in the Lower Dicotyledones. *Ann. Bot.*, Jan., 1911.

E. monostachya, shows a very early development of several broad rays. Some of them which lack cell contents are to be distinguished as areas in which there are no vessels. As a rule, however, the broad rays do not appear until a considerable zone of wood has been formed.

With the increase in circumference of the young stem the rays become proportionately broader. If the increase went on indefinitely the rays would soon become too broad for the proper organization of the stem tissues. In *Ephedra* the stems rarely become large enough to cause this difficulty, but when they do it is met by the secondary obliquely vertical division of the rays. In tangential view the rays are found to be divided by oblique strands of fibres into a number of segments which then become scattered horizontally through the wood, as the strands of fibres increase in size. This division of broad rays with the increase in diameter of the stem is similar to that described by the writer¹ as occurring in certain of the Fagaceae and Casuarinaceae. Zilztra² has observed the same phenomenon in several Dicotyledonous plants. It was used in the former contribution in support of the theory that the smaller multiseriate rays of the Dicotyledones have been derived from the broad aggregate ray by the diffusion of the latter throughout the wood. In *Ephedra* the stems rarely become large enough to make the dissection process a necessity, but its occasional presence shows that the same rule holds as in the Dicotyledones.

Bailey³ has shown that oak wood formed immediately after an injury is likely to present primitive conditions of ray structure. In such areas one may find only uniseriate rays, and these later undergo the compounding process to form broad rays again. These phenomena are in agreement with the well-established principle that traumatic areas tend to revert to primitive conditions. In *Ephedra* such a reversion is extremely rare, although it is occasionally to be seen. For the most part, however, wounding has very little effect on ray structure, the rays continuing about the same size as before the wound. Occasionally, indeed, the wound causes the enlargement of rays already present, and even the introduction of new ones. As Bailey has suggested for a similar phenomenon in the oak the wound appears in these cases to stimulate the development of broad rays. On the whole, however, the effect of wounding is very indefinite.

One other respect in which the rays of *Ephedra* resemble those of the Dicotyledones is their retarding effect on the growth of the stem. In the oak the growth is slower in the vicinity of the broad ray, and the result is manifested in a distinct 'dip' in the contour of the annual rings which

¹ Thompson, W. P. : Origin of the Multiseriate Ray of the Dicotyledons. Ann. Bot., October, 1911.

² Die Gestalt der Markstrahlen im sekundären Holze. Recueil des Travaux Botaniques Néerlandais, vol. v, 1908.

³ Bailey, I. W. : Reversionary Characters in Traumatic Oak Woods. Bot. Gaz., Nov., 1910.

increase with the diameter of the stem. As Bailey¹ has shown this has had an important effect on the structure of the stem, for it has resulted in the production of the so-called depressed segments alternating with projecting ones. The depressed segments had formerly been considered to represent the 'interfascicular' wood. Fig. 30 shows the presence of the dip in *E. californica*, and its increase in the successive annual rings. Owing to the lack of association between broad rays and leaves in *Ephedra* the depression has not the regularity which it exhibits in the oak.

To summarize the important features of ray structure: The most primitive condition is obviously that presented by the first-formed secondary wood which has uniseriate rays, the individual cells of which are lignified. In both these respects, the uniseriate condition and the lignification, the rays differ from those of the Cycads and Bennettitales, and resemble those of the Conifers. For the rest the relationship is with the lower Dicotyledones, as is manifested by the process of compounding, the ultimate multiseriate condition, the presence of false rays, their retardation of the growth, the form and arrangement, and especially the pitting of the individual cells. A condition typically Dicotyledonous has therefore been derived from a condition typically Coniferous in a method which is to be expected from a study of Dicotyledonous anatomy.

The different constituents of the secondary wood which we have been considering show very little specific variation, so that a diagnosis on the basis of wood structure would be very difficult to make. What variation exists is mainly one of degree. Thus *E. monostachya* has more septated wood parenchyma cells than the others; *E. Gerardiana* and *E. monostachya* exhibit a greater tendency towards the ring-porous arrangement of the vessels; *E. californica* usually presents a larger number of 'false' rays, &c. But these features vary greatly in different pieces of wood and in different regions of the same plant. Accordingly, it is very difficult to make a specific diagnosis with any degree of certainty. But this difficulty is only in keeping with the recognized conservatism of vascular structures.

BAST.

The bast of *Ephedra*, unlike the wood, shows little indication of Angiospermous affinities. Indeed, except for the presence of broad rays, it is typically Gymnospermous.

Fig. 34 represents a transverse section of the bast as well as the cambium and a little secondary wood. The biseriate ray in the centre of the field is seen to broaden out in a characteristic manner. In addition to the ray parenchyma there are other bast parenchyma cells which are arranged in radial rows and elongated vertically. They do not bear the

¹ loc. cit.

relationship of companion cells to the sieve-tubes, but are arranged rather in groups.

The sieve-tubes themselves are visible in this photograph as smaller cells which lack contents and are somewhat collapsed. They are never present in abundance, but, as shown here, are usually confined to small patches. In very large stems of the American species which have been examined they become proportionately much more numerous. In longitudinal section they are found to lack well-defined end walls, but to be long and tapering, as is typical of Gymnospermous sieve-tubes. This feature is shown in the tangential section photographed in Fig. 35. The sieve areas are not confined to the end walls of the tubes, but are scattered rather uniformly along the lateral radial walls, as may also be distinguished in Fig. 35. The same condition is shown in radial section in Fig. 36, in which the sieve areas appear in face view.

Outside the zone of actively functioning bast many of the cells collapse, but others become strongly sclerified. The latter are scattered singly or in small groups. They represent part of the parenchyma of the living bast.

The bast of *Ephedra*, then, in all the characters of its sieve-tubes and in most of those of its parenchyma, possesses no Angiospermous affinities, but is typically Gymnospermous. Strasburger¹ states that in its general appearance and arrangement it resembles most closely the bast of *Araucaria*.

CORTEX, EPIDERMIS, ETC.

As may be seen in the transverse section of the entire young branch (Pl. XCIV, Fig. 1) the external surface is strongly ribbed. Each rib marks the position of a bundle of sclerenchymatous fibres immediately below the epidermis (Fig. 1 and Pl. XCVII, Fig. 37). The fibres are extremely hard, and do not take the usual lignin stains. Others of the same type are scattered either singly or in groups through the rest of the cortex, and large groups occur in contact with the primary phloem. The outermost living cells are arranged more or less in the form of a palisade and are abundantly supplied with chloroplastids. Beneath this layer the tissue is more irregular and contains air-spaces. Thus the structure of the cortex is remarkably like that of a leaf, whose function it performs.

The epidermis is thick-walled and heavily cutinized. It is abundantly supplied with stomata like a leaf, but these are confined to the furrows between the projecting ridges (Fig. 37). The guard cells are strongly lignified, and deeply sunken under overarching accessory cells (Fig. 37).

The periderm formation which eventually throws off the cortex begins just outside the soft bast and inside the primary bast fibres. Its radial rows of cells are in line with those of the bast.

¹ loc. cit.

ROOT.

The root of *Ephedra* presents few features of special interest. The primary wood is diarch and small in amount. In the large primary root near the base of the stem it is arranged in two triangular masses whose outermost apices are occupied by the two protoxylem groups, and whose broad bases are separated by a lignified pith. In the secondary roots the primary wood is very small in amount and extremely difficult to recognize. Indeed, in most cases it appears to have completely disappeared, as has the fundamental parenchyma, so that the centre of the root is occupied by a solid mass of secondary wood.

This secondary wood is in all essentials like that of the stem, differing chiefly in the relative amounts of the various constituents. Thus the wood parenchyma is more abundant and the rays larger, features which are to be anticipated from the function of the root in storage. The vessels are also more frequently of the primitive type, and the bars of Sanio more conspicuous.

LEAF.

The leaves of *Ephedra* occur in opposite decussating pairs or in whorls of three according to the species. They are extremely reduced, in most cases being small brown functionless scales a few millimetres in length. In seedlings and young plants they may be much better developed, probably reverting to an ancestral condition. They then consist of a sheathing base and long needle-shaped extremity.

A section through the sheathing base of one of the best developed leaves is represented in Fig. 38. Only the thickest part of the leaf in the region of the vascular bundles is included. Laterally, where it joins its fellow of the opposite side the leaf is only two or three cells in thickness. Stomata are exceedingly rare, but when present are deeply sunken like those of the stem. The mesophyll is not differentiated into layers and contains at best very little chlorophyll.

Such a leaf as this is enormously developed in comparison with the ordinary adult leaves, which are only three or four cells thick. Moreover, the cells soon become thick-walled and perish. In most cases sclerenchymatous fibres are scattered throughout the substance and may occasionally be arranged in bundles as in the stem.

The tissue of the leaf is early separated from that of the stem by the development of a layer of absciss periderm. The whole of the sheathing base is involved. In Fig. 42 the dark band across the centre represents the periderm layer, below which is the tissue of the cortex and leaf-trace, and above is the empty thick-walled mesophyll of the leaf. The presence of the absciss periderm is a distinctly Angiospermous character.

The vascular system of the leaf consists of two bundles, the continuations of the double trace whose course we have already examined. The two strands continue distinct and unbranched to the apex of the leaf. They are visible at low magnification in Fig. 38, and one of them is shown more highly magnified in Fig. 39. Each bundle is without a sheath of any kind and is flattened in a dorsiventral direction. The tracheides, which are very few in number, are arranged in radial rows. There is no trace of centripetal wood, all the larger elements being developed centrifugally to the protoxylem. The phloem is very poorly developed. At the edges of the bundle, as Strasburger¹ has noted, there is an occasional transfusion tracheide, one of which can be distinguished in Fig. 39 by its bordered pits and thickening bars. The bundle figured is better developed than is usually the case, for as a rule the tracheides are very few in number, the bast practically absent, and the transfusion tracheides rare. Such a bundle with its lack of centripetal wood and possession of transfusion tracheides is exactly like a reduced Coniferous bundle, and quite unlike that of the Cycads with its large development of centripetal wood.

In their basal portion the long needle leaves of the seedling have the same vascular organization as the typical adult leaves. But in their tips this organization becomes modified. The secondary wood of the two bundles diminishes (Fig. 40) until it quite disappears (Fig. 41). Meanwhile, the transfusion tissue increases laterally, and also develops centripetally. In the latter position it increases in amount towards the tip until it forms a solid mass between the two fast vanishing groups of centrifugal wood (Fig. 40). As it increases in amount, the form of its cells also changes; they become longer and more like true tracheides. Finally, in the extreme tip of the leaf the centrifugally developed tracheides have completely disappeared, and only a group of the centripetal ones remain (Fig. 41). Some of the latter are like typical transfusion tracheides, and some of them are more like ordinary tracheides, and might for this reason be considered centripetal wood.

The conditions just described might be used to support Worsdell's contention² that the transfusion tissue has been derived phylogenetically from the centripetal wood of the ancient Gymnosperms. The transitions between centripetal wood and transfusion tissue which he observed in several forms, notably in *Cycas* and *Araucaria*, are duplicated here. The evidence is thus the same as he presents. It should be emphasized that the leaves in which these conditions are found are the abnormal seedling ones, and that the elongated tip to which the centripetal wood is confined is not ordinarily present.

The structure of the vascular bundles of the leaf strongly indicate Coniferous affinity. The development of centrifugal and typical absence of

¹ Über den Bau, &c.

² Origin of Transfusion Tissue. Trans. Linn. Soc., 1895.

centripetal wood are quite like the conditions in Conifers, and quite unlike those in Cycads. The small amount of centripetal wood in the abnormal seedling leaves has its counterpart in several of the Conifers.

•

CONCLUSIONS AND RELATIONSHIPS.

A complete discussion of the affinities of the Gnetales as indicated in an anatomical study is deferred until the other members of the group have been subjected to a similar study. Certain facts brought out in this investigation, however, may be emphasized here.

As we have already noted, there is an increasing tendency at the present time to regard the Gnetales as derived from Cycadalean stock. The opinion has no doubt sprung from the conviction of many botanists that the Angiosperms have had the same origin, namely, from the Bennettitales, and that there is a real affinity between the Angiosperms and Gnetales. The fullest expression of this idea has been given by Arber and Parkin,¹ whose conclusions have been reached almost entirely from a consideration of floral organization. They maintain that these two great groups have developed along parallel lines from a common ancestor which was in turn derived from forms like Bennettitales. Deferring the consideration of the Angiospermic relationship, let us see what bearing the results of the present study have on the idea of a Bennettitalean origin for the Gnetales.

It may be stated at once that on the anatomical side there is very little evidence for connecting the Bennettitales with *Ephedra*, although this genus, being the most primitive of the Gnetales, is the one where the evidence ought to be found. The only notable feature of resemblance is the possession by both of multiseriate rays, but, as we have seen, those of *Ephedra* have undoubtedly been developed from a condition quite different from the Bennettitalean one, namely, from a uniseriate lignified condition. Therefore the only real anatomical point of resemblance proves valueless in establishing a connexion.

On the other hand, there are a great many differences so vital as to make any real affinity extremely doubtful. Among those differences should be mentioned the course and arrangement of the primary bundles, the pitting of the tracheides, bars of Sanio, tertiary spirals, wood parenchyma, primitively lignified uniseriate rays, adult rays derived by fusion, double leaf-trace, absence of centripetal wood, and development of centrifugal wood in the leaf-trace. Thus almost every tissue presents grave obstacles to this view. All these differences constitute too great a mass of evidence to be overlooked, especially since there appear to be no anatomical resemblances on which to base a relationship.

¹ Studies in the Evolution of the Angiosperms: The Relationship of the Angiosperms to the Gnetales. Ann. Bot., 1908.

With regard to the more recent Cycads they possess one feature of resemblance lacking in the Bennettitales, namely, the double leaf-trace whose two strands were inserted separately in the stele. But as the double leaf-trace is common to so many groups of Gymnosperms it might be used with equal force to connect any of them with the Gnetales. As for the fact that the two strands are inserted separately in the stele, we have seen that this is a variable feature, even the ancient Gymnosperms showing both a condition of separation at the stele (*Poroxylon*), and one in which the strands unite before entering (*Lyginodendron*). Miss Sykes, in her study of *Welwitschia*, brought forward other points of resemblance to Cycads, namely, the occurrence of centripetal wood in the peduncle and of inversely oriented and concentric bundles in the reproductive axis. A preliminary study of the reproductive organs of *Ephedra* has failed to reveal any of these features. On the whole it may be said that the differences between *Ephedra* and the modern Cycads are almost as strongly marked as between *Ephedra* and the ancient Bennettitales. Moreover, if the Gnetales have been derived from Cycadalean stock, most botanists would agree from the evidence of floral organization that it must have been from the Bennettitales, so that any advantages of the modern over the ancient members of that alliance should not have weight.

With the growth in favour of the idea of Cycadalean affinity the older view of the Coniferous relationship of the Gnetales is being supplanted. The present study has led the writer to conclude that the older view had much more in its favour than the more modern one. Every one of the points enumerated as opposed to the Cycadalean relationship may be used in an argument for the Coniferous relationship. To emphasize only the strongest points one should mention the arrangement and structure of pits of the tracheides, bars of Sanio, tertiary spirals, trabeculae, primitive uniseriate and lignified rays, lack of centripetal and development of centrifugal wood in the leaf-trace, and the structure of the vascular bundles of the leaves. These points of remarkable resemblance do not prove a descent from any modern group of Conifers. Indeed, such a descent seems difficult to establish. Opposed to it is the very generalized character of the secondary wood combining many characters found in the various groups of Conifers, such as Araucarian and Abietinean pitting, bars of Sanio, tertiary spirals, trabeculae, resin plates, and wood parenchyma. These points would rather indicate an affinity with that Abietinean-Araucarinean stock which it is now generally conceded gave rise to the modern Conifers. Of course it is possible that the Gnetales represent a line of development paralleling to a considerable extent that of the Conifers. But, however opinions may differ as to the exact point of origin of the Gnetalean line, there is a large mass of evidence to indicate an affinity with the base of the Coniferous line of descent.

Evidence from other sources supports this view. Hill and de Fraine,¹ from their study of the vascular system of the seedlings, conclude that in this respect *Ephedra* strongly resembles *Araucaria* and the Podocarps. Miss Sykes states that the transition phenomena between root and stem in *Welwitschia* strongly resembles that in *Araucaria*.

If the anatomical evidence leads to these conclusions the gametophytic evidence is just as conclusive. According to Land's² description the male gametophyte is typically Coniferous in all details. The female gametophyte differs from that of Coniferales only in the long neck of the archegonium and presence of a pollen-chamber, features which he explains on a physiological basis.

Thus all the essential features, both gametophytic and anatomical, indicate some relationship to the Conifers. Opposed to these and in favour of the Cycadalean affinity we have so far only the evidence of floral organization.

With regard to the Angiospermous relationship *Ephedra* presents several points of interest. Prominent among these is, of course, the possession of vessels. But, as has been pointed out, the vessels of *Ephedra* exhibit vital differences from those of the Angiosperms, although the rare occurrence of fusion of perforations lessens this difficulty. An equally striking feature and one which has been overlooked is the possession of broad rays like those of the lower Dicotyledonous woods, and especially their origin by compounding. This is really a feature of first importance. Among those of lesser value one should recall the separation of the leaf-traces on the stem and the presence of an absciss periderm in the leaf.

SUMMARY.

The pith presents two striking features in the presence of a peridermal diaphragm at the base of each internode and occasional patches of lignified cells simulating centripetal wood.

The primary vascular bundles run regularly through one internode and lose themselves in a nodal girdle of tracheides. Throughout the internode their structure is endarch, but at the node occasional elements like transfusion tracheides are present in a centripetal direction. Transfusion tracheides also occur laterally to the bundles in the internodes of some species.

The leaf-traces are double and the two strands are inserted separately, usually with a vascular bundle between. In structure they are endarch throughout.

The tracheides of the secondary wood are characterized by the arrangement of the pits in both the Abietinean and Araucarinean fashion, structure

¹ On the Seedling Structure of Gymnosperms, IV. Gnetales. Ann. Bot., 1910.

² Spermatogenesis and Oogenesis in *Ephedra trifurca*. Bot. Gaz., 1904.

of pits typically Coniferous, tangential pits, bars of Sanio, and occasionally by tertiary spirals, trabeculae, and resin plates.

The vessels possess all the features just enumerated for the tracheides, and have also perforations which represent bordered pits. The transitions between tracheides and vessels are remarkably complete, all stages in the disappearance of torus and border being visible even in single elements. The vessels are very few in number and of a primitive character in the seedling, and more numerous though of the same character in the first-formed secondary wood of the branches. Fusion of perforations may be observed rarely.

The wood-parenchyma cells, which occur abundantly either scattered or in tangential rows, resemble tracheides in size, shape, lignification, and sometimes in pitting, and have probably been derived from tracheides. They are often multinucleate. They appear to resemble most the so-called fibrous cells of Angiosperms.

The medullary rays of the first-formed secondary wood are uniseriate, and from these the broad rays of the adult are derived either by simple enlargement, addition through the transformation of tracheides to ray parenchyma, or by compounding. The latter process is the same as in Dicotyledones. False rays are common. The individual cells are lignified and pitted like those of Dicotyledones. The broad rays have a retarding influence on the growth of the surrounding wood.

The bast is typically Gymnospermous.

The cortex is abundantly supplied with chlorophyll and functions as a leaf. The stomata in the epidermis of the stem are numerous, and are confined to furrows between projecting ridges due to hypodermal bundles.

The leaves are small and non-functional, except a few on the seedling. The vascular bundles are two in number, small and endarch. Transfusion tracheides are common. At the tip of the seedling leaves the transfusion tracheides develop centripetally and become more like centripetal wood.

The idea of Cycadalean and Bennettitalean affinity receives little support from the anatomy of *Ephedra*. On the other hand, there are many points which are opposed to it, and in favour of Coniferous relationship: the arrangement of the primary vascular bundles, double leaf-trace, arrangement and structure of pits on the tracheides, bars of Sanio, tertiary spirals, trabeculae and resin plates, primitive uniseriate lignified rays, wood parenchyma, and endarch vascular bundles of the leaf. The Gnetales do not appear to have arisen from any modern group of Conifers, but rather from or close to the base of the Coniferous line.

An Angiospermous affinity is indicated by the possession of true vessels, broad rays, formation of broad rays by fusion, and separation of the leaf-traces on the stem.

This investigation has been carried on by the writer in the Phanero-

gamic Laboratories of Harvard University, as an 1851 Exhibition Science Research Scholar of the University of Toronto. He is indebted to Professor E. C. Jeffrey for material and advice.

Some Plant Formations from the Arid Regions of Western China.

BY

F. KINGDON WARD, B.A., F.R.G.S.

THE arid or semi-desert regions to which the following notes apply comprise several deep trench-like valleys, trending for the most part north and south, which dissect the complicated mountain systems of far western China in the provinces of Kansu, Ssü-chuan, and Yun-nan, or as this country may be comprehensively termed, Chinese Tibet.

As examples to which I shall have occasion to refer we may instance the headwaters of the Min river in Southern Kansu, the T'ung-ho, and the Kin-sha-kiang (or upper Yangtze) in Ssü-chuan, the upper Mekong in North-West Yun-nan, and the upper Salween in South-East Tibet, north of lat. 28° . The arid nature and peculiar vegetation of these gorges in the midst of a region of copious rainfall, certain historical questions which obtrude themselves in connexion with one of the most characteristic components of the open formation met with, and the morphological adaptations of the flora, are interesting points which deserve to be considered in turn; but at the outset it will be well to explain how these barren gorges have come into existence in the first instance.

The rivers referred to here flow at altitudes varying from about 6,000 to perhaps 10,000 feet above sea-level, while the mountains immediately overshadowing them rise to very much greater altitudes, more especially in the case of the Mekong and Salween rivers.

Apart from the xerophytic nature of the vegetation, the fact that these rivers have been able to cut their way straight down between their investing walls is sufficient evidence for the dryness of the climate in the valleys themselves, but the big alluvial cones debouching into the main valleys speak just as eloquently of a furious rainfall above.

Where the rock is limestone clean-cut gorges are indeed always formed, owing to natural jointing; but even where the rocks are of granite, or of metamorphic origin, these rivers have managed to cut their way straight down, often leaving cliffs of rubble as much as 700 feet high.

Through these funnel-like valleys a daily wind blows up from south to north throughout the summer months with the regularity of a trade wind, springing up shortly before mid-day and dying away after sunset.

I have remarked this scorching blast in all the valleys alluded to, particularly on the three biggest rivers, the Kin-sha, Mekong, and Salween, strongest of all perhaps on the Mekong, where it is more confined than anywhere else. Throughout the day it increases in ferocity, till about four o'clock in the afternoon it reaches a climax, then gradually calms down towards nightfall; and though rather of the nature of a sirocco, it is always extremely welcome after the intense heat of the day.

This wind is of course caused by the cold air sweeping down from the surrounding peaks to fill the partial vacuum caused by the great heating of the shut-in valleys during the day, and it greatly intensifies such desert conditions as are already imposed owing to the proximity of the mountains, which act the part of rain-screens. It is indeed a peculiarly desiccating wind, since it has already rid itself of its moisture, and throughout the summer it comes up the valleys like the breath from a hot furnace, till the withered vegetation on the cliffs seems gasping for water. Thus the severity of the conditions increases automatically as one travels northwards, for the intensity of the wind itself increases with the dryness produced by its action.

On the Salween and Mekong rivers an abrupt transition from a rainy region to one of extreme aridity corresponds to a general elevation above the snow-line of the dividing watersheds; the only break in the dreary scene is where a mountain torrent has flung out an alluvial cone which, terraced, and green with cultivation, forms a little oasis in the wilderness.

Travelling up the Mekong valley I have frequently noticed a long ribbon of blue sky faithfully following the valley, while the clouds, though perhaps clear of the mountain peaks, are massed in great puffs of cumulus on either hand, showing plainly enough that columns of hot air are ascending from the valley.

Once in the Mekong valley I watched the clouds in the south, from which snow and rain were actually falling at the time, trying to force their way up the valley into the arid region beyond, where blue sky prevailed; however, they failed signally to cross the dividing line, and it was as though some invisible barrier was forcibly holding them back, the truth being that the hot air rising from the bare rocks prevented any cloud existing as such.

Again, in the Salween valley I have watched the clouds gathering black in the west over the Irrawaddy, watched them sweep slowly over the valley, and reinforced still further, burst again over the Salween-Mekong divide to the east, a few scattered drops hissing on the scorched rocks of the Salween valley alone announcing their passage of that river.

It is abundantly clear then that the arid valleys of Western China owe their inception to just those causes which, on a much larger scale, give rise to continental deserts.

The scarcity of rain, which probably does not exceed five inches in a year, would of itself be a serious hindrance to plant life, and this is

aggravated by the scorching winds which blow throughout the vegetative season; consequently we here meet with an open formation of stunted shrubs and herbs more or less specialized to combat the hostile conditions.

Characteristic shrubs are *Sophora viciifolia*, *Bauhinia densiflora*, and several other Leguminosae, *Clematis Delavayi*, *Ceratostigma Griffithii*, species of *Pertya*, *Wikstroemia*, and so on, none of them rising more than two or three feet from the ground.

A good deal of bare rock is necessarily exposed—indeed viewed from any distance these gorges often look quite devoid of life, except for the cultivable oases above referred to.

It is worth noting that the usual structure of river valleys is completely reversed in the case of mountain streams entering these arid gorges, and this is particularly true where the rock is of limestone. A river as a rule flows through ravines and gorges near its source, its valley gradually growing broader, till finally the stream is wandering sluggishly across a flat flood-plain. Here, however, a stream having its source high up in the mountains flows in a comparatively broad valley, winding through alpine pastures; gradually the valley contracts, passing from a typical U-shape in cross section to a pronounced V, the stream plunges down a long stairway, and finally cuts its way abruptly through a deep gorge to join the main river.

In this case the phenomena of reversed valley structure is emphatically a function of the climate apart from the nature and jointing of the rocks. I have drawn attention to it because it accounts satisfactorily for the fact that, while the main valley presents nothing but a dreary waste of rock, scattered amongst which are withered herbs and dwarfed spiny shrubs, the side ravines are often densely choked with vegetation, fresh and green.

This is not due to the fact that the stream itself supplies water to the cliffs and precipices of the gorge, which it certainly does not, but to the circumstance that the sunlight is kept out nearly all day, and consequently the heavy dews in a region of intense radiation are able to supply the requisite amount of water, a point I noticed frequently in the Mekong valley. Future travellers in these regions may however note that this reversed valley structure makes a journey up the Salween or Mekong one of the most appalling nightmares possible.

Though the bigger torrents enter the main valleys through richly vegetated gorges, the smaller and more intermittent ones throw out alluvial cones, and it is under these circumstances that irrigation by means of terracing becomes possible, so that villages occur only where a small stream debouches from the mountains.

Since in South-Eastern Tibet the rain-bearing winds pass over the mountains from the west, the valleys as we go east receive less and less rain, so that the most abrupt transition from a rainy to an arid climate

occurs, not in the easternmost valley, which is already shut out of a great part of its normal rainfall, but in the most westerly—the valley of the Salween ; nothing indeed could be more striking than the abrupt change from semi-tropical jungles in the southern rainy part of the valley, to semi-desert further north, a change rendered all the more striking by a correlated change in the people, from the tribesmen of the jungles to the Tibetans of Tsa-rüing in the north.

Granite occurs frequently in these valleys, and can be recognized from a distance by the clumps of Prickly Pear (*Opuntia vulgaris*) which grow amongst the 'tors' and boulders of the weathered rock ; it apparently grows nowhere else but on granite rocks, and, conversely, wherever granite occurs there also will be found the Prickly Pear. Its interest lies in the fact that *Opuntia vulgaris* is a native of Mexico or California, and it is worth while inquiring how it found its way into Western China. I have traced it from Kansu through Ssü-chuan to South-East Tibet and Southern Yun-nan, cultivated of course for the sake of its fruit, and such a wide, if discontinuous, distribution at that distance from its original home is curious.

It is not of course the only plant which has wandered far from its home under circumstances hitherto unexplained, or merely conjectured ; we need only instance the maize, also said to be a native of Mexico, now cultivated throughout the world. But a cereal of such general utility as maize, in common with rice and other staple grains, was probably distributed over the globe from the very earliest times, whereas such is not likely to be the case with *Opuntia*, which after all is of no very great importance as a source of food.

Two suggestions present themselves,—the first that it was brought across the Pacific by the Chinese themselves, the second that it was introduced from Europe after it had been brought into the Mediterranean region from across the Atlantic ; a third alternative, that it was quite recently introduced by the Jesuit missionaries who came from America to China about the time of the fall of the Spanish Empire, is hardly tenable in view of its present wide distribution in Western China.

There can be little doubt that the Chinese visited California long before Columbus or possibly even the Norsemen discovered America, being carried across the Pacific accidentally by the Kuro Shwio, and voyaging across it when the intrepid Chinese mariners sailed those seas to the Indies, to Japan, perhaps even to Australia. It is equally well established that there was considerable intercommunication between Europe and Asia, particularly between Greece, India, and China, in very ancient times ; and if during this intercourse ideas on art and religion were exchanged, it is highly probable that other things were also, more especially useful plants and the ordinary commodities of trade.

Let us lastly consider the xerophytic flora in general, noting that one of its most constant features is the 'rosette' habit.

It is well exhibited by *Didissandra lanuginosa* and other species (10,000-12,000 feet), *Androsace Bulleyana* (9,000-11,000 feet), *Saxifraga candelabrum* (10,000 feet), and even *Eremurus chinensis* (9,000 feet) with its rosette of stiff spear-like leaves.

It is scarcely necessary to point out that the 'rosette' habit is not peculiar to xerophytes, being common for example on lawns (*Taraxacum*, *Bellis*), where it is doubtless brought about by the necessity for exposing as much surface as possible in a limited space, or to mutual pressure of parts.

But when the most successful plant of all found growing under abnormal conditions adopts a peculiar habit, and when moreover this identical habit is found in several other plants growing under similar conditions, we are justified in believing that this habit is in fact an adaptation to withstand those conditions.

Thus the most characteristic plant of all, growing in the semi-desert and arid valleys down as low as 7,000 feet, is *Selaginella involvens*, which covers the rocks in its thousands.

The 'rosette' habit protects the plant to a considerable extent against undue transpiration, the small, closely packed and overlapping leaves shading one another and forming an admirable protection for the growing point; moreover, the resulting dwarfed habit implies a minimum exposure of the plant to the desiccating winds, and is doubtless largely due to the brilliance of the direct and reflected light.

But the *Selaginella* referred to amply protects itself throughout the driest weather by rolling up into a ball like a hedgehog, thus exposing only the under surface of the leaves, which is silvery. Almost exactly the same device is adopted by the Fern *Cheilanthes farinosa*, each frond of which curls up into a little ball during the dry season, exposing a brightly silvered surface. It will probably be found that this surface, by reflecting the light and heat rays, reduces still further the transpiration from the under sides of the leaves.

Other familiar adaptations are fleshiness, found in several species of *Sedum* (stem and leaves), besides *Opuntia*, and the very thick cuticle of *Eremurus*; we need say nothing about them. But it may be noted that the 'rosette' habit often carries with it a biennial existence, e. g. *Androsace Bulleyana* and *Saxifraga candelabrum*, the first year being employed in storing the rosette with reserve food for the final effort of flowering in the second.

Finally, we may point out that there are not a few plants characteristic of the higher arid valleys which present none of the above obvious peculiarities; such are *Amphicome arguta* and the twining *Dregea sinensis*. But it is only fair to add that these are not found at the bottom of the deep

trenches where flow the Salween and Mekong rivers in the real semi-desert regions. On the whole perhaps the arid regions of Western China present features more interesting to the geologist than to the botanist, since we find practically the same adaptations to combat the hostile conditions here as are found in waterless regions elsewhere; nevertheless, a comprehensive survey of the flora and its various morphological peculiarities, with a knowledge of all the physical conditions which react on the vegetation, would be most instructive when we come to deal with distribution. For it is just these deep semi-desert valleys which intervene between the Himalayan flora and the flora of Western China.

On the Comparative Anatomy of the Genera *Ceraria* and *Portulacaria*.¹

BY

MARGARET RUTHERFORD MICHELL, B.A.,

Queen Victoria Scholar of the University of the Cape of Good Hope.

With Plate **XCVIII** and four Figures in the Text.

THE three species of the genus *Ceraria* are all typical xerophytes, well adapted to the dry situations in which the plants grow. The material for this investigation was obtained by Dr. Pearson in South-West Africa. As both species were found during the flowering season, which does not coincide with the period of greatest vegetative activity, some interesting points connected with the structure of the stem could not be determined with certainty. *Ceraria gariepina* was found on granite hills in Bushmanland, on the same slopes as *Pachypodium namaquanum*, in January, 1909 (Text-fig. 1).

Ceraria namaquensis, material of which was obtained in the Richtersveld in January, 1911, had previously been found by Atherston and Wyley in undefined localities in Namaqualand.² Both these species are small trees, averaging about twelve feet in height. Until recently *C. namaquensis* was known as *Portulacaria namaquensis*, under which name it appears in the 'Flora Capensis'.³ It has now, on account of important characters of ovary and fruit, been placed in a separate genus, *Ceraria*,⁴ of which two other species are known, *C. gariepina* and *C. fruticulosa*. *Portulacaria afra*, now the only species in the genus, is a large shrub common in the Karroo.

On account of the close systematic relationship between the two genera it was thought that a comparative study of the anatomy might prove interesting. The stem of *Ceraria* is covered with thick leathery bark, interrupted at regular intervals by the prominent nodes, each of which bears several minute sessile leaves. The plants were only seen during the flowering period, when the number of leaves was small. At other seasons the leaves are probably more numerous. They are extremely small (2-4 mm. in length), obovoid in shape, and extremely fleshy. The branching

⁴ Pearson and Stephens ('12) (3).

in this genus is pseudo-dichotomous,¹ therein differing from that in *Portulacaria*, where the branching is of the ordinary lateral type.

Solereder gives a brief account of the anatomical features of the Portulacaceae,² but little work appears to have been done with regard to this order. Mention is made of a few of the outstanding characters of *Portulacaria afra*. None of the features of this order, upon which Solereder lays stress, is absent in *Ceraria*, although in a few minor details this genus seems

TEXT-FIG. 1. *Ceraria gariepina*. Photograph taken at Aggenys in Bushmanland in 1909 by Dr. H. H. W. Pearson. From the 'Gardeners' Chronicle'.

to have no parallel in the other genera. The arrangement of the mucilage cells, and the occurrence of calcium oxalate in the intercellular space beneath a stoma, may be quoted as instances of this.

ANATOMY.

A. Leaf.

C. namaquensis.

The structure of the leaf corresponds very closely with that of *Portulacaria afra*, to which genus *Ceraria* is closely allied. Proceeding from without inwards, it is found that the epidermis has its outer and inner walls cutinized to a very great extent (Pl. XCVIII, Fig. 1). The radial walls are

¹ Pearson and Stephens ('12) (3).

² Solereder ('08), vol. i, pp. 111-13 (6).

only to be seen with difficulty, and with a low-power objective the outer and inner walls alone are visible. The guard cells (Pl. XCVIII, Fig. 2) are spherical in section, and are accompanied by two subsidiary cells (Pl. XCVIII, Fig. 3) placed parallel to the pore. A peculiar feature of the leaf is the occurrence of calcium oxalate crystals in the intercellular space beneath several of the stomata.

De Bary¹ and Sachs² both cite a few cases in which calcium oxalate is present in the cell-walls of the epidermis, though the formation of crystals of this substance in intercellular spaces is unrecorded by them. According to Sachs the occurrence of calcium oxalate in the cell-walls is rare among Angiosperms, only having been observed by Solms-Laubach in certain species of *Mesembryanthemum* and in *Sempervivum calcareum*. Pfeffer has recorded the occurrence of these crystals in the cell-walls of some *Dracaenas*, and in these cases calcium oxalate is not confined to the epidermis, but is found also in cells lying deeper in the tissue. On the authority of Solms-Laubach it is stated that these crystals occur commonly in the Gymnosperms, being formed in the middle lamellae of the cell-walls. No indication of a similar origin of the crystals in *Ceraria* is given. No definite palisade tissue occurs, the outer cells of the mesophyll containing numerous chloroplasts. These decrease in number as the centre of the leaf is approached, though none of the central cells is devoid of them. Below the epidermis, large brown mucilage cells are found in which there are no chloroplasts. In this species the mucilage cells occur scattered in the first two rows of cells beneath the epidermis. The vascular bundles are small in section and vary but little in size. There are from seven to eleven bundles in a leaf, and these are deeply embedded in the tissues, so being invisible from the outside. The appearance in transverse section is that of a parallel-veined leaf, but it can be shown by cutting a section in the plane of venation that the bundles form a loose reticulum. Each bundle leaves the primary vein at a small angle, and almost immediately assumes a direction parallel to that of the central bundle. At the tip all the bundles branch and anastomose, so giving rise to a complex network.

Clustered crystals of calcium oxalate occur in the mesophyll. There are two kinds of these crystals. The first has a rough sandy appearance, due to the fact that all the crystals in a cluster are not of the same length and some project beyond the others, so giving the whole mass, when highly magnified, a spiny appearance. These crystals resist the action of nitric acid longer than the large crystals which are found beneath some of the stomata. This second kind of cluster is made up of a large number of slender wedge-shaped crystals, radiating from a centre and so forming a hemispherical mass.

¹ De Bary ('84), p. 102 (1).

² Sachs ('82), p. 66 (4).

C. gariepina.

This species resembles the former in all its outstanding features. The following differences, however, must be noted :

(a) The mucilage cells are less numerous, and only occur in the cell row immediately below the epidermis.

(b) The crystals of calcium oxalate are more numerous, and the larger clusters occur in the cells of the mesophyll as well as below stomata. Crystal-blocked stomata are more frequently found in this species, about 20 per cent. of the stomata possessing the crystals.

The leaf of *Ceraria* affords a good example of the xerophytic structure so common in plants growing in dry regions. The size and shape of the leaf are to be noticed in this connexion. In *Ceraria* the xerophytism is more pronounced than in the allied genus *Portulacaria*, and the differences which exist between the leaves of the two genera are correlated with this fact.

B. Stem.

C. gariepina.

The most striking feature in a transverse section is the broad band of dark-brown mucilage cells occurring in the cortex. This ring does not appear to be found in the other genera of this order.¹ The stem is surrounded with a thick bark, an account of which is given below.

Cortex. In the cortex there are three distinct bands of tissue (Fig. 4). Next the bark are large water-storing cells, separated from one another by radial bands of parenchyma. The mucilage band occupies the greater part of the cortex, and consists of large mucilage-containing cells interrupted here and there by small parenchyma cells. The innermost layer of the cortex consists of ordinary ground tissue with groups of sclerenchymatous cells immediately opposite the bundles.

Endodermis. The endodermis is not marked.

Stele. The vascular bundles are arranged in a ring, and are very similar to those of *Portulacaria afra*, the chief difference in the vascular cylinder being that in *Ceraria* three or four of the medullary rays are broader than the rest. There are about twenty open bundles of the usual collateral type, and in the oldest stem available three faintly marked annual rings could be distinguished (Fig. 6).

Phloem. The phloem is characterized by a great development of fibres on the outer side of each phloem mass. All elements of the phloem have an extremely small transverse diameter, and for this reason the separate elements are difficult to identify. The sieve plates occur on both the lateral and the end walls of the sieve-tubes, but owing to their small size, and the difficulty experienced in obtaining microtome sections, their

¹ Solereder ('08), p. 112 (6).

structure could not be determined (Pl. XCVIII, Fig. 5). A small amount of parenchyma occurs in the phloem, but companion cells have not been recognized with certainty.

Cambium. The xylem is separated from the phloem by a definite cambium, usually two or three cells wide.

Xylem. The most striking feature of the xylem is the entire absence of bordered pits,¹ simple pits being found in the vessels, tracheides, parenchyma, and fibres. The pits are often horizontally elongated, though

TEXT-FIG. 2. *Ceraria namaquensis*. Diagrammatic representation of a transverse section through the stem. P = pith; i.c. = inner cortex; m.r. = mucilage ring; o.c. = outer cortex; b = bark. $\times 16$.

not enough so to justify the use of the term scalariform. Lignified parenchyma cells are present, but not to any great extent. Fibres are abundant as in the phloem, differing, however, in this case in being slightly pitted. The pits are more numerous on the walls adjoining the other xylem elements than elsewhere. Spiral tracheides, constituting the protoxylem, show no peculiarities.

Pith. The pith is small in amount, and consists entirely of parenchyma.

¹ Solereder ('08), pp. 111 and 113.

Clustered crystals of calcium oxalate are found in great abundance. In the large water-storing cells beneath the periderm, clusters occur which may extend over two or three cells. These clusters are larger, but otherwise resemble the second type described in the leaf (Pl. XCVIII, Fig. 7). Clusters of the first type are abundant in the parenchyma of the stem.

No starch is found in this species, probably owing to the fact that the material was obtained during the early part of the vegetative season.

Throughout the stem, drops of some fixed oil occur. These stain easily with either a 1 per cent. solution of osmic acid or an alcoholic solution of alkannin, but of the two alkannin is the more reliable stain. Certain organic compounds, as well as oil, are stained black with osmic acid; and as the mucilage ring stains easily with this acid, some organic compound must accompany the mucilage, which of itself is not affected by this reagent. The suberized cell-walls of the bark appear to be impregnated with some fat or oil, which, however, differs from the oil occurring in drops in being insoluble in ether, chloroform, or benzol. In the 'New Phytologist' an account is given by T. G. Hill of the use of 'Scharlack R' as a micro-chemical test for oil in plant tissues.¹ Any oil present stains pink, while other substances are not affected. In *Ceraria* this reagent only stains the oil in the cell-walls of the bark, leaving the oil drops colourless. As these drops stain easily with both the other reagents used, the result obtained with 'Scharlack R' cannot be considered a proof of their non-oily character. The cells of the innermost layers of the periderm have cellulose walls in which no oil is found. The oil appears simultaneously with the change in composition of the wall from cellulose to suber.

C. namaquensis.

The stem of *C. namaquensis* is very similar to that described above. The quantity of mucilage, however, is so great that sections cut and placed even in 70 per cent. alcohol swell immediately, and are unfit for staining. The chief differences are:

(a) The bands of parenchyma separating the large water-storing cells are in this case extremely narrow.

(b) Annual rings are absent, which fact, however, is not remarkable, as there are two rainy seasons a year in the regions in which this plant grows.

(c) The material of this latter species was gathered at the end of the principal vegetative season, and therefore it is not surprising that large quantities of starch are found in the parenchyma throughout the stem.

(d) The oil which is present in *C. gariepina* is found here as well, the only difference being that the quantity is considerably less. The suberized cells of the bark do not stain as deeply with alkannin in this species as they do in *C. gariepina*.

¹ Hill ('12), (10).

TEXT-FIG. 3. Bark of *Ceraria gariepina*. Photographed by J. A. Michell.

From what has been said it would appear that two distinct kinds of oil are found in the stem:

1. The drops of oil occurring throughout the stem in the cell cavities.
2. The oil permeating the corky walls of the bark.

It is possible that the oil-drops have been converted from starch into oil during the resting period, and that these plants are of the same nature as those designated by A. F. W. Schimper 'fat trees'.¹ The fact that no starch but much oil is found in *C. gariepina* which was gathered during the resting period, and that *C. namaquensis* which was obtained at the beginning of the resting period has a large quantity of starch and little oil, tends to support this hypothesis.

Periderm.

An interesting feature of *Ceraria* is the great development of leathery bark. This can easily be separated from the rest of the stem, and thus hollow cylinders of bark may be obtained in an unbroken condition (Text-fig. 3).

In the bark of *C. gariepina* there is some inflammable substance which does not appear to be present in as large quantities in *C. namaquensis*, and which causes the living plant to burn easily. The results of a chemical investigation of the constituents of the bark are not yet available. This phenomenon suggests a comparison with *Dictamnus albus*, the Candle-plant,² which secretes an extremely volatile oil. On calm hot days, if a match be applied the surrounding air takes fire and the plant itself burns.

In *Ceraria namaquensis* the apex of the stem is protected by a number of scale leaves, the base of which consists of mucilage cells similar to those of the stem (Pl. XCVIII, Fig. 8). Immediately behind the scale leaves the epidermal cells appear to give rise to a cambium which persists throughout the life of the plants, cutting off cells on its outer side only. It cannot be stated with certainty that this is a cambium, although it seems probable. Only in three or four cases have cells been seen to have divided recently, but considering that the material was gathered at the end of the vegetative season, it would appear that the cambium had entered upon a period of rest. Support is lent to this supposition by an examination of two lots of material of *Portulacaria afra* obtained in the Cape Peninsula. Material (A) was collected in June at the commencement of vegetative activities, and this shows that a large number of cells of the phellogen had recently divided. Material (B) was gathered in January, during the resting period, and in this only two or three cells of the cambium had recently divided. There is no phelloderm formed and the number of cell rows separating the cambium from the large water-storing cells of the cortex is constant. As a rule only one row of these cells is present. The cambium first of all cuts

¹ Schimper ('08), pp. 436-7.

² Willis ('04), p. 350 (9).

off tubular thin-walled cork cells, and continues doing so until from fourteen to eighteen rows of cells have been formed. The cells which are now cut off have not the definite rectangular outline which characterizes the first type (Pl. XCVIII, Fig. 9) of cell formed, and they possess slightly thickened cellulose walls (Pl. XCVIII, Fig. 10). These cells become more and more crushed and stretched as new cells are cut off from the cambium. It is not, however, till their outline is hardly recognizable that they become suberized.

TEXT-FIG. 4. *Portulacaria afra*. Diagrammatic representation of a section through the stem.
P = pith; xy. = xylem; ph. = phloem; C = cortex; mc. = mucilage cells. $\times 16$.

In the older parts of the stem it is these cork cells which constitute the bark, the first formed cork having worn away. In this no cell outlines are visible, and the lamellated appearance in section is due to the tangential walls of the original cells remaining distinct, while only traces of the radial walls are left. In *C. gariepina* the cork consists of a number of layers easily separated from one another, and in the young stem every alternate layer stains with safranin. Later on the cork stains uniformly, but the layers still remain distinct (Pl. XCVIII, Fig. 11). Possibly each of these layers represents the total amount of growth in one year. The fact that in

C. namaquensis, where the xylem shows no annual rings, the cork is not as distinctly layered as in *C. gariepina* favours this supposition.

It is quite probable that when suitable material is obtainable, phellogen may be found to be present, and in that case the position assigned to the cambium will be incorrect.

Material for examining the apex of the stem of *C. gariepina* was not available, but as the formation of bark on the lower parts of the stem in this species is identical with that in *C. namaquensis* it is not probable that any differences of a serious nature are to be anticipated.

In *Portulacaria afra* the bark is less strongly developed, but in the older stems it shows the same structure as in *Ceraria*. The phellogen arises in the epidermis (Pl. XCVIII, Fig. 12) and cuts off cells on the outside only, as in *Ceraria*. These cork cells are thin-walled but are not rectangular in outline, and become crushed almost as soon as they are formed. No band of cellulose cells separates the cambium from the cork (Pl. XCVIII, Fig. 13). In *Portulacaria afra*, therefore, only one type of cork cell is found, while in *Ceraria* there are two. The stem apex is protected by two young foliage leaves and not by scale leaves as in *Ceraria*.

The anatomy of the stem agrees very closely with that of *Portulacaria afra* (Text-fig. 4). The points in which these two genera differ may be tabulated as follows:

CERARIA.

PORTULACARIA.

LEAF.

- | | |
|---|-------------------------------------|
| 1. Leaf club-shaped. | 1. Leaf flat and obovoid. |
| 2. Cuticle very marked. | 2. Cuticle not conspicuous. |
| 3. Palisade tissue slightly differentiated. | 3. Tissues not differentiated. |
| 4. Crystals beneath the stomata. | 4. No crystals beneath the stomata. |

STEM.

- | | |
|--|---|
| 1. Thick bark of a peculiar structure. | 1. Bark thinner but of same structure. |
| 2. Large water-storing cells in cortex. | 2. No water-storing cells. |
| 3. Mucilage cells in a ring and of a large size. | 3. Mucilage cells forming a network in the cortex and of same size as rest of cortical cells. |
| 4. Four medullary rays larger than the rest. | 4. Medullary rays all of same size. |
| 5. Vascular cylinder occupying about one quarter of total area of stem as seen in section. | 5. Vascular cylinder occupying about one-third of total area of stem as seen in section. |

- | | |
|---|---|
| 6. No tangential bands of parenchyma in the xylem. | 6. Tangential bands of parenchyma in the xylem. |
| 7. Large quantities of oil present. | 7. Very few oil-drops in the cortex. |
| 8. Scale leaves protecting the growing regions during the resting period. | 8. No scale leaves present. |

Nodes.

The leaves fall off when the plant is preserved in spirit, and therefore the exact position of the leaves at each node could not be ascertained. A section through a node showed a large number of scale leaves, each consisting of mucilage cells at the base and a dark-brown suberized mass at the apex. A growing point seems to be situated at each node, and in a large number of cases in the material worked upon this has given rise to an inflorescence. In order to investigate this point thoroughly it is necessary to have materials obtained at the different seasons, and this is impossible at present owing to the long journey which must be undertaken to reach the home of these plants. The following suggestion may be made as to the changes taking place.

In the axil of each leaf a growing point arises protected by scale leaves. These fall off as soon as the need for protection ceases, and the bud gives rise to a short branch bearing a number of closely packed leaves. At the end of the vegetative season scale leaves again arise to protect the growing point, and, as before, these fall off and the short branch terminates in an inflorescence.

In *C. namaquensis*, of which stem tips were available, scale leaves exactly like those of *C. gariepina* were found on all the nodes and also surrounding the stem apex. *Portulacaria afra* has no scale leaves, and the foliage leaves arise in a decussate manner at the nodes. Structurally there is no great difference between *Ceraria* and *Portulacaria*, and in comparing the two plants one is struck with the resemblances rather than with the dissimilarities. From the anatomy of these plants, therefore, one is led to conclude that a close relationship exists between these two genera.

In conclusion I wish to express my thanks to Dr. H. H. W. Pearson for supplying the material, and for many helpful criticisms during this investigation.

I am also indebted to the publishers of the 'Gardeners' Chronicle' for the loan of the block from which Text-fig. 1 was taken.

SUMMARY.

1. In *Ceraria* the nodes are arranged in four longitudinal rows, many leaves being borne at each node. *Portulacaria* has decussate leaves.
2. Scale leaves occur in *Ceraria* at the nodes and at the stem apex,

probably protecting the growing parts during the resting period. *Portulacaria* has no scale leaves.

3. The leaves of *Ceraria* and *Portulacaria* are very similar. They are fleshy, have no palisade tissue, and possess mucilage cells in the mesophyll.

4. Calcium oxalate is common in the stem and leaf of both genera. In the leaf of *Ceraria* alone, however, crystals occur in the intercellular space beneath a stoma.

5. In the stem of *Portulacaria* and probably of *Ceraria* the phellogen arises in the epidermis; apparently no phelloderm is formed.

6. A large mucilage ring occupies the middle of the cortex in *Ceraria*. In *Portulacaria* the mucilage cells form a network in the cortex.

7. In both genera the vascular bundles, which are numerous, are arranged in a ring and are separated by medullary rays.

8. Fibres occur in both xylem and phloem. Simple pits only are found.

9. Drops of oil occur in the cells of the stem of *Ceraria*. The cell-walls of the periderm are impregnated with some fat or oil insoluble in chloroform, ether, or benzol.

NOTES.

A BISEXUAL 'GYMNOSPERMOUS' BEGONIA.—Cases of teratologica interest, both floral and vegetative, are not infrequently exhibited by Begonias, but the instance here figured and alluded to is as unique as it is rare.

Begonia semperflorens, var. *gigantea*, Lemoine. 1. Abnormal flower $\times 3\frac{1}{2}$, showing stamens, styles, and exposed ovuliferous placentas. 2. Stamen with subacute connective. $\times 10$. 3. Style. $\times 5$.

It represents a bisexual flower of *B. semperflorens* var. *gigantea*, a floriferous garden hybrid (*B. semperflorens* \times *B. Lynchiana*), having the gynaeceum entirely

superior, while the ovules are wholly exposed owing to the disappearance of the protecting ovary-wall. This specimen was discovered among a batch of normally flowering plants in the Conservatory of the Royal Gardens, Kew, and proved to be the only example despite a careful search. The two petals had the colour and form usually associated with those of staminate flowers, the stamens numbering thirteen and being in every point a replica of normal ones, except that several of their connectives were subacute at their apices instead of truncate. Like the stamens, the styles originated from the base of the superior, exposed, ovuliferous lamellae, which latter appeared twisted and folded among themselves, and thickly studded with normally anatropous ovules of a dingy translucent grey. Three of the styles were perfectly normal, the remaining two exhibiting fusion with stamens. An instance of a somewhat similar nature¹ has been recorded and figured by Professor P. Magnus, but here the flower was undoubtedly of a more pistillate character, the gynaeceum varying between a superior and an inferior condition, and the normal stamens being exceedingly few in number.

THE MEDULLARY RAYS OF FAGACEAE.—Professor J. W. Moll has kindly directed my attention to a valuable paper that I overlooked in my recent work, namely, 'Die Gestalt der Markstrahlen im sekundären Holze,' written by K. Zijlstra ('Recueil des Travaux botaniques Néerlandais,' vol. v, 1908), who traced individual rays of *Fagus* and *Quercus* through numerous successive annual rings and was thus able to give a complete record of their change of shape and height. He confirmed L. Jost's observation that the tall primary rays of *Fagus sylvatica* undergo dissection in an outward direction. He also showed that when the secondary rays of this species are traced outwards they are seen to increase in height, to be joined by others which after linking become fused with them, and finally to fray out into more or less separate smaller rays. Zijlstra also demonstrated similar increase in height and outward fraying of the secondary rays of *Quercus Robur*. He thus proved that in *Fagaceae* the linking up of separate rays from within is not confined either to the annual rings of the seedling stem or even to primary medullary rays, and that both primary and secondary rays can fray outwardly into separate smaller ones.

A correction as regards fact is required in connexion with J. W. Bailey's paper occupying pp. 647–651 of this volume. Bailey refers to a specimen of wood that I described as belonging to '*Quercus (Pasania) fenestrata* (*Q. spicata*)' (*sic*), and goes on to write that he 'recently examined material of *Q. spicata* . . . and is unable to agree with Professor Groom in stating that vessels are absent from the depressed segments between the approximated pairs of foliar rays'.

Bailey's attachment of the name *Q. spicata* to my material, and his statement as above quoted, imply that we both examined the same species of *Quercus*, and that the rays which I discussed were necessarily primary. Neither of these two implications

¹ Sitzungsab. Bot. Ver. Brandenburg, xxvi (1884), 72, f. 2.

is justified. As fully explained in my paper, the identity of my specimen (sent to me in log form direct from the forest) is dubious, and the evidence inclines against its belonging to *Q. spicata*. Hence the indication *prima facie* is that my specimen and Bailey's (obtained from Dehra Dun Research Institute) come from two different species. But the evidence is obviously incomplete, and the difference in structure of the two specimens does not necessarily imply that they come from two species, as in other species of *Quercus* transitional stages in the disintegration or integration of multiseriate rays demonstrate that vessels may occur in a region corresponding to one which is devoid of them in annual rings farther inwards or outwards.

PERCY GROOM.

NOTE ON THE ANATOMY OF STRIGA LUTEA, LOUR.¹—A brief description of the general habit of this semi-parasite has been given in the present number of the 'Annals of Botany', in a study of its haustorium,² in connexion with which its anatomical structure has now been investigated. The plant in its mature (flowering) state shows in its aerial stem the general features—the dense, closed woody cylinder, the narrow lumina of the vessels, the absence of medullary rays, &c.—which characterize the majority of the Order Scrophulariaceae.³ Its structure is almost identical with that of *Melampyrum pratense*, as described and figured by Hovelacque,⁴ almost the only difference between the two being the presence of hairs in *Striga*, and the absence of the scattered 'trachées initiales' which are figured as occurring outside the protoxylem in *Melampyrum*. As in the latter, no cork or collenchyma is formed—a fact which may be correlated with its herbaceous habit. The hairy covering consists of both simple and glandular hairs. The former are large stiff glandular hairs, consisting of a single cell with thickened cuticularized wall, mounted on a base of several epidermal cells, and generally sharply recurved towards the apex of the stem. Among these are scattered the smaller glandular hairs, which consist of a short one- or two-celled stalk and a peltate head of three or four cells; similar hairs occur in a number of genera of the same order.⁵ The transition from the aerial to the subterranean stem presents the usual features.⁶ The stem becomes rounded instead of square in outline, the bast fibres disappear, and the width of the cortex increases, while that of the pith diminishes. The closed vascular ring breaks up into separate bundles, four main bundles and two leaf-trace bundles from the node immediately above.

¹ This investigation has been assisted by a grant from the Union Government.

⁶ Costantin, J.: Tiges aériennes et souterraines. Ann. Sci. Nat., Bot., sér. 6, vol. xvi, 1883, p. 164.

The aerial leaf also presents no distinctive features. It is bifacial, with one or two rows of palisade parenchyma, and four to six of spongy parenchyma. Stomata are found on both surfaces, rather more abundantly on the lower. Hairs of the same character as those on the stem are found on both surfaces, the large simple hairs being always sharply bent backwards towards the apex of the leaf. In the transition to the tooth-like subterranean leaves, the mesophyll becomes less in amount and the palisade parenchyma is no longer differentiated. The stomata and hairs become much less frequent, and, as in the subterranean stem, the simple hairs are here thin-walled and point in any direction.

The root bears no root-hairs, which are seldom or never found on the roots of the Personate parasites.¹ The vascular bundle is diarch in structure; secondary thickening sets in very early. For figures showing the general structure of the root, those given by Hovelacque for the root of *Melampyrum cristatum*² may be consulted, as these show in all respects the same structure as that of *Striga*. I have been unable to demonstrate sieve-tubes in the root, though elongated parenchymatous cells, having the appearance of sieve-tube initials, are present. It is possible that these are sufficient for the purposes of translocation in the delicate tissues of the root, though of course it is equally possible that they may later on develop into sieve-tubes which have escaped notice.

It will be seen that *Striga* in its anatomical structure shows a general resemblance to other members of the order, and a close resemblance to certain other members of the section Rhinanthoideae. Its most distinctive feature is the comparatively feeble development of mechanical tissue, which may be correlated with its small size and partially subterranean habit.
